In the application of the aseptic method, nasal surgery has not kept pace with other branches of the surgical art; and, therefore, the result of intra-nasal operations cannot compare favorably with operations upon other parts of the body in which aseptic measures are more thoroughly and efficiently employed. It is on this account that some rhinologists regard with disfavor the performance of any important surgical operations in the nasal cavity. The intra-nasal surfaces are considered so intolerant to foreign substances that it is quite generally believed that any method which renders the nasal cavity aseptic after an operation cannot be tolerated by the patient. It is my purpose to show in this paper that aseptic measures can be as adequately and successfully employed in intra-nasal as in other surgical operations; that the field of operation can be as thoroughly cleansed and sterilized; that during the operative procedure all the aseptic measures which are deemed essential in operations upon other parts of the body, can and should be carried out in the nose; and that in the dressing of the wound the parts can also be completely sterilized and sealed both to internal and external noxious influences.

[1] Read before the Laryngological Section of the Tenth International Medical Congress, Berlin, August 7, 1890. (In the first report of this Section sent to the journals by its Secretary a synopsis of this paper was omitted, for the reason that the copy of it sent to him was lost in the mail. *Vide* Internat. Centralbl., Nov. 1890, p. 234.)

In order to ascertain the methods which are at present employed by different operators in this field of surgery, I wrote to a number of distinguished specialists, requesting from each a brief statement of the procedure which he adopted in the dressing of wounds of the nose after operations. I regret that the limit of this paper does not permit me to give full credit to my friends for their valuable communications, but I shall reserve this for another article. Only one of the number adopted a method which he deemed aseptic in its nature. Nearly all, however, considered the employment of some kind of antiseptic measures after operations of very great importance; but everyone who expressed himself upon the subject believed that the comparative inaccessibility of the nasal cavity and the peculiar office and function of the nose precluded the possibility of employing any other than the "open method" in the healing of intra-nasal wounds.

The disadvantages attending the open method and the dangers to which the patient is subject are many. The first and most immediate danger is that of hæmorrhage after the styptic effects of the cocaine have disappeared. Again, there is a danger arising from infection due to the absorption of purulent or other noxious substances which may be generated in the nose, or to the germs of infectious diseases, such as erysipelas and the like, to which the unprotected surface is exposed. Moreover, there is the general inconvenience due to the great amount of care and attention required, and to the very frequent use of antiseptic washes and sprays necessary, which cannot be employed by the surgeon as often as the conditions require, and which, if left to the patient, will in almost every case be very imperfectly performed.

The disadvantages and inconveniences of the open method have suggested to some operators the use of some form of closed dressing. The method, however, that is usually employed is covering the wound with small pledgets of borated, bichloride or iodoform cotton, wool, or gauze. The inadequacy of such coverings is apparent. They are not only insufficient to exclude from the wound the germs contained in the acrid nasal secretions and those floating in the atmosphere, but such bits of cotton or wool simply lie in the nostril as foreign irritating substances.

Firmly convinced of the importance of some form of closed dressing, I was some time ago led to adopt certain measures which would avoid the defects just mentioned, and which would render the nasal cavity as nearly as possible aseptic during the healing of the wound. The methods which I have found best suited to this purpose I will briefly describe.

Previous to the performance of the operation, the nasal cavity is thoroughly cleansed with a warm

alkaline antiseptic solution, consisting of salt, boric acid, and bichloride of mercury (1 to 4000). It is needless to say that the instruments should be as scrupulously clean and sterilized as in operations upon other parts. A sterilized cocaine solution is then thoroughly applied (either in the form of a spray or by means of cotton wound upon a probe) until the parts are rendered insensible. The advantages of cocaine are very great. It not only relieves the pain of the operation, but, by contracting the soft tissues and by preventing hæmorrhage, it greatly facilitates carrying out the subsequent aseptic procedure.

After the operation is completed, and the wound is completely cleansed from all débris, irrigated with a hot solution of sodium chloride and bichloride of mercury (1 to 4000), and thoroughly dried, the wound, or rather the whole of the nostril, is dusted full of iodoform powder. The nose is then carefully and thoroughly filled with an antiseptic dressing, so as to seal hermetically the cut surfaces against bacterial invasion. This is done by means of plugs, consisting of thin metallic plates evenly, carefully and firmly wound with antiseptically prepared Angora wool or bichloride cotton, and which before being introduced are dipped into a solution of bichloride of mercury (1 to 3000). The utmost care must be exercised in plugging the nostril. The metal plugs should be of such size and shape that, when wound with cotton and inserted in the nostril, they completely cover the wounded surface. The thickness of the plug, which is regulated by the amount of cotton or wool that is wound on it, should be carefully adapted to the size and shape of the cavity which is to be plugged, so that it exerts an equable and somewhat firm pressure upon the whole of the wounded surface. The plug, when thus prepared, is firmly grasped with a pair of strong dressing forceps and carefully inserted, the nostril being dilated with a suitable speculum, and illuminated to enable the operator to guide the plug to its proper place. The metal plates can be made of any material. A flexible metal, like tin or copper, in thin sheets is preferable, as it permits the plugs to be bent to the exact shape and contour of the cavity. Ordinarily the plate is covered so thickly with the cotton as to prevent any irritation from chemical combinations with the metal. However, to guard against the possibility of this, they can be made of aluminum. The plug should not, when inserted, exert so much pressure as to be irritating to the patient, who should experience no more than the slight discomfort of being unable to breathe through that nostril.

When an operation in one nostril is sufficiently extensive to involve both the upper and lower portions, it is impossible to introduce a plug wide enough to cover the whole extent of the wounded surface. It then becomes necessary to introduce two or more plugs, beginning at the top of the nostril. The first plug is so shaped that it will fit the upper contour of the passage, and the successive plugs are put in below, until the last one passes evenly and snugly along the floor of the nostril. The length of the plugs should be governed by the extent of the wound and also by the depth of the nasal passage. There is no danger of introducing in the upper portion plugs which are too long, as the nostril will not permit it; but the one along the floor of the nose should not be long enough to reach the orifice of the Eustachian tube, and thereby to cause any obstruction of this canal.

When the plugs are removed, if the wound is not sufficiently healed, the nostril should be thoroughly irrigated with the sodium chloride and sublimate solution, dried and dusted with iodoform powder, and the antiseptic plugs again inserted. It is not necessary at this time to use plugs that fit so tightly as at the first dressing, since the danger of bleeding has passed. The second plugs can almost always be allowed to remain until the wound is sufficiently healed to require cleansing only, which should be done two or three times a day with an antiseptic wash or spray. In cases in which both nostrils require operations, if they can be dealt with separately, it is best to operate on but one at a time, performing the operation on the second after the first has healed. Thus, by obstructing but one nostril at a time, nasal respiration is maintained as far as possible.

It will be seen that in this method of rendering the nasal passages thoroughly aseptic, I have not employed any new antiseptic or aseptic agents. But this form of dressing for the purpose of hermetically sealing the passages after they have been rendered thoroughly aseptic, has not hitherto been advocated or employed.[1]

The advantages of this procedure over the open method of treatment are very great.

1. It effectually prevents hæmorrhage. In certain cases in which extensive operations are performed, not more than a slight oozing of blood from the wounded surface can take place, on account of the firm and uniform pressure which this flat packing exerts. In all cases this method of arresting nasal hæmorrhage is far superior to the old method of plugging the nose posteriorly, or packing it anteriorly with cotton or similar substances.

2. All purulent formation is prevented. Septic

[1] Dr. Kitchen, of New York, has proposed a method of plugging the nose similar to that which I have described (Medical Record, January 7, 1888). He does not, however, emphasize the antiseptic uses for which this form of dressing is especially adapted.

absorption cannot take place, and, therefore, constitutional disturbances, except those that are the immediate results of the operation or the effects of the cocaine, are averted.

3. It enables the operator to complete at one sitting all the operative procedures required in one nostril, however extensive, with no subsequent disturbance to the patient greater than that which commonly results from a slight operation when the open method is adopted.

4. The inconvenience of frequently cleansing or irrigating the nostril with an antiseptic solution after the operation is avoided; for this dressing, if properly placed in the nostril, can be allowed to remain from four to six days, or even longer, according to the thoroughness with which the wound and the dressing have been made aseptic.

5. Under this form of dressing the wound heals readily, quickly and smoothly. Granulations are not permitted to spring up, so that when the parts are healed the passage remains free and unobstructed; and when opposite walls of the nostrils are wounded, the liability of those surfaces to grow together, or of fleshy bands to form across the cavity, is entirely prevented.

6. It may be mentioned also that this method of plugging the nose in case of epistaxis is much less likely to cause aural complications than is the ordinary method of plugging the posterior nares.

7. In the dressing of fractures of the nose or operations for correcting deviations of the septum, this form of dressing is superior to any other for the purpose of holding the parts in place; and when applied it is not necessary to replace it or to disturb the wound for a number of days, so that the union of the fractured parts is not interfered with, as is the case with the ordinary methods of holding the parts in place by metallic clamps, hard rubber plugs, and similar devices.

In conclusion I would call attention to the importance of such a form of dressing after the employment of the galvanic cautery. The actual cautery is generally believed to be the best sterilizer, and is often used for searing the surface of wounds after cutting operations in order to prevent hæmorrhage and the absorption of septic material. Gerster says: "The actual cautery is the most effectual sterilizer."[1]

This is true so far as it relates to the destruction of the germs with which the cautery comes in direct contact; but it must not be forgotten that a burned mucous surface is the most active absorbent surface, and the most productive of copious purulent formations.

In the case of a simple burn of the skin, if it is allowed to remain exposed to the atmosphere extensive inflammatory action will set in, owing to the active infection of the surface by germs. On this account it is rare for even slight cauterization of any part to be unattended with swelling and constitutional symptoms far in excess of those which usually attend a cutting operation upon the same region. In the treatment of all burned surfaces, therefore, the most thoroughly aseptic precautions are of the utmost importance.

Looking at this subject from a scientific point of view, when we consider the large number of varieties of benign and of disease-germs which are found in the nasal secretions, and when we consider that the tissues of the nasal passages are the most rapid absorbents of the mucous surfaces of the body, it would seem to be inexcusable to treat a wounded surface in the nose by the open method, and thus to afford a feeding-ground for the numerous bacteria which with every breath are deposited upon this exposed surface.

The form of dressing by means of intra-nasal plugs prepared and applied in the way that has been pointed out, is therefore recommended as a practical mode of dressing intra-nasal wounds, and one which fulfils all the aseptic precautions required in every branch of modern surgery.

ORIGINAL LECTURES.

LUPUS VULGARIS.

A Clinical Lecture
delivered at Freedman's Hospital, Washington, D. C.

By N. F. GRAHAM, M.D.,

PROFESSOR OF THEORY AND PRACTICE OF SURGERY AND CLINICAL SURGERY, MEDICAL DEPARTMENT, HOWARD UNIVERSITY; CONSULTING SURGEON TO FREEDMAN'S HOSPITAL.

[Reported by E. A. Balloch, M.D., Lecturer on Minor Surgery, Medical Department, Howard University.]

Gentlemen: The discovery of the bacillus tuberculosis by Professor Koch and his recent utterances in regard to curing or alleviating the diseases caused by this microscopic organism, give renewed interest to every form of tubercular disease.

The hopes of a great multitude of victims of tuberculosis in every form are now hanging upon the results of the various trials of the new remedy which are being made, with more or less accuracy as to detail, both in Europe and in this country.

I take pleasure, therefore, in bringing before you, today, three cases of lupus vulgaris, the diagnosis in two of which has been placed beyond question, both by careful microscopic examinations and by the results of Koch's lymph.

All the signs, objective and subjective, which characterize the disease in question, are present in the cases now before you. The history of the development in each case has been obtained by Dr. Balloch, and I will give a brief *résumé* of them:

CASE I. *Lupus exulcerans.*—L. D., colored, male, aged thirty years. First noticed the disease three years ago. Made its appearance as a small pimple. Owing to intense itching the pimple was kept irritated by constant scratching. From this focus the disease spread until it reached its present proportions. It now affects the nose, upper lip, and both cheeks, which are in a state of superficial ulceration, accompanied by a discharge of pus and blood. Glands of neck much enlarged and very hard.

CASE II. *Lupus hypertrophicus.*—L. J., female, colored, aged twenty-five years. States that disease began "when she was a little girl," probably about the age of puberty. Began in the form of one or two small pimples, which would dry up and be followed by others more numerous. Began on nose and caused an ulcer which slowly spread. No pain. Scabs would form and drop off, leaving a raw surface. Always a profuse discharge. After the disease had continued a year or two she received an injury to the face which caused a more rapid spread of the ulceration.

Her appearance now is typical. The nose is enormously swollen and warty. The disease also involves the upper lip and face, causing blindness by reason of patient's inability to open her eyes, owing to swelling. All the parts involved are in a state of active ulceration, and pour out a profuse discharge of pus and blood.

FIG. 1.

FIG. 2.

CASE III. *Lupus exulcerans* (?).—E. B., female, aged forty years, colored. Duration of disease nine months. First noticed as a small pimple on nose, which was kept irritated by constant scratching, finally resulting in a spreading ulcer. No pain. Always had nasal catarrh, with constant secretion of mucus. Now has superficial ulceration of nose and neighboring parts of both cheeks. Cartilage of nose gone. Discharge of blood and pus.

You will understand that the descriptions apply to the cases as they were before the use of the lymph, and, in order that you may have a good idea of the extent of the disease in each case, I will hand around these photographs, kindly taken for me by Dr. A. H. Lee on the day before the injections were begun.

All these cases have been under treatment by the Koch method. The lymph used was some of that sent personally to Dr. John S. Billings by Prof. Koch, so that there can be no possible doubt as to its purity. The injections have been made by Dr. Wm. M. Gray, of the Army Medical Museum, which is a sufficient guarantee that they have been accurately and scientifically carried out.

Dr. Gray has followed his own methods, and will shortly publish the full details. Suffice it to say that he has used much larger doses than other American experimenters, and his results have been correspondingly better, approaching more nearly those obtained by the German investigators than any I have seen.

The results in two of the cases have been marvellous. The improvement in Case II. is particularly remarkable. You would hardly recognize her as the same person. The huge, warty protuberance, which she formerly called her nose, is gone, and in its place she has a nearly natural nose, covered with soft, velvety, pink skin, without a trace of ulceration or discharge. She can once more see the light of day, and, as you perceive, presents but few evidences of the existence of her former trouble. In Case I. the improvement is not so apparent at first sight, but is none the less real. The discharge has ceased and the parts are covered by dry, brownish scabs. These will soon drop off, leaving healthy skin; in fact, this healthy skin is now visible between the crusts. The cervical glands have lessened in size one-half and are softer and altogether more normal to the touch. In Case III. no material improvement is manifest. The ulceration looks cleaner, brighter, and more healthy, and the discharge has nearly ceased, but this is all we can say. She has never exhibited any decided reaction to the lymph, while the other two cases showed marked reaction, the temperature in Case II. going at one time to 105° F. and remaining there for twenty-four hours.

But it is more of lupus in its clinical aspects that I desire to speak to-day. Lupus is now believed to be one of the forms of cutaneous tuberculosis due to the bacillus tuberculosis. The variety under consideration, and with which at least two of these patients are affected, is known as lupus vulgaris.

It differs from lupus erythematosus in the important fact that the latter affects the skin and subcutaneous cellular tissue only, and never goes on to a stage of softening or ulceration. Also the latter never affects the

deeper tissues, soft or hard, as muscle, tendon, cartilage or bone, while lupus vulgaris in its destructive march is not limited even by bone.

Lupus vulgaris commences with deep-seated points in the skin, from the size of a pin's head to that of a split pea. You will recall that the history of each of these cases shows a beginning as a small pimple. The color varies in accordance with the complexion of the individual. In the white it is orange-red or a shade of brown, and in the dark-skinned races, simply a tint lighter than that of the natural skin.

These points or centres of inflammation are sharply defined from the beginning. At a later period they become elevated above the surface, to form distinct nodules or tubercles. The disease may spread from a focus, peripherally, and so extend until a large patch is formed, or several tubercles may appear in a patch of skin which, in time, run together to form sores of varying sizes. Case II. illustrates this mode of spreading. The extent of involvement of the skin and deeper tissues gives rise to a number of clinical varieties of lupus vulgaris, such as lupus maculosus, lupus exulcerans, lupus serpiginosus, lupus exfoliaticus, lupus hypertrophicus, and so on, as long as the adjectives hold out. Time will not permit of a consideration of all these varieties, so we will confine our attention to the cases before us.

Cases I. and III. I had formerly considered to be cases of lupus exulcerans. The result of the injections in Case I. confirms this diagnosis, while it renders it doubtful in Case III. To the eye both had the same general appearance. In this variety of lupus vulgaris there is evidence of cicatrization under the skin at points, the result of infiltration of the subcutaneous tissue by the disease. At other points, by reason of the intensity of action as well as on account of the irritation to which the surface is necessarily subjected, you will find necrosis of the skin and a destruction of deeper tissues, not even sparing cartilage. This is what I had thought to be going on in Case III.

Ulceration soon takes place, and the surface of the ulcer will be covered by yellow and brown crusts, which show a secretion. I wipe off the secretion in Case III., and the granulations are plainly seen. As a rule, in cases of lupus the granulations are soft and friable, so that they are easily scraped away with the nail or curette. We have here an ulcer which has slowly progressed, destroying the deeper structures until the end of the nose is nearly gone. The granulation-tissue found in this disease is different from that found in healthy, constructive inflammation, in that it is liable to, and generally does proceed to, destructive ulceration, and not, step by step, to repair, as is the case in healthy sores.

Case II. presents the variety of lupus vulgaris clinically known as lupus hypertrophicus. In this form of the manifestations of lupus, the products of inflammation thrown into the connective tissue at the base of the nodules or tubercles overbalance the process of necrosis on the surface, and large and prominent granulations are heaped up in masses.

These masses are sometimes covered over with a thin skin and remain as warty-looking growths; whilst in other, and by far the larger number of cases, they remain soft and fungous, easily broken down and bleed at the least touch. The nodules, even when hard to the touch, are very friable, and can be penetrated by an ordinary probe or scraped out of their beds by the lightest touch of the curette, leaving well-defined excavations with normally solid margins and bases of sound tissue, or, more likely, tissue infiltrated with the products of inflammation. This, in itself, is a crude factor in making a diagnosis in a case of lupus.

The disease may occur in any part of the body, but has a decided preference for the face first, and next the extremities. In each of our cases it happens that the face is the part involved. As a general rule, the extent of surface involved is not large, varying from a patch the size of a dime to one, two, or three inches in diameter. Exceptionally a large surface may be affected, even to the whole side of the face or the entire thigh. Case II. is one of these exceptional cases.

The first signs of lupus manifest themselves early in life, from the third to the tenth year as a rule. The beginning, however, is generally so insignificant that it often escapes observation until about the age of puberty, or later, when new and increased action becomes manifest and the disease spreads, though slowly, with great persistence. This factor has been made use of as a means of diagnosis.

Until the discovery of the bacillus tuberculosis, the etiology of lupus was a matter of speculation, but it is now generally believed and accepted by pathologists, as I have stated, that it is simply tuberculosis of the skin, induced by the same bacilli found in tubercle in other portions of the body. The best and surest means of diagnosis, therefore, is in the examination of a portion of the suspected tissue by the microscope, when, if bacilli are found, the fact that the disease is lupus may be accepted. The bacilli are found in little pockets beneath the connective tissue, and in examining tissue one must, therefore, go rather deeply into the ulcer to get a proper specimen. Comparatively few professional men are supplied with the means of making this diagnostic test, and still fewer have the leisure; so, as a result, the majority must depend upon the ordinary clinical signs presented by the disease.

Lupus is of interest from a surgical point of view, for the reason that it is often mistaken for other diseases. It may be confounded with certain late manifestations of syphilis (tubercular syphiloderm), with epithelioma, with eczema, or with psoriasis. From syphilis it is differentiated by the fact of its very early appearance and of the area involved, as compared with the hereditary manifestations of syphilis. In lupus the ulceration is, as a rule, limited to one region, is comparatively superficial, has a slight and not offensive discharge. The margins of the ulcer are not well defined, it develops slowly, is covered with scales, and in the early stages, from the chronic nature of the malady, there are no constitutional symptoms.

In syphilis the ulcers are deep, with sharply-defined borders, attended by an abundant and foul discharge; they develop rapidly, and are often found on many parts of the body at the same time. Frequently, also, there is suppuration of glands and disease of bones. This, with the history of the initial lesion, which is usually obtainable, in connection with the speedy benefit obtained

from treatment by the iodine preparations and mercury, makes the diagnosis of syphilis quite conclusive.

The differential diagnosis between lupus and epithelioma is somewhat easier. Lupus is generally found in young persons; is not painful; is slow in its progress; without marked ulceration, and usually affects the skin of the face. Epithelioma is more commonly found in the old or middle-aged; is very painful; grows rapidly (as compared with lupus), with marked, circumscribed induration, and forms a deep, discharging ulcer.

Eczema may be diagnosed by the fact that it never proceeds to true ulceration; that it is hard and firm, and cannot be penetrated by the probe nor scraped out of its bed, like lupus. Eczema spreads to neighboring parts peripherally, by a uniform inflammatory infiltration; it is liable to fissure and crack, and there is burning heat, with itching and pain.

In making the diagnosis between lupus and psoriasis you will remember that in the latter, we have the bright red patch, profusely covered with pearly scales, the removal of which shows numerous small blood-points. There is, too, a more general distribution of psoriasis over the body, and it is more liable to attack the extensor surfaces of the limbs.

In the matter of treatment, nothing could better show the uncertainty of the effect of drugs on this disease than the great number that have been recommended and tried; a few with benefit, but the greater number without any effect. I have always placed some reliance upon the internal administration of arsenic in the form of Fowler's solution, beginning with five drops three times a day, and increasing until ten, or even fifteen, drops are taken three times daily. I continue this treatment a long time, going back, at stated intervals of four or five weeks, to the minimum dose, and again increasing as before.

Cod-liver oil does good, and it is best given in the form of an emulsion, of which there are a number of most palatable ones on the market.

Suitable and sufficiently nourishing food should be allowed the patient, and his body should be kept warm and dry.

As to topical remedies for the cure of lupus I have but small faith in any of them. If the part affected be small, its complete destruction by caustics might be followed by good results. When practicable, removal by the knife is easy and the method most tempting to the surgeon. When thoroughly extirpated in this way the results are very good, although there is a liability to return sooner or later.

Another method is by linear scarification, which has for its object the division, in all directions, of the vessels, and, in this way, the starvation of the lupus by cutting off its blood-supply. Inflammation is also excited in the sound tissue, causing the separation of the necrosed tissue, and leaving a healthy sore, which will heal up in the ordinary way.

Of course, if the lymph treatment is capable of accomplishing all that we hope, and if it will effect a cure in all, or a majority, of the cases of this disease, the matter of the treatment of lupus will become easy, and no other methods, such as those I have spoken of, will, in the future, be required.

In the cases before you, the results, so far, are most encouraging. The only question is as to the permanence of the cure.

However, gentleman, even if the lymph treatment should be successful, many of you will, doubtless, practise your profession in localities where its benefits may not be obtainable. It is in view of this that I have been particular in describing other modes of diagnosis and treatment, upon which you will probably have mainly to rely.

PERSISTENT PAIN AFTER LAPAROTOMY.

A Clinical Lecture,
delivered at the New York Polyclinic.

BY HENRY C. COE, M.D.,
PROFESSOR OF GYNECOLOGY.

GENTLEMEN: These two patients belong under the same category and are of peculiar interest to me as illustrating a point on which I have laid considerable stress.

CASE I.—This young woman states that she was operated upon over a year ago on account of severe dysmenorrhœa. She did not leave her bed for seven weeks, which fact, together with the appearance of the cicatrix of the abdominal wound, would seem to show that her recovery was retarded by some complication, of which she is unable to give any clear account. She only knows that she has not menstruated since the operation and that instead of the periodical pain which she suffered before, she has now a constant pain in the lower part of the abdomen, associated with obstinate constipation and colicky pains in the bowels. The patient is positive that the pains are worse than they were before the operation. She is naturally hyperæsthetic, but I can find no particularly sensitive spot around the uterus, which is small, anteverted, and fairly movable. No painful indurations can be felt in the usual location at the uterine cornua. Pressure above the symphysis causes considerable pain. Taking into consideration the history of the case, together with the negative results of the examination, I infer that the patient had localized peritonitis after the operation, which resulted in the formation of intestinal adhesions which hinder and render painful the peristaltic movements. Due allowance must be made for the neurotic element.

CASE II.—This patient I have had under observation since her operation, nearly three years ago. During that period she has not menstruated, but has rarely been free from an intense congestive headache, which has made her life miserable. I was unable to relieve her, but she is now somewhat better, though still far from well. Her ovaries and tubes were removed for the relief of dysmenorrhœa, though they were not much diseased. Her convalescence was uninterrupted. For many months she suffered from pelvic pains, and you see, when I make pressure, that the uterus and its surroundings are still quite sensitive to the touch.

These cases, and a similar one which you saw at the last lecture, are worthy of your careful consideration, as they show the possible after-effects of laparotomy of which you should not lose sight. As a rule, you only witness the operation, and are impressed with its brilliant and successful performance by the skilful operator. You probably seldom think of the subsequent history of

the patient; if you hear from her at all, you merely learn that she made a good recovery and was discharged "cured" at the end of four or five weeks. Now, this is the least important part of the history, as you will find when you come to operate on private patients. Be careful that you do not promise too much. I refer, of course, to cases in which you expect to remove the moderately diseased adnexa for the relief of pain. It is remarkable what a change has taken place in our views during the past four or five years. Now the removal of tubes and ovaries not seriously diseased is regarded as rarely justifiable; not one empirical operation is now done where twenty were performed a few years back. But even when laparotomy is clearly indicated and is skilfully performed, where no complications are present and the convalescence is normal and without elevation of temperature, there still remain a certain proportion of cases (by no means insignificant) in which it is a question if the remedy is not worse than the original disease. Such patients are afflicted with persistent pains in the pelvis, metrorrhagia, cerebral congestion, vesical irritation, and various neuroses, which are either extremely difficult or quite impossible to relieve. I need only call your attention to the cases which you see here one, two, or three years after operation to assure you that this picture is not an imaginary one. Last winter I operated upon two patients before the class in the same afternoon. Both were young women upon whom abdominal section had been performed by prominent surgeons a year or more before, followed by normal convalescence, and yet both had such severe and persistent pains that a secondary laparotomy was necessary in view of the absence of relief from palliative treatment. In one case, in which both ovaries and tubes had been removed, the pain was due to a firm intestinal adhesion, which was separated. The patient was much relieved and has since married. In the other case only one ovary and tube had been extirpated for the relief of pain which continued after this operation. I removed a pyosalpinx and small ovarian cyst, and broke up some pelvic adhesions. This patient has not only failed to be relieved, but in addition suffers from profuse metrorrhagia at irregular intervals, as well as constant severe pain at the site of the stump which I left. The latter is enlarged and is extremely sensitive. I examined her under ether a few weeks ago, having previously introduced tents, explored the uterine cavity thoroughly and removed a few "fungosities," but all to no purpose; she continues to suffer and to flow as before. Two other patients (perfectly simple cases) operated upon last winter, who have been kept under constant observation, give a precisely similar history. We do not understand why these phenomena occur; but they prove most forcibly that removal of the adnexa does not always cause a sudden and miraculous disappearance of the symptoms for the relief of which the laparotomy was performed.

Now, I trust that you will understand my reasons in calling your attention to the subsequent history of these cases. It is not with any desire of belittling the results of abdominal surgery. We have every reason to feel proud of the work of American laparotomists, and of the conscientious way in which it is done. Only extremists pretend to cure advanced disease of the ovaries and tubes without resort to the knife. What I wish you to remember is that while life may be saved, absolute recovery from pain, which is the chief desideratum to the patient, can never be positively guaranteed by the surgeon, nor can he promise that the disturbances incident to the sudden establishment of the menopause may not be profound and lasting. It is only by keeping our patients under careful observation for years, not weeks or months, after the operation, that we can arrive at any scientific estimate of the value of laparotomy as a curative measure.

MEDICAL PROGRESS.

Liniments for Pruritus.—*La Semaine Médical* gives the following liniments for pruritus:

℞.—Pure resorcin . . . . 1 drachm.
Glycerin . . . . 2 drachms.
Water . . . . . 4 ounces.

Mix and label "To be Used Externally;" or,

℞.—Menthol . . . . 3 drachms.
Glycerin . . . . 2 drachms.
Water . . . . . 4 ounces.—M.

This is to be labelled "Use Externally," and is to be shaken before using.

Finally, the following mixture may prove of value:

℞.—Ichthyol . . . . 1 to 3 drachms.
Glycerin . . . 2 drachms.
Alcohol } of each . . 2 ounces.—M.
Water }

Use externally.

Trinitrine for Angina Pectoris.—Trinitrine or nitroglycerin has been very largely used, particularly in France, in the treatment of angina pectoris, and is without doubt a valuable remedy for this disease. According to the studies of HUCHARD, POTAIE, and HERARD, who have studied its physiological action particularly in relation to its use in angina pectoris, the drug is a vaso-dilator resembling very closely nitrite of amyl. BOCQUILLON uses it in the following manner:

℞.—Alcoholic solution of trinitrine
(1 per cent.) . . . . 30 drops.
Distilled water . . . . 10 ounces.—M.

Two teaspoonfuls morning, noon, and night.

For subcutaneous injection he uses the following solution:

℞.—Alcoholic solution of trinitrine
(1 per cent.) . . . . 30 drops.
Cherry-laurel water . . . 3 ounces.—M.

Twenty minims of this may be given hypodermically.

Salt Solution in Acute Anæmia and Cholera Infantum.—In the *Archives of Pædiatrics* for March, 1891, the following translation is to be found: A six-tenths of one per cent. solution of salt was first used in four cases of cholera infantum, two dying and two recovering. To the solution was added a little alcohol. The solution was sterilized, and kept at a temperature of from 39° to 40° C. The apparatus used was a glass funnel with a

rubber tube, about three feet long, to which a cock was attached, the end of which fitted into the canula connected with a small trocar. In place of the foregoing, one may use for children a small syringe, holding about five drachms, to which a long aspirating needle may be attached. The transfusion was made into the skin of the abdominal wall, and absorption was assisted by massage over the point of injection. For infants, from 1 to 2 ounces is a sufficient quantity for injection, and it could be repeated if collapse rendered it necessary. No unpleasant phenomena are likely to accompany the injections. After the operation the head should be lowered, the feet raised, elastic bandages wrapped around the child, and other excitants used as occasion calls for them. The same treatment may be used in collapse following extensive hæmorrhage, either in children or adults.

Treatment of Eczema in Children.—In the *Revue Mensuelle des Malades de l'Enfance* for August, 1890, Sallfeld gives the following treatment for eczema: Some interesting considerations are presented concerning the treatment of eczema in children, which differ essentially from those which are usually adopted in adults. Of all varieties of local eczema which are developed under the influence of external causes, the most important in children, in the author's opinion, is intertrigo. It is particularly common in fat children, and is frequently located near the margin of the anus, in the inguinal folds, in the folds of the neck, and in the vicinity of the chin. Intertrigo thus localized is readily cured by the use of bland and inert powders, but if the disease includes large portions of the surface of the body, the local treatment should be supplemented by change in the diet, and if diarrhœa exists, it should be energetically treated as well. If the skin is the seat of an intense inflammation, cold compresses should be used for several days which have been moistened with a mixture composed of equal parts of a five-per-cent. solution of boric acid and the officinal solution of subacetate of lead, an ointment of boric acid being used after the former preparation has been discontinued. If the skin is very moist it should be dried with a suitable absorbent powder before using the ointment. In the treatment of eczema of the face and scalp which is so common in fat children, it is well to diminish the quantity of nourishment, to eliminate fatty materials from the diet, and to combat habitual constipation with appropriate enemata. The crusts upon the head and face should first be softened with olive oil, and after they have been removed the surface should be anointed with the following ointment:

℞.—Boric acid . . . . 45 grains.
Zinc oxide. . . . . 75 "
Vaseline } of each . . 450 " —M.
Starch }

If there is generalized eczema of a scrofulous character, the organs of digestion must be carefully interrogated, and if the alimentation is insufficient, it must be supplemented with cod-liver oil combined with phosphorus or arsenic. The local treatment should be limited to the use of vaseline inunctions, followed by the use of bland powders upon the skin. Applications of tar preparations should be avoided, as they only irritate the skin. The following formula may be used with advantage:

℞.—Ammoniated mercury . . 30 grains.
Peruvian balsam . . . 75 "
"Wilson's ointment" . . 450 " —M.

—*Archives of Pædiatrics*, March, 1891.

Cremasteric Reflexes in Chloroform Anæsthesia.—An excellent test for surgical anæsthesia by chloroform exists in the cremasteric reflex. When it is lost sensation has disappeared.

The Dose of Salol for Infants.—*Lyon Médical* states that the proper dose of salol for a child of six months is 3 grains, for one of two years 6 grains, and for one of five years 15 grains. [These doses are certainly as large as they should be.—Ed.]

The Action of Saccharine on the Heart.—Loutzensko has studied the action of saccharine upon the heart of the frog, and finds that when 1½ grains of a two-per-cent. solution of saccharine with bicarbonate of sodium is injected into a frog the animal in one hour appears to be better. It is insensible to the touch, but pinchings provoke feeble reflexes. The heart is finally arrested in diastole, but if pinched will once more begin to contract. Electrical stimulation also produces these contractions of the heart. In doses twice or thrice as large as that named, Loutzensko found that saccharine causes irregular cardiac movements. The effect of the drug upon the vagus nerve after such doses is very feeble.—*Revue Général de Clinique et de Thérapeutique.*

Treatment of Seat-worms.—Success in the treatment of cases of seat-worms depends upon the prolonged and constant use of a vermifuge or some active vermicide. The worms are generally attacked by means of injections, suppositories, or ointments. Of the injections, a favorite prescription is a solution of common salt in the proportion of 1 to 5. Sometimes sugar and water may be used, and an infusion of absinthium is employed by some French practitioners. Still others employ simply cold water. It is said that West and Barthez recommended astringent injections composed of the perchloride of iron and lime-water, as follows:

℞.—Lime-water . . . . 6 ounces.
Perchloride of iron . . 10 drops.—M.

And also,

℞.—Lime-water . . . . 4 ounces.
Decoction of marshmallow . 1 ounce.—M.

For the same purpose Trousseau prescribed suppositories of tannin, made up as follows:

℞.—Tannic acid . . . . 15 grains.
Cocoa butter . . . . 1 drachm.—M.

Other physicians have employed injections of asafœtida, and many have found the following treatment useful:

℞.—Alcoholic extract of senna leaves 30 grains.
Boiling water . . . . 4 ounces.

Make an infusion and sweeten with syrup of wild cherry, 4 drachms. This may be given to an infant

of four or five years as a laxative, and if it does not act may be followed by from a half to one drachm of the sulphate of magnesium. After this an injection may be given composed of 1 ounce of powdered quassia chips to 1 pint of water, or of carbolic acid in the proportion of from ½ to 1 drop to 4 ounces of water. An emulsion of calomel may be employed composed of calomel 3 grains and mucilage of flaxseed 4 ounces.

GUERSANT is said to employ sulphuretted potash 2½ drachms, water 4 ounces; while ROSSBACH finds naphthaline of great service, and administers it as an injection as follows:

℞.—Naphthaline . . . . . 15 grains.
Olive oil . . . . . 1½ ounces.

This quantity may be doubled or tripled in adults. Sometimes he prefers to use naphthaline from 2 to 10 grains and decoction of marshmallow 6 ounces. If the worms inhabit the lowest portion of the intestine it may be well to follow the treatment of Cruveilhier, viz.—to employ mercurial ointment or to rub into the anus an ointment composed of calomel 8 grains and cocoa butter 1 drachm.

TROSSEAU is said to employ the following suppositories:

℞.—Calomel . . . . . 1 drachm.
Vaseline . . . . . 3 drachms.

When the worms inhabit the higher portions of the rectum they will probably resist all therapeutic measures unless they be attacked through the stomach. Under these circumstances it may be well to employ calomel and santonin, of each ½ grain, which is to be administered early in the morning in order that the calomel may act by evening. This dose is the proper one for a child of two to three years.—*Revue Général de Clinique et de Thérapeutique.*

Pill for Tuberculosis.—According to *L'Union Médical* CHAUVIN uses the following pill in tuberculosis:

℞.—Iodoform . . . . . ¼ grain.
Dover's powder . . . . 1½ grains.
Extract of gentian enough to make a pill.

Give one pill three times a day immediately after meals.

Cholagogue Powders for Hepatic Colic.—In the *Revue Général de Clinique et de Thérapeutique* the following treatment for the relief of hepatic lithiasis is given, based upon the fact that BINET and others have found that the benzoate and salicylate of sodium act as cholagogues. The nux vomica in the prescription aids in regulating the bowels and in relieving anorexia and dyspepsia.

℞.—Benzoate of sodium } of each . 75 grains
Salicylate of sodium }
Powdered nux vomica . . 7 " —M.

This is to be divided into 20 powders, of which the patient should take 1 three times a day for two months.

Treatment of Typhoid Fever.—The *Revue Général de Clinique et de Thérapeutique* gives the following method used by TEISSIER in the treatment of typhoid fever. Morning and night a powder composed of 5 grains of alpha-naphthol and 3 grains of salicylate of bismuth is given. In addition four cold injections are used, at intervals of twenty-four hours, with the object of increasing diuresis. After the midday injection he prescribes the following tonic and antipyretic mixture:

℞.—Extract of cinchona . . . 1 drachm.
Sulphate of quinine . . . 15 grains.
Tincture of valerian . . . 1 ounce.—M.
Teaspoonful at a dose.

Teissier also applies cold compresses to the head and abdomen, and the patient is allowed 10 ounces of Bordeaux wine and one and a half pints of milk or broth in the twenty-four hours. He employs alpha-naphthol in preference to beta-naphthol because the latter is very much more poisonous; thus, to produce poisoning in a man of ordinary weight it is necessary that twice as much alpha-naphthol be given as of beta-naphthol. In consequence it is possible to give larger doses of alpha-naphthol without danger, and obtain thereby a greater degree of intestinal antisepsis. The cold baths which he recommends augment, in his opinion, the elimination of toxic substances in the urine, and the naphthol stops their production in the intestine.

The Employment of Kola Nut.—HUCHARD gives the following prescription in the *Revue Général de Clinique et de Thérapeutique* for the administration of kola nut:

℞.—Tincture of kola . . . 1 ounce.
Tincture of coca . . . 1 "
Tincture of squills . . ½ "
Tincture of digitalis . . 2 drachms.
Simple syrup . . . . 2½ ounces.
Red wine . . . . 1 pint.—M.

Allow the sediment to settle, and then decant and filter. Two or three teaspoonfuls of this mixture may be given each day for eight or ten days in cases of cardiac disease requiring tonics. In other cases the following may be employed:

℞.—Fluid extract of kola } of each 6 drachms.—M.
Fluid extract of coca }

A small teaspoonful should be taken after luncheon, with a little simple syrup or Malaga wine. This mixture should not be given at night, because the kola produces insomnia in some patients. The dose of it should be from 20 to 30 drops three times a day: as, for example, at 8 o'clock in the morning, at midday, and at 4 o'clock in the afternoon.

Treatment of Seborrhœa of the Scalp.—LIEBREICH employs the following prescription in the treatment of seborrhœa of the scalp:

℞.—Spirits of ether . . . . 1½ ounces.
Tincture of benzoin . . . 1 drachm.
Vanillin . . . . . ½ grain.
Heliotropin . . . . 3 grains.
Oil of geranium . . . 2 drops.

Mark "For external use, combustible."—*Wiener medicinische Presse.*

Current Literature.

SATURDAY, MARCH 28, 1891.

NATURE AND PATHOGENY OF MUSCULAR ATROPHIES FOLLOWING LESIONS OF THE ARTICULATIONS.

Duplay and Cazin, in a paper upon this subject (*Archives Générales de Médecine*, January, 1891), mention some of the numerous theories which have been proposed from time to time to explain the pathogeny of muscular atrophies consecutive to articular lesions, and which have, to-day, been very properly abandoned. Among these they recall the mechanical theory of Roux, in which the atrophy is explained by a mechanical distention of the synovial membrane by a serous effusion, but which does not hold good in cases of atrophy occurring independently of intra-articular effusion; the theory of functional inactivity, which has also been controverted by numerous instances of atrophy occurring with no immobilization of the joint; the theory of the propagation to the muscles of the articular inflammation, which will not apply to amyotrophies developed at a distance from the joint, or generalized in an entire member, nor does it take into consideration the rapidity with which these atrophies may appear; and, finally, the reflex vaso-dilator theory of Schiff, and the reflex vaso-constrictor theory of Brown-Séquard. While the general theory of to-day inclines toward the opinion of Vulpian, it is worth while, nevertheless, to make special mention of a theory conceived by Sabourin, and developed by several writers, more especially by Descosse (*Thèse de Paris*, 1880). According to this theory, which may be designated as the neurotic theory, the inflammation of the peri-articular fibrous tissues is propagated to the fibrous envelope of the muscular fasciculi, and from them to the neurilemma of the final nerve ramifications, from which the nervous element itself becomes altered. This theory, however plausible, has not been confirmed by any histological examination, and in the presence of the inadequateness of these various theories, the consensus of opinion remains with the reflex theory of Vulpian. This theory will suffice to explain the rapidity with which the atrophy frequently appears, and is in accord with the results of clinical observation. It is also supported by microscopical examinations of the muscles, which always present the characteristics of a simple atrophy. Nevertheless, for this theory to be definitely adopted, it is necessary that careful and sufficiently numerous experiments be made to establish positively the condition of the cord and of the nerves in these amyotrophies of articular origin. In most of the cases observed hitherto no appreciable lesion of the cord could be discovered, but M. Klippel (*Bulletin de la Société Anatomique*, November, 1887, and January, 1888) reported to the Anatomical Society a case of chronic arthritis of the right knee with degenerative atrophy of the crural triceps, in which there were some alterations in the cells of the anterior and posterior horns of the cord of a granulo-fatty nature. Professor Charcot was, therefore, led to the opinion that there may be two degrees of the articular amyotrophies: the one, in which the spinal affection is purely dynamical, and expresses itself by a simple atrophy of the muscular fibres; the other, more grave, in which the spinal affection is characterized by appreciable organic lesions, and expresses itself in the muscles by degenerative lesions.

Duplay and Cazin have performed a number of experiments upon dogs and rabbits, in which they produced an inflammation of the joint by means of injections of tincture of iodine, of solutions of silver nitrate, by the thermo-cautery, or by violent torsion, tearing the lateral ligaments. In every instance there were pronounced evidences of atrophy, as shown both by mensuration and weighing. The histological examinations of the muscles constantly revealed the characteristics of simple atrophy without any appearance of granular degeneration of the striæ. The substance of the spinal cord was found to be intact in every portion, as were also the spinal roots. In no case were the observers able to note any appreciable change, either in the size of the anterior horns, or in the number or size of the nerve-cells, or in their form. The only lesions which they were able to prove were found in the articular nerve filaments, which were the seat of an inflammation extending from the peri-articular tissues. They have drawn the following conclusions:

1. Amyotrophies secondary to lesions of the articulations consist in a simple atrophy of the muscles, as has already been indicated by most of the writers upon the subject.

2. This atrophy cannot be explained by a dynamic action resulting from a simple reflex due to an irritation of the terminal filaments of the articular nerves.

3. This pathogeny, clearly indicated by Vulpian, and accepted by a large number of writers, has never received, up to the present time, an absolutely rigid anatomo-pathological demonstration. The constantly negative results of their researches relative to the existence of lesions of the nerve-trunks, of the spinal roots, and of the cord, seem to the authors to constitute a definitive demonstration.

THE VARIETIES OF HYDROCELE.

Duplay mentions a large variety of hydroceles which may be encountered in the inguino-scrotal region, together with the means of differentiating them. It is an easy matter to distinguish the so-called "hydrocele by infiltration" from hydrocele with effusion, since the former is simply an œdema, and is not accompanied with fluctuation and transparency, while the tissues retain the imprint of the fingers. More difficult is the diagnosis between encysted hydrocele of the testicle and epididymis and vaginal hydrocele. The differences here consist in the variable connections which exist between the sac and the testicle. The effusion in hydrocele of the tunica vaginalis entirely surrounds the testicle, and the latter occupies a postero-

inferior position, and is a little internal to the tumor. This is the rule, but it is well to remember that in cases of inversion of the epididymis the testicle is found in front of the effusion. In encysted hydrocele there is a cyst which takes its origin between the testicle and the epididymis, either on a level with the head of the latter, or a little lower. This cyst increases in volume, little by little, until it conceals the testicle, but it always remains attached to the head of the epididymis by a point more or less constricted, as large as the thumb or two thumbs, and it is always possible to outline the gland, which is impossible when it is enveloped by an effusion.

It is necessary to distinguish several varieties of vaginal hydrocele, and to describe separately congenital hydrocele, and hydrocele in Dupuytren's pouch. In the fœtus there is nothing in the tunica vaginalis, and it is at the time of the descent of the testicle that a prolongation of the peritoneum is dragged down, constituting the serous cavity. Congenital hydrocele is that in which the peritoneo-vaginal prolongation is not separated from the large abdominal cavity. The liquid which the sac holds is then very easily reducible, and returns into the abdomen very rapidly when the passage is large. If, on the contrary, the passage is small, it may require some time to return all of the fluid. Hydrocele in Dupuytren's pouch is a second variety of congenital hydrocele. It is easy to confound this variety with bilobar hydrocele. The latter is that in which, owing to the resistance of the fibrous tunic of the pouch, a bridle is formed which divides the sac into two portions. Hydrocele in the pouch is a variety in which the peritoneo-vaginal conduit, instead of becoming obliterated after the passage of the cord, is closed only in its upper portion, this closure completely shutting off communication with the peritoneal cavity. If, under these circumstances, an effusion occurs into the tunica vaginalis, it will divide into two portions, the one occupying the cavity which extends from the base of the sac to the orifice of the canal, and the other an intra-canalicular dilatation. Occasionally the peritoneum is pushed back, and it then forms a subperitoneal sac, which may be felt in the iliac fossa. In some cases, vaginal hydrocele runs even to the external orifice of the vaginal canal.

Of hydrocele of the cord there are two varieties: in one, the cavity presents itself above the line of the cord, and evidently consists of the non-obliterated remains of the peritoneo-vaginal canal. It is seen as a small, resistant, transparent tumor, at a point more or less elevated above the passage-way of the cord. Some cysts of this kind at times descend to the lower portion of the pouch, and it is then possible to confuse them with ordinary hydrocele. On the other hand, the obliteration of the peritoneo-vaginal canal may take place in its lower portion, all the upper portion remaining patulous, and forming a serous cavity which may be taken for an hernia or an effusion. In this variety, which is very rare, the effusion descends along the inguinal canal, and forms a transparent, reducible tumor. This is, if we adopt the name given by Chassaignac, a peritoneo-funicular hydrocele.

Finally, there is hydrocele of the hernial sac, which may extend the length of the inguinal canal, and even reach to the base of the pouch. The hydrocele is a serous cavity filled with liquid; sometimes the intestine and omentum are absent, and there is no communication with the peritoneum, but at other times an organ is found in the sac which should be in the abdominal cavity. Hydrocele of the hernial sac does not descend to the base of the scrotum, and it is easy to recognize it. Nevertheless, the diagnosis between it and peritoneo-funicular hydrocele, or cysts of the cord, may be quite difficult.—*L' Union Médicale*, January 1, 1891.

HYDRASTIS CANADENSIS IN UTERINE HÆMORRHAGES.

Jules Bataud refers to the paper by Schatz, and to the recent theses by Cabanès and Pigache, which contain a *résumé* of the recent literature upon hydrastis. Bataud himself has studied the effects of hydrastis in four cases of uterine hæmorrhage which occurred in the wards of the Saint-Lazare.

The first case was that of a prostitute, twenty-seven years old, with secondary syphilis, who was unexpectedly arrested while street-walking, and was taken to Saint-Lazare. She was of a very nervous and impressionable temperament. Menstruation was regular, scanty, and accompanied with dysmenorrhœa. The patient had never had a child or a miscarriage, and, though she had been at the hospital a dozen times before, had never had uterine hæmorrhage. At the time of admission it was found that she had an enormous papulo-hypertrophic syphilide of the vulva and anus. On the night of admission she was seized with profuse hæmorrhage from the uterus, preceded by dysmenorrhœal pains, though she had menstruated only fifteen days before. The cause of the hæmorrhage was thought to be congestion of the ovaries and uterus, induced by the shock of her sudden arrest—such an effect is said not to be uncommon in patients brought to Saint-Lazare. An examination of the uterus and ovaries showed no cause for the hæmorrhage. The patient was given ten drops of fluid extract of hydrastis thrice daily, and the hæmorrhage ceased nine days after its first appearance. It is not clear from the text whether she took the hydrastis from the beginning of the hæmorrhage or not. The drug was continued for twelve days after the hæmorrhage had ceased. The following menstrual period continued only three days, and the flow was scanty as usual.

The second patient, a woman, twenty-one years old, was admitted for gonorrhœal urethritis and vaginitis, with discrete vegetations about the anus and vulva. Menstruation was regular and painless, lasting four or five days. She had had neither children nor miscarriages. While descending the stairs, one day after admission, she fell, striking her side over the region of the kidney. Two hours later she was seized with acute pain, and was obliged to go to bed. The same night very profuse and painful hæmorrhage from the uterus came on. There was a large ecchymosis in the left lumbar region. Forty drops of fluid extract of hydrastis were given

daily, in four doses. The next day pain and hæmorrhage were less, and in five days from the beginning of the administration of hydrastis, and in six from the time of the accident, the hæmorrhage had ceased.

In the third case, a woman, twenty-three years old, was admitted for syphilitic erosions of the mouth. Her menstruation had always been regular, scanty, and painless, lasting four or five days. She had had neither children nor miscarriages, and had never had menorrhagia or pain in the abdomen until three months before admission, when she rolled down stairs. This accident was followed by a sensation of heat and weight in her abdomen. Two days later menstruation set in, and was painful and much more profuse than normal, and continued ten days. In the interval between her menses the pains continued, and leucorrhœa developed. The last menstruation before admission was similar to the one just described. The uterus, vagina, and vulva were intensely congested. The dull curette disclosed no lesion of the endometrium. At the next menstruation the patient was kept in bed, and was given forty drops of fluid extract of hydrastis a day, beginning on the second day after the appearance of the flow. Menstruation lasted only seven days, and was less painful. The hydrastis was continued until the next menstruation appeared, which was not painful, lasting only five days, and was not as profuse as before. The congestion of the uterus is said to have been completely cured.

In the fourth case, a woman, thirty-nine years old, had been curetted eight months before for metrorrhagia due to an endometritis following abortion. The patient was cured by the operation, and menstruation became normal as to quantity and duration. On the second day of one of her menstrual periods, she had intercourse with her husband. Instead of the flow ceasing on the fourth day as usual, it continued for eight days longer, the patient suffering at the same time from sensations of heat in the pelvic organs. Bataud saw the patient on the tenth day of the hæmorrhage, and gave her four one-grain pills of hydrastin a day. The sensations of heat and the hæmorrhage diminished from the first, and ceased on the second day. Since then she has had two periods, each lasting only four days. Absence of endometritis was proved by curetting the womb. Hydrastin was used instead of the fluid extract of hydrastis, because of the disagreeable taste of the latter.—*Revue Médico-Chirurgicale des Maladies des Femmes*, Jan. 25, 1891.

TACHYCARDIA.

At a meeting of the Society of Internal Medicine of Berlin, January 19, 1891, Fraentzel spoke upon tachycardia. Since the first publications upon this disease the number of communications on the subject has increased from year to year. But a mistake has crept in. The habitual acceleration of the pulse which is present in the most diverse diseases of the heart, and which persists without recognizable change for years, should not be called tachycardia; this name should be reserved for the paroxysmal acceleration of the pulse—the essential paroxysmal tachycardia of the French, in which the disease occurs suddenly, and the pulse increases to 180 or 200 beats per minute.

The symptoms of tachycardia may be explained in two ways, as the result of palsy of the vagus, or from irritation of the accelerator fibres of the sympathetic. The latter cause is more easily understood, the symptom occurring as a spasm, or neuralgia, or a colic occurs. Although from the very beginning the tendency has been to attribute tachycardia rather to a palsy of the vagus than to a stimulation of the sympathetic, yet there are individual symptoms inexplicable by that hypothesis; for example the attack ceases if a blow is struck upon the thorax, and the paroxysm begins with pallor and dilatation of the pupils and subsides with such symptoms as sweating, flushing, and contraction of the pupils.

Excitement of the sympathetic is often cured by a dose of morphine, while in palsy of the vagus digitalis acts very well, or the attack may be cut short by compression of this nerve. Recovery, however, does not always occur so quickly; frequently the disease lasts for years, and then ceases suddenly.

The lack of a clear understanding of the cause makes the treatment uncertain. One should not, however, following Nothnagel, discard all treatment, on the ground that the attacks are not serious and that the disease will subside of itself. Fraentzel, for example, has seen several grave cases, in one of which there was extensive stasis in the lungs and veins, with cyanosis, orthopnœa, catarrh of the lungs, and swelling of the liver. Morphine was of no use in this case, but digitalis overcame the condition. The severity of the symptoms at that time convinced Fraentzel that the disease might result fatally, and since then he has discovered two fatal cases in the literature of the subject, and has subsequently seen one himself. His own case was that of a workman, thirty-five years old, who complained of dyspnœa, which occurred suddenly; he had formerly had cardiac palpitation. The heart was not enlarged, and its sounds were normal. On the day after admission, his pulse was 180, and the respirations 40. Digitalis caused the symptoms to disappear within twenty-four hours, and was just as prompt in several other attacks. Finally, however, this drug failed in a fresh attack, and the heart became visibly enlarged; the pulse was 172; cyanosis appeared, followed by death. At the autopsy both ventricles were found dilated, and the papillary muscles flattened. There was also fibrous thickening of the endocardium. The valves were intact.—*Münchener med. Wochenschrift*, February 3, 1891.

THE POLYURIA OF PREGNANCY.

M. Voituriez writes that the modifications observed in the urine during gestation are of frequent occurrence, and have for a long time attracted the attention of practitioners. According to Monod, 26 per cent. of all women suffer from urinary disorders during pregnancy. The cases have been divided into two great classes, namely, disorders of secretion

and disorders of excretion, among the former being placed the albuminuria of pregnancy. Independently, however, of the disorders of secretion which have been fully described by various writers (W. Duncan, J. Williams, Lecorché, and others) the great changes produced by gestation in excretion are especially worthy of note. These, as has been pointed out by Monod, most frequently depend upon a concomitant cystitis. Monod has divided these interesting and but little known forms of cystitis into several groups, according to the period of gestation in which they occur. Thus, he describes a cystitis appearing about the fourth week, which is characterized by intestinal pains, very frequent micturition, and the presence of a muco-purulent deposit. From a pathogenic point of view he explains this as due to the vascular relations existing between the bladder and uterus, relations which were well studied by Gillette in 1869. Physiologically, the menstrual uterine congestion reacts upon the bladder, and determines a vesical congestion; pregnancy in profoundly modifying the circulatory conditions of the pelvic organs acts in the same way, and the vesical congestion, in some respects normal, may terminate in a true cystitis. Secondly, he mentions a cystitis arising from retro-displacement of the uterus, which is but seldom encountered before the end of the third month of gestation. It results from fixation of the retroflexed uterus within the pelvis, and becomes very grave if the displacement is not quickly corrected. It is frequently accompanied by absolute retention, and later even by alterations in the walls of the bladder. This is the exfoliating or gangrenous cystitis recently investigated by Mm. Pinard and Varnier. Third, there is a form of cystitis observed toward the end of pregnancy, accompanied by tenesmus and frequently by retention of urine. It is due to the presence of the fœtal head which has passed the superior strait. In cases of narrowing of the pelvis, or when labor is prolonged, mortification of the wall of the bladder occasionally occurs following an arrest of the circulation from the excessive and continuous pressure. Finally, after labor, and particularly after instrumental interference, the so-called "post-partum retention of urine" is seen. This retention is analogous to that which Verneuil has described as occurring after operations performed upon the genito-urinary tract.

In the matter of diagnosis, there is but little danger of confounding the polyuria attending pregnancy with diabetes and cystitis. Diabetes occurring in the course of gestation, frequently reveals itself by emaciation, tuberculosis, or cachexia of the mother, or by the death of the fœtus and abortion. A chemical examination will remove all doubt. It is easier to mistake this polyuria for cystitis. The latter is sometimes accompanied by polyuria, but this is never considerable. Moreover, there are tenesmus and intestinal pain, often quite severe, which do not exist in true polyuria. Micturition is frequent in both cases, but in cystitis the urine is passed in small amounts, a few drops at a time, whilst in polyuria the urine is abundant at each micturition. Finally, in true polyuria the urine does not deposit urates, phosphates, muco-pus, or blood; there is no pain in the intervals between micturition, the bladder preserving its normal capacity and being susceptible of a certain amount of distention; each micturition completely relieves the patient. The urine of the polyuria of gestation is clear, slightly acid, and of a normal composition, its density being diminished by dilution of the salines and extractives. The prognosis of this condition seems to be good.—*Archives de Tocologie*, December, 1890.

CIRRHOSIS OF THE LIVER IN CHILDHOOD.

HEPATIC cirrhosis is rare in children, as all observers since Gerhardt have noticed. If we except those due to hereditary syphilis, not more than one hundred cases have been reported. Syphilitic infection of the liver was first described by Gubler, in 1847; and Virchow, in 1860, added a remarkably exact description of the histological features of the different forms. With cirrhosis due to syphilitic infection must be included that form due to tuberculosis. One of the first cases of cirrhosis of the liver observed in a child, that of Becquerel (1840) was in a tuberculous patient, but it was not until 1883 that Sabourin spoke of the etiological *rôle* of tuberculosis in the formation of hepatic cirrhosis. After these two great causes the eruptive fevers must be classed as most prominent in giving rise to hepatic inflammation, as proven by Laure and Honorat (*Revue mens. des Mal. de l'Enfance*, March, 1887). According to a table published by Edwards in the *Archives of Pædiatrics*, one-third of all the cases reported were due to infectious diseases. Congenital obstruction of the bile-duct has been recognized in one case as a cause of hepatic cirrhosis. Cardiac lesions are frequent causes of cirrhosis in childhood, quite a number of cases arising from this cause having been reported. While alcohol is not so frequent a cause of cirrhosis in children as in adults, it nevertheless is a more frequent cause than generally supposed. In one hundred cases, seventeen were probably of alcoholic origin, and eleven of the seventeen were certainly due to that agent.

As regards the pathological anatomy of the cirrhotic liver, the following alterations are noticed: There is a dilatation of the interlobular vessels; a proliferation of the connective tissue in the dilated portal spaces, with prolongations extending into the interior of the lobules, even to the central vein; fibrous thickening of the walls of the vessels; proliferation of the biliary canaliculi; and sometimes, at the periphery of the lobules, fatty degeneration of the hepatic cells. Ordinarily the cirrhotic process is generalized, but at times it is disposed in islets. In the first stage of the disease the organ is large, soft, brownish-red or violet in color. Then, as the cirrhosis is established, the liver diminishes in size and becomes hard and elastic.

As in adults, the symptomatology varies much, according to the stage of the lesion and the age of the patient. Thus in young infants vomiting is very frequent, and gastric disturbances are marked. Con-

stipation is the rule, but sometimes diarrhœa accompanies the vomiting. Hæmatemesis is frequently encountered, and occasionally intestinal ulcerations with melæna. Epistaxis is very frequent; hæmorrhages from the mouth, subcutaneous hæmorrhages, hæmorrhagic purpura, and chronic urticaria are also quite common. Two symptoms are especially frequent, namely, jaundice and ascites, and contrary to what occurs in adults, these symptoms often occur together. Their intensity varies much according to the case. In some cases the ascites is scarcely noticeable; in others, on the contrary, it is necessary to tap two or three times. Especially does the ascites play an important *rôle* in cases in which the cirrhosis succeeds a scarlatinous infection or in cases where alcoholism is manifest. The jaundice is frequently only perceptible, whilst in other cases it is pronounced and permanent. Œdema occasionally occurs. Dilatation of the veins of the abdomen and chest are very constant, and especially prominent in cases in which the ascites is pronounced. In one-fifth of the cases reported albuminuria with renal sclerosis was noticed. Convulsions, coma, and ataxo-adynamic phenomena are advanced symptoms indicating a fatal termination. The prognosis is bad, a fatal termination usually following in two or three years. The progress of the disease is more rapid than in adults. From a diagnostic point of view the greatest difficulty lies in differentiating this disease from tubercular peritonitis, and care must be exercised in this respect in each case.—Blanche Edwards in *Le Progrès Médical*, January 10, 1891.

REGULATION OF PROSTITUTION.

Moeller in the *Journal des Maladies Cutanées*, December, 1890, makes the assertion that the measures adopted in the regulation of prostitution are inefficient from a hygienic point of view. While admitting that the danger of contagion is greatest during the primary stage of syphilis, and slightly less during the secondary period when the external manifestations of the disease are present, he claims that during the entire secondary period the person infected is able to transmit the disease, even when there are no external manifestations, as has been proved by the infection of nurses from infants and *vice versâ*, and by the infection of women during intercourse. This contagiousness of syphilis during the latent stage of the secondary period, is but little marked if the body of the infected person does not present any external solution of continuity; but the slightest scratch or laceration of the skin or mucous membrane considerably increases the danger of contagion. For this reason Moeller claims that persons afflicted with syphilis should abstain from sexual intercourse not only during the existence of the primary sore, or when the secondary manifestations are present, but in the latent period as well. This is the duty of every man or woman affected with syphilis, to neglect which is culpable. He goes on to say that our present regulations are based upon the assumptions of physicians at the beginning of this century, who believed that gonorrhœa, soft chancre, and syphilis, were all of the same nature, and only contagious in the initial stages. The researches of the succeeding years have entirely revolutionized these views, hence the necessity of altering the laws governing prostitution to meet the dangers which have been discovered.

As a substitute for the present laws upon the subject he suggests a system as follows: Every person who is convicted of certain offences relative to prostitution, or who has committed some infraction of the articles of the penal code, should be, if he be sentenced to imprisonment, submitted to a physical examination at the moment of arrest. This examination should be repeated at the expiration of punishment. If the physician confirms the presence of syphilitic lesions, the patients should be admitted into a hospital for treatment. In addition, they should be forbidden to resume their trade, and instructed not to indulge in sexual intercourse as long as the dangers of contagion exist. They should likewise be obliged to submit to periodical visits during a variable time, to be determined at the beginning of the sickness. The advantage which Moeller claims for this system is, in the first place, the suppression of the registration of prostitutes; second, in place of leaving to hazard or to arbitrary attention the designating of the prostitutes who should be submitted to sanitary visits, it is the prostitutes who, by the infractions they have committed, would designate themselves, in virtue of a positive law which they know and which they ought to recognize. Moreover, the civil authorities would no longer recognize the right of the infected prostitutes to continue their business, and would interdict them from the practice of their profession, so long as they could be dangerous to the public health. Thus would disappear that security which the public accords, rightly or wrongly, to the registered prostitutes, who are considered as healthy in virtue of the certificate delivered after the inspector's visit. Finally, the prophylactic system thus designed would neither violate individual liberty nor the moral law.

THE ELIMINATION OF MERCURY.

The following table illustrates the results obtained by Dr. H. Stern in his investigations regarding the elimination of mercury.

The second column shows the total amount of mercury given. In the majority of cases it was administered hypodermically in the form of the oleum cinereum of 50 per cent. strength; in Case VI. it was used as a plaster, and in one, as inunctions with blue ointment.

In the third column are shown the number of days which had elapsed since the last treatment with mercury, at the time the examinations of the urine began. In the fourth column the number of days during which the total daily amounts of urine were tested for mercury by quantitative analysis, and in the fifth column the total amount of mercury found during those days is shown.

Case	Mercurial treatment.	Time elapsed since last treatment.	Total quantity of urine examined during—	Amount of mercury found.
I.	0.35 c.c. ol. cin. 50 per ct. (hypoderm.) (= 2.713 gr. Hg.)	91 days.	10 days.	0.0002 grm. (0.0031 gr.)
II.	0 41 c.c. ol. cin. 50 per ct. (= 3.1 gr. Hg.) + 0.10 c.c. ol. cin. 50 per ct. (= 1.55 gr. Hg.)	174 "	10 "	0.0006 grm. (0.0093 gr.)
III.	0.45 c.c. ol. cin. 50 per ct. (= 3.40 gr. Hg.)	58 "	10 "	0.0005 grm. (0.00775 gr.)
IV.	0.35 c.c. ol. cin. 50 per ct. (= 2.713 gr. Hg.)	181 "	10 "	Traces.
V.	0.45 c.c. ol. cin. 50 per ct. (= 3.49 gr. Hg)	35 "	6 "	0.0031 grm. (0.04805 gr.)
VI.	Ca. 10 × 10 c.c. (= ca. 4×4 in.) emplastr. hydr. ol. during 69 days (changed three times).	24 "	7 "	0.0007 grm. (0.01085 gr.)
VII.	Blue ointment rubbed into the skin abundantly for two years, 444 grm. (= 6882 gr.) blue ointment.	21 "	5 "	0.0077 grm. (0.11935 gr.)

—*Wiener klin. Wochenschrift*, Dec. 25, 1890.

REVIEWS.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS. By FRANK H. HAMILTON, A.B., A.M., M.D., LL.D. Edited by STEPHEN SMITH, A.M., M.D. Philadelphia: Lea Brothers & Co., 1891.

IN any work upon general surgery adapted, as so many are, to the needs of the practitioner who is hurried too greatly to look up more than the necessary facts, a complete treatise upon any one subdivision would be out of place. Dr. Hamilton's work has always been recognized as the leading American authority upon fractures, and its great utility has been evidenced from the rapidity with which it has undergone revision after revision, until the volume which lies before us, edited by the author's pupil and at one time assistant, has reached its eighth edition.

Dr. Hamilton's opportunities for observation both in private and military practice during his long professional career, his profound knowledge of the anatomical relations and mechanical adjuvants in the causation and treatment of fractures and dislocations, together with the results of numerous and carefully conducted post-mortem dissections have rendered his book in its later editions of far more value than any other text-book upon these two subjects. The present edition, with none of its former valuable data eliminated and with such additions as the recent advance in surgical treatment (especially in antisepsis) has taught, makes *Hamilton on Fractures* a necessity not only to the surgeon but also to every physician.

The author has condensed and rearranged many of the clinical reports and added much thereto. Over one hundred new illustrations fully explaining the context, both old and recent, have been inserted, many of which are photographic reproductions of the lesion *in situ*.

The present volume follows its predecessors to a great extent in its general arrangement, part first being devoted to the consideration of fractures, part second to dislocations.

In the preliminary chapters a very thorough exposition is given of the classification of fractures in general, together with their causes, symptoms, diagnosis, treatment, complications and sequelæ. Many theories, a few years ago unknown or doubtful, are here proven correct by numerous cited cases. No more complete collection of the factors in causation and symptomatology has ever appeared. In discussing treatment, the author always presents and strongly upholds his own method in each case, but due weight is also given the opinions and results of others, no matter how widely at variance with his own views. Every method of treatment that has ever been tried in the case in point is mentioned, its good side commended, or its fault detected and the remedy suggested. The chapter upon delayed, vicious, and non-union of bones is especially clear, and must, if carefully studied, be of immense value and comfort to everyone who, if he practises surgery at all, at some time meets with some one of these troublesome results even after most careful treatment. Non-union, about which concerning the frequency of its occurrence statistics are so variable, the author estimates as happening but once in five hundred cases. As far back as the decade 1830–1840, of 946 cases of fracture treated in the Pennsylvania Hospital, not a single false union occurred. We note gladly that Dr. Hamilton does not approve of a primary "fixed" or "immobile" starch, plaster-of-Paris, or silicate-of-sodium dressing in the treatment of recent fractures. Nor does he recommend the "primary roller," so-called. "Immovable dressings are not only liable to become too tight as the swelling augments, but the surgeon may omit to notice that as the swelling has subsided they become too loose." "Except in rare cases and for especial reasons . . . . I cannot recommend the employment of any bandages next the skin."

The author then takes up in regular order, commencing with those of the face, all the bones in the skeleton, thoroughly discussing every fracture to which they are liable, giving cause, symptoms, diagnosis, complications, and treatment. Not even the most trivial point is overlooked, and one having read the book feels that all that is known to science upon the subject has been given him from which to draw his own conclusion. It is impossible to give precedence to any one chapter over another, but if any be named, those upon fracture of the vertebræ, humerus, femur, and pelvis are especially full and valuable. As Dr. Hamilton was one of the surgeons in attendance upon the late President Garfield, his account of the gun-shot fracture of the vertebræ, with the course of the case prior to death and photographs of the specimens and official post-mortem records, are most interesting.

Part second—dislocations—follows in arrangement the previous pages. And here the most careful labor has evidently been bestowed upon the chapters describing luxations of the shoulder and hip, the illustrations,

especially those depicting the various mechanisms in reduction, being exceptionally good.

Too much praise cannot be bestowed upon a work of such magnitude, so carefully written. It is everywhere clear, compact, concise. Principles are plainly enunciated and thoroughly elaborated; clinical examples of all possible cases abound. The seven hundred illustrations with which the work is embellished are by far the best we have ever seen in a text-book of this character. Typographically the appearance is good, and subordinate matters being in small print, one sees at a glance the important facts in larger type.

CORRESPONDENCE.

NEW ORLEANS.

The Charity Hospital Board of Administrators have presented their report to the State Legislature for the year 1890. The total number of patients treated was larger than it has ever been before. 6680 patients were admitted into the wards, 13,315 were treated in the outdoor consultation clinics, 1247 in the dental department and 1349 were attended by the ambulance surgeon. There were 1023 deaths during the year. The mortality of the hospital patients was materially increased during the last three months of the year owing to the large number of cases of pneumonia which occurred during the epidemic of "la grippe" prevailing at that time. The hospital is in good condition and two new buildings for the out-door clinic will be erected in a short time.

On March 5th the Board of Administrators of the City Eye, Ear, Nose and Throat Free Hospital held their first annual meeting. They decided to drop the words "city" and "free" from their title, as many patients, thinking that this hospital is supported by the city, go there when they could pay a physician. The affairs of this hospital are in a prosperous condition. From December, 1889, to December, 1890, 627 surgical operations were performed, and 4816 patients received medical treatment. The number of visits made by applicants for treatment was 3816.

There were thirty-five applicants at the competitive examination for resident studentship in the Charity Hospital for the next two years, of whom the following gentlemen were successful: J. J. Ayo, C. M. Brady, H. S. Lewis, J. R. Jiggitts, C. L. Horton, H. F. Thigpen, H. R. Bohn and E. J. Reeves. The examination was oral, written, and clinical.

About the middle of April an examination will be held for the position of Assistant House Surgeon of the Tours Infirmary. Applicants must be graduates of medicine, and the successful candidate must live in the infirmary. The salary of the position is $600 a year and board.

The Eye, Ear, Nose and Throat Hospital has reserved rooms for the treatment with Koch's lymph of tubercular patients. One patient, who had lupus, died while under treatment. On the third day after the injections were commenced a large amount of blood and albumin, with granular and hyaline casts, was noted in the urine. The patient died with symptoms of peritonitis. His urine is said to have been normal before the injections and there was no sign of tubercular trouble elsewhere. The autopsy showed that he died of acute peritonitis and nephritis. Prof. Jos. Jones tendered the bottle of lymph sent him by President Harrison to the authorities of the Charity Hospital, but it was never used.

The Board of Administrators of the new Hospital for Women and Children have made an excellent selection in Dr. E. D. Martin, whom they have elected to the position of House Surgeon. This hospital will be run by the "Ladies' Unsectarian Aid Society." It is a "pay" hospital, and any physician can send his cases there and have them under his own care.

The hospital at the U. S. Barracks has been finished, and reflects credit on Surgeon Wm. Kneedler, who has superintended its construction. It is a frame building, situated in the rear of the officers' quarters, and has all modern conveniences. It will have accommodations for twenty-four patients. The rooms are comfortable and well lighted.

REFLEX PAIN IN REMOTE REGIONS AN EVIDENCE OF INTERNAL HÆMORRHAGE.

To the Editor of The Medical News,

Sir: Referring to your valuable article in the last number of The Medical News on "Abdominal Pain in Hæmorrhage into the Pericardium" I wish to communicate the following three cases taken from my records:

Sept. 1880, J. K., a German, aged fifty-nine years, while engaged in playing chess with me complained of an excruciating pain in his left knee, which had developed a few hours before and gradually became more intense. He had never suffered with rheumatism or neuralgia of any kind, never met with any injury and never felt any pain in that knee. An examination gave no result; there was neither redness, swelling nor tenderness. He went home promising to use certain anodynes as directed by me. Late the same night I was sent for, the pain not having diminished. A hypodermic of Morph. sulph., one-sixth grain, gave no relief, and it was followed fifteen minutes later by a second injection of one-fourth of a grain and the pain became less severe. The next day the pain remained about the same; he refused another hypodermic and I had a blister applied at 11 A. M. Otherwise his health was undisturbed, there being no symptom or sign of any other morbid condition. As I was informed later, the pain subsided somewhat about five o'clock in the afternoon, probably from the effect of the blister still covering the spot. A few minutes before 6 P. M. the pain again became suddenly intense; he expressed a desire to use the commode, and while sitting upon it he was seen to fall forward. An immense hæmorrhage extending over the entire base of the brain had caused the fatal issue before I reached him an hour later.

Z. S., aged sixty-three years, a remarkably active and healthy-looking Israelite, while visiting, on the afternoon of Dec. 14, 1884, a lady friend with whom he had been very intimate for years, complained of a severe pain in the left leg, a little below the knee. This pain became so severe that a neighboring physician, a homœopath, was sent for. He had the patient go to bed and administered various internal remedies. At about 9 P. M. the

pain became easier, when suddenly all the symptoms of the classical apoplectic seizure developed. In this state he was removed to his home, where I saw him about 11 P. M. Venesection, the application of croton oil to his tongue, and the internal use of tartar emetic caused him to regain consciousness; but when I saw him the next morning his temperature was 102° and the fatal issue seemed imminent. Later in the day the hæmorrhage recurred and he died the same night.

October 11, 1886, J. F. S., aged fifty-three years, a Catholic bishop, consulted me about a severe pain in his back. The closest examination failed to reveal its cause. It was not lumbago, for no movement of any kind augmented or diminished the pain. After several days of fruitless medication a blister cured it. The bishop then remained well for three months, when the same pain suddenly returned while he was at his home on the night of January 16th. Nothing seemed to give relief, and a little after 5 A. M. death occurred from cerebral hemorrhage.

No autopsy was made in the last two cases, but the diagnosis was clear. I report these cases without at present desiring to discuss the nature of these reflex pains. DR. HUGO ENGEL.

NEWS ITEMS.

Army Medical Board.—An announcement was recently made that an Army Medical Board would be in session in New York City during April next for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. At the time of that announcement there were only five vacancies to be filled. Recent Congressional legislation has, however, permitted the retirement of certain officers, so that there are now fourteen vacancies in the grade of assistant surgeon, with the probability that the number will be increased to seventeen by the time the examining board begins its labors.

As already stated, persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 1, 1891, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his Diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, Washington, D. C. C. SUTHERLAND,
Surgeon-General U. S. Army.

The Medical and Surgical College of New Jersey.—It affords me much pleasure to inform you that our bill repealing the charter of the Medical and Surgical College of this State has been passed by the Legislature and approved by Governor Abbett. It is hardly necessary for me to say that this Board feels that it has, in the first year of its existence, done something toward the improvement of the medical profession, not only in New Jersey, but throughout its sister States.

Yours very truly,
WILLIAM PERRY WATSON,
Secretary of the State Board of Medical Examiners.
JERSEY CITY, March 11, 1891.

Notice to the Military Surgeons of the National Guard.—DR. NICHOLAS SENN, of Milwaukee, Surgeon-General of Wisconsin, is desirous of obtaining the name and address of every surgeon of the National Guard for the purpose of taking the preliminary steps toward the formation of a permanent National Association.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 17 TO MARCH 23, 1891.

By direction of the Acting Secretary of War, PASSMORE MIDDLETON, *Major and Surgeon*, is relieved from duty at St. Francis Barracks, Florida, and will proceed to Newport Barracks, Kentucky, and await further orders. The travel enjoined is necessary for the public service.—Par. 8, *S. O. 62, A. G. O., Washington, D. C.*, March 19, 1891.

BIRMINGHAM, HENRY P., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, with permission to apply for an extension of one month, to take effect upon the arrival at Boise Barracks of Robert R. Ball, First Lieutenant and Assistant Surgeon.—Par. 2, *S. O. 39, Department of the Columbia*, March 13, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 21, 1891.

CLEBORNE, C. J., *Medical Director.*—Detached from Naval Hospital, Norfolk, Va., and ordered to Naval Hospital, Chelsea, Mass.

PENROSE, T. N., *Medical Inspector.*—Ordered in charge of Naval Hospital, Norfolk.

STEELE, JOHN M., *Passed Assistant Surgeon.*—Detached from Coast Survey Steamer "Bache," and granted three months' leave of absence.

GAINES, JAMES H., *Surgeon.*—Placed on the Retired List, March 18, 1891.

RUTH, M. L., *Surgeon.*—Granted a month's leave from April 2d next, with permission to leave the United States.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

ORIGINAL ARTICLES.

A SUCCESSFUL PORRO-MÜLLER OPERATION FOR MALFORMATION OF THE UTERUS AND VAGINA.

BY WILLIAM E. ASHTON, M.D.,
OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL.

THE patient, a mulatto woman, was brought to me in September, 1890, by her physician, Dr. James L. Kite, of Philadelphia, for an opinion as to the possibility of delivery by the natural passages. The history of the case was as follows:

Sophie D., aged twenty-five years, born in Virginia, and married for one year. She was at the time seven and a half months advanced in pregnancy. She was healthy as a child and began to menstruate at seventeen years of age. Her periods occurred regularly, lasting two days, and were always followed by leucorrhœa which continued for from three to seven days; during the last three years, however, the vaginal discharge has increased in quantity. At the time of the menstrual flow she suffered from the reflex symptoms common to all women; there was, however, no great pain at any time. She was examined six years ago by her family physician, who told her that owing to absence of the womb she could never menstruate. Her statement that she had menstruated every month was discredited. She was married in September, 1889; pregnancy occurring in January, 1890. During her entire pregnancy there was hæmorrhage from the vagina every twenty-eight days.

On examination I found the vagina to be only two inches in length, and ending in what at first seemed to be a blind *cul-de-sac*. More careful manipulation, however, revealed a number of small elevations radiating in all directions from a slight depression in the centre of the vaginal pouch. This I took to be the sinus through which the vagina communicated with the uterus. Examination through the rectum showed the cervix to be above the vaginal *cul-de-sac* and separated from it by a distance of at least half an inch.

Taking these anatomical conditions of the organs into consideration I decided that I was dealing not with atresia but with a malformation of the upper segment of the vagina and the lower part of the uterus. This anomaly had so altered the normal relations between the organs that delivery by the natural passages was impossible. I, therefore, did not feel justified in advising the patient to allow nature to take its course, especially as I was uncertain, prior to the operation, as to the character of he structures uniting the vagina with the uterus. And, again, as the dangers of a section are but slight, in the hands of an abdominal surgeon, I urged the patient to undergo the Porro operation. Prior to operating the case was examined by Drs. Robert P. Harris and J. M. Baldy, and my colleagues Drs. E. E. Montgomery and Barton Cooke Hirst, all of whom concurred with me in the diagnosis and in the advisability of a section.

Operation.—The operation was performed in the amphitheatre of the Philadelphia Hospital on October 17, 1890, in the presence of a large number of physicians and medical students. I was assisted by Drs. Barton Cooke Hirst and E. E. Montgomery, and my resident physician, Dr. Bitting.

The patient was prepared in the usual manner employed for all forms of abdominal operations. The only instruments used were a scalpel, six hæmostatic forceps, one pair of scissors, a needle-holder, and needles and sutures for uniting the abdominal wall and for stitching the parietal peritoneum to the stump, four surgical sponges, Tait's uterine constrictor, and a rubber ligature.

Abdominal incision.—The incision was begun at 11.18 A. M. It extended from within three fingers' breadth of the pubes to about one inch above the umbilicus and was six inches in length.

Eversion of the uterus.—At 11.20 A.M. the uterus was everted. Before the organ was delivered it was given a quarter of a rotation upon its long axis so that its antero-posterior diameter instead of the transverse presented at the abdominal opening.[1] After eversion of the uterus dry bichloride towels were placed around the cervix so as to close the abdominal cavity, thus preventing the access of fluids and the escape of the intestines.

Constriction of the cervix.—At 11.21 A.M. a rubber ligature was thrown loosely around the cervix and the ends secured by hæmostatic forceps. Dr. Hirst then encircled the neck of the uterus with his hands, making, however, no pressure.

Incision of the uterus.—At 11.21 A.M. an opening large enough to admit my finger was made into the anterior part of the body of the uterus. This opening was then rapidly enlarged by tearing the muscular fibres with my fingers.

Extraction of the child.—At 11.21 A. M. the membranes were ruptured, the child grasped by the hips, delivered, and the cord cut after constricting it with a pair of forceps. The child was then handed to

[1] This plan was suggested to me by Dr. E. E. Montgomery,

Dr. Montgomery, who placed it in the incubator. The liquor amnii was caught in a basin held by Dr. Bitting when the membranes were ruptured. After the child was delivered Dr. Hirst tightened his grasp around the cervix, thus absolutely controlling the hæmorrhage until I made taut the rubber ligature and kept it in that condition by securing the ends close up to the cervix with forceps.

Removal of placenta and membranes.—At 11.22 A.M. the placenta was detached and removed along with the cord and membranes. The uterus at once contracted strongly.

Sutures.—The abdominal wall was closed with silkworm-gut, using four sutures to an inch. I used a curved needle threaded with catgut to stitch the parietal peritoneum to the stump.

Removal of the uterus.—Tait's constrictor was now applied to the cervix below the rubber ligature, and the wire tightened, the constricting band of rubber being then removed. The uterus was amputated close up to the wire, leaving, however, enough tissue for the stump. It was 11.40 A.M. when the uterus was removed, just twenty-one minutes and forty seconds from the time I began my incision into the abdominal wall.

History of the case subsequent to operation.—The pulse after the operation was eighty, and at no time during convalescence exceeded eighty-eight. The recovery was afebrile, the stump coming away on the twenty-first day after the operation. A free movement from the bowels was induced by a dose of salts twenty-four hours after the operation. The feeding and general care of the patient were the same as usually carried out during convalescence after abdominal operations not involving the intestinal canal.

Child.—The baby, a female, weighed at delivery six pounds and ten ounces; its weight, January 19, 1891, was twelve pounds and twelve ounces. The following are the measurements of the fœtal head taken immediately after the operation: M. 13; O. M. 11½; O. F. 11; Sub. O. B. 10 cm.; Bi. P. 10½ cm.; Bi. T. 8½ cm.; T. B. 9½ cm.; and the F. M. 8½ cm. The great circumference was 36½ cm., and the small 31¼ cm. The baby was placed at the breast at half-past seven o'clock in the evening of the day of operation, and was nursed regularly from that time on.

REMARKS.—I found the tissue connecting the uterus with the vagina to be simply a reflection of the peritoneum. If the woman had been permitted to fall into labor, the head, being driven down by the uterine contractions, would have ruptured the peritoneal connection between the uterus and the vagina, and the child would have escaped into the abdominal cavity. Giving the uterus a quarter of a rotation on its long axis I consider of great importance in the technique of the operation, as the incision through the abdominal wall need not be so long. This manœuvre enables the Müller modification to be performed through the same length of incision as is the simple Porro, doing away entirely with the objection to the former method of operation. The remarkably short incision—only six inches—which I made, proves this beyond dispute. Whatever the opinion of surgeons regarding the increased danger to life by long abdominal incisions may be, certainly no one can deny the fact that a short opening reduces largely the risk of ventral hernia.

After the eversion of the uterus, sutures were not introduced at the upper part of the incision, but the peritoneal cavity and intestines were protected with dry bichloride towels. This, I believe, to be the better plan, as the fœtus can be delivered more rapidly, and the operation itself is more aseptic and orderly—results sufficient in themselves to recommend its use.

The cervix was not constricted until the child was delivered, when my assistant compressed the neck of the uterus between his hands while the rubber ligature was being drawn taut; this plan prevents the child from being asphyxiated.

It is very easy to select a point at which to begin the opening into the womb, as the fœtal extremities can be accurately located through the uterine wall. The opening into the uterus was made of sufficient size to admit the index finger; the incision being further enlarged by tearing the muscular fibres. This lessens the danger of cutting the fœtus, and, at the same time, greatly increases the rapidity of the operation.

The plan adopted for securing the rubber ligature after it had been drawn taut enables the operator to remove it quickly as soon as the wire constrictor is in position.

Irrigation of the peritoneal cavity was not necessary, as the towels kept everything out of the abdomen. The placenta was situated on the posterior wall of the uterus, near the left oviduct. The quantity of blood lost during the operation was less than the amount which escapes during a natural labor.

In suturing the abdomen four threads of silkworm-gut to an inch were introduced to guard against ventral hernia. I always adopt this precaution in abdominal operations, as I believe there are many cases in which the abdominal wall gives way because too few sutures are used.

I believe the Porro-Müller operation is always preferable when its performance is possible. Notwithstanding the success attained by German surgeons with the Sänger method, I believe the Porro-Müller modification to be the safest. After the child is

delivered the operation becomes a hysterectomy, with the stump treated outside of the peritoneal cavity. The mortality of Martin and others, who advise the intra-peritoneal treatment after hysterectomy, is greater than that of those operators who use the extra-peritoneal method. I believe, therefore, that the complete extirpation of the body of the uterus is the safest plan. Again, a woman who is subjected to a Cæsarean operation, because of an obstruction, should never be allowed to run the risk of a subsequent pregnancy. Furthermore, the Porro-Müller operation can be done with rapidity, which is a great advantage, especially in those cases in which the operation is performed after labor has begun and the patient is exhausted. That the Müller modification necessitates a very long abdominal incision is no argument against the method, as I have shown that the uterus, prior to extraction of the child, can be everted through an opening of only six inches in length.

In conclusion, I desire to enter my protest against slow operations, especially those involving the abdominal cavity. Although the peritoneum may be invaded, and operations of the gravest character successfully performed, it is a great mistake to imagine that the cavity of the abdomen can be kept open and its contents insulted by prolonged manipulations, without retarding convalescence and causing many cases to die of shock, which could be saved by rapid work. The speedy recovery of this case of Cæsarean section, I believe, was due, in no small measure, to the rapid execution of the operation. The character of the pulse, and the condition of the stomach subsequent to the operation, indicated that there had been no shock or ether-saturation of the patient. A large number of the abdominal operations, especially intestinal resections and the like, which I have performed on the lower animals, have been simply to gain manipulative dexterity. Without this dexterity no surgeon can hope to be successful in abdominal work, no matter how profound his knowledge of the subject may be.

THE SHURLEY-GIBBES TREATMENT OF PULMONARY TUBERCULOSIS.[1]

By E. FLETCHER INGALS, M.D.
of Chicago.

The treatment for pulmonary tuberculosis, proposed by Drs. Shurley and Gibbes, consists of hypodermic injections of solutions of the chloride of gold and soda, or of iodine and inhalations of chlorine gas. The injections should be made with an absolutely clean syringe, which should always be washed with pure alcohol before and after using. The treatment should be commenced with small doses, which may be gradually increased until some constitutional effects are observed, or until the largest dose recommended is reached. It is usually best, excepting in advanced cases, to begin with the iodine (though it is apt to cause considerable smarting), and it should be continued for from ten to fourteen days, and then it may be given alternately with the chloride of gold and soda solution, and later on (after four or five weeks) the latter solution may be used alone if everything is going well. With some patients the chloride of gold and soda answers best. I, however, think more benefit will be derived from the iodine solution.

The dose of iodine is from $\frac{1}{20}$th to $\frac{1}{6}$th of a grain, and of the chloride of gold and soda from $\frac{1}{24}$th to $\frac{1}{8}$th of a grain. The minimum dose should be used at first and it should be increased by about 20 per cent. each day until the maximum dose is obtained, unless constitutional symptoms occur. When iodine is used it is to be increased as just directed, unless symptoms of iodism appear, or unless there is some loss of appetite, disturbance of the bowels, or complaint of unusual fatigue. If any of these symptoms occur the iodine may be substituted by the chloride of gold and soda for a day or two and then given again in diminished doses, which may subsequently be gradually increased. Sometimes while patients are receiving the chloride of gold and soda in large doses pains are experienced in the bowels, or in some instances there are uncomfortable sensations in the head; occasionally, also, profuse sweating has been noticed. If any of these symptoms develop the dose should be at once diminished, or the remedy substituted by the iodine.

The most favorable place for the injection is in the loose skin in the gluteal region, and care should be taken that it is thrown simply into the cellular tissue beneath the skin, and not into the muscles, which would cause unnecessary pain. I have found that rubbing the part for two or three minutes after the injection will sometimes greatly relieve whatever pain it may cause. In ladies, where it is difficult to get at the point mentioned on account of the clothing, I usually make the injections in the back just below the inferior angle of the scapula or between this and the spinal column.

I would advise daily injections for about two weeks, every second day for the two following weeks, and subsequently once in three, four, five, six or seven days, gradually diminishing the frequency according to the result. When these remedies are acting well the appetite and strength gradually improve, the weight increases, and the cough and expectoration gradually diminish. For the first two weeks Dr. Shurley states the temperature is apt to be increased, but subsequently, in favorable cases,

[1] Read before the Chicago Medical Society, March 2, 1891.

it decreases until the normal point is reached. I have frequently found the temperature subnormal in the forenoon, particularly if the patient had been out in the cold.

The iodine seems to be the better acting, but after using it for a time the chloride of gold and soda appears to maintain (at least for some time) the effects produced by the iodine. Where I have used the chloride of gold and soda alone (as has been recommended in the advanced stages of phthisis) I have not, as a rule, obtained as favorable results as where I have first used the iodine, though occasionally it acts well from the first.

It is very important that the solutions be chemically pure. These I obtain from Dr. J. E. Clark, of the Detroit Medical College, but they may be prepared by any skilful chemist who will consult Dr. Clark's recently published description of his method.

The chlorine inhalations may be given either by means of some of the common or specially devised inhalers, or in a room filled with chlorine gas. The latter is applicable to hospitals where small rooms can be so prepared, or even to small bedrooms, where the arrangement is readily made in the following manner:

First, a steam atomizer is made to throw into the atmosphere of the room a solution of chloride of sodium of the strength of about fifteen grains to the ounce; this is continued until the atmosphere of the room is so permeated by the spray that a person on the opposite side from the atomizer can taste the salt. One or two teaspoonfuls of chlorinated lime are then placed upon a plate or saucer and wet with a mixture of hydrochloric acid, one part, and water, two parts, which causes the rapid generation of chlorine gas. This is then held directly under the spray of the chloride of sodium solution and the gas is carried by it into the atmosphere of the room, where the patient sits for ten or fifteen minutes—as long as he can well tolerate the inhalation.

For use in an office, or other place where a room cannot be appropriated for the inhalation, some of the atomizers already in use for giving deeper inhalations may be employed. Dr. Shurley uses a glass flask such as is ordinarily used for table water, capable of holding two or three quarts, or in lieu of this a large bottle will answer the purpose. This has a hole about an inch in diameter drilled in one side, and has fitted upon the month a rubber face-cap, such as is used by dentists for their nitrous oxide inhalers. It is placed upon a suitable stand and then a mixture of chlorine water with a solution of chloride of sodium, ten to fifteen grains to the ounce, is thrown, by any suitable atomizer, through the opening in the side against the opposite wall of the flask, which breaks it into a fine vapor; the patient at the same time inhales, and the air which is drawn in through the opening in the side of the flask takes up a sufficient quantity of the vapor and chlorine gas. I use the Davidson No. 66 atomizer with from thirty to forty pounds air pressure. Some patients do not bear the chlorine well, and for these I use in the same way a spray of iodine made with four minims of the compound solution of iodine and one drachm of glycerin to the ounce of water. Its effects seem almost if not quite as good as those of the chlorine. Occasionally patients who are using the chlorine inhalations regularly will experience, without apparent cause, an alarming sensation of constriction of the chest some time after the inhalation has been taken.

It is very difficult to obtain chlorine water of uniform strength on account of the various methods employed in its manufacture, and because the gas rapidly escapes when the bottle is uncorked; therefore, a solution which may be strong one day may be comparatively weak the next, and by the following day may have little effect. I have tried various methods to overcome this objection. First, I placed a definite amount (3 or 5 grains) of the chlorinated lime in the flask and added to two ounces of the chloride of sodium solution a half drachm of dilute hydrochloric acid. In this way, as the acidulated spray was thrown against the opposite side of the flask, it ran down upon the chlorinated lime and liberated the chlorine gas; but I found that at first it was liberated too rapidly, if 5 grains of the chlorinated lime was used, while during the latter part of the inhalation little or no gas would be evolved. Hoping to have the gas liberated more uniformly, I had the chlorinated lime made into compressed tablets, but with these I succeeded no better, for from them very little gas was evolved, and even on breaking up the tablet the amount was not much increased, which seemed to indicate that it had disappeared in consequence of the pressure, or from other causes. I then tried the euchlorine gas, which Professor Haines suggested to me as having greater germicidal properties than chlorine and to be less irritating. This we easily prepared by treating pulverized chlorate of potash with chemically pure hydrochloric acid, but in spite of all precautions we obtained with it a large amount of hydrochloric acid fumes, which were extremely irritating. To neutralize these I introduced into this solution prepared chalk, but I found that the carbonic acid liberated in this way carried off with it a large portion of the euchlorine gas, so that the liquid remaining possessed only feeble germicidal properties, and was therefore not suited to the purpose. More recently I have used the U. S. P. chlorine water prepared by Hance Brothers & White, of Philadelphia, of which from ½ to 1 drachm to 2 ounces of the chloride of sodium

solution will make as strong a chlorine gas as can be tolerated by the patient. To avoid the deterioration in strength caused by frequently opening the bottle I adopted a suggestion given me by Dr. Bridge, and had several small glass-stoppered bottles filled from the large one, and used the solution from them. In this way it is not necessary to open the large bottle more than two or three times, and a nearly uniform strength of chlorine gas can be obtained.

I have now been using the Shurley–Gibbes method about eight weeks and have treated by it between forty and fifty patients. In a disease like consumption this length of time is not sufficient to enable us to draw accurate conclusions as to its effect. Dr. Shurley wrote me in the beginning "that the results were certainly encouraging," and I can, from my own experience, heartily corroborate this statement, yet I cannot say exactly how much good has been done. In most of the cases which had reached the third stage of the disease, with large cavities in one lung and the other lung more or less involved, I cannot see that any appreciable good has been done; yet in one of these there has been very marked improvement, as the patient has gained strength and weight, has much less cough and fever, and upon the whole appears very greatly improved. With some patients in the second stage of the disease, with a whole lung involved, we at first appeared to be bestowing benefit, but subsequently concluded that the treatment was useless; while in others of this class very decided improvement has occurred. In the first stage of the disease, where not more than a third of the upper lobe of one lung was involved, the patients as a rule have been so greatly improved that I expect ere long to say of many of them that "they have been cured." Three are now apparently well.

This treatment is based upon careful experimentation, is scientific, thoroughly professional, and seems to be beneficial; therefore, I hope that the profession will give it a careful trial, even to the minutest detail, for it must be remembered that experiments often fail by neglect of some of the details, which to certain observers seem unnecessary. I would not, however, advise the use of this treatment to the exclusion of other remedies which physicians have found of benefit in certain cases, for we cannot experiment upon our patients. I recommend this treatment to patients simply as giving an additional chance. Many failures will undoubtedly be experienced and recorded. Those who use the method in a slip-shod way will surely obtain unsatisfactory results, and even though it be employed in the most skilful manner, with the judicious administration of other remedies, there will necessarily be many patients who cannot be cured by it. However, if properly carried out, I feel confident that much good will come of it and no harm can result.

If even a few patients only are cured, Drs. Shurley and Gibbes will receive the commendation of the profession and will be entitled to the gratitude of the public for their painstaking and laborious efforts to find some way of remedying this dread disease. We congratulate these gentlemen upon having given us what from present indications is one of the most promising methods of treatment yet discovered for pulmonary tuberculosis; but their work is not yet completed, and they and others must work on until instead of from 25 to 30 per cent. from 85 to 90 per cent. of these cases may be prevented or cured.

A CASE OF CEREBRAL SYPHILIS.[1]

By HOWELL T. PERSHING, M.Sc., M.D.,
Professor of Nervous Diseases in the Gross Medical College, Denver, Col.; Physician to the Arapahoe County Hospital.

On November 12, 1889, I was called to see Mrs. N., age twenty-one years; married two years; no children; no miscarriages. Persistent cough for three years, with loss of weight. Otherwise well until present illness. Two days ago, while lying down, but not asleep, she suddenly found herself unable to speak to her husband, and in terror began to cry. Getting up immediately, the right arm was found to be useless. There was no convulsive movement, loss of consciousness, nor giddiness at the time of the paralysis, and no premonitory symptoms could be ascertained to have existed. According to the patient's statement considerable improvement had already occurred. On examination râles were heard at the apices of both lungs. Heart normal. Pupils and movement of the eyes and optic papillæ normal. Face drawn to left side; right side moved very little in attempting to show the teeth. Tongue protruded to the right. Motor aphasia was present. Words were readily recalled and used in their proper connection, but indistinctly articulated. Marked weakness throughout the right arm, but with an effort it could be placed above the head. No weakness of leg. Wrist-jerk exaggerated on right side; absent on left. Knee-jerks above average, but equal. No ankle clonus.

Examination showed no loss of sensibility to touch; no pain nor any elevation of temperature, but patient positively stated that a touch on the right hand or cheek caused a different sensation from that experienced on the opposite side.

The lesion was readily localized in the speech, face, and arm centres of the left side of the brain, the three being in close proximity, or else in the fibres proceeding from these centres, not lower than the internal capsule. Only within these limits could a single lesion produce just the symptoms exhibited. One below the internal capsule would

[1] Read before the Denver Medical Association and Arapahoe County Medical Society, January 15, 1891.

almost certainly have involved some of the cranial nerves, as well as the fibres controlling the leg. For reasons that will appear subsequently I think the lesion was cortical.

A focal brain lesion occurring suddenly must be due to hæmorrhage, embolism, or thrombosis. The age of the patient and the absence of any cause of high pressure in the arteries made hæmorrhage very improbable. There was no endocardial disease or anything else to suggest an embolus, so a diagnosis of arterial thrombosis was arrived at by exclusion. But in youthful, vigorous patients thrombosis is practically unknown, except in connection with syphilitic endarteritis. No history of the symptoms of syphilis could be obtained from the patient, nevertheless the diagnosis was adhered to, and iodide of potassium with mercuric chloride prescribed.

The husband, in a subsequent interview, gave a clear account of a venereal sore occurring during an absence from home about a year previous, followed by indurated glands, macular eruption, and palmar psoriasis.

The patient improved steadily and rapidly. In ten days the symptoms had nearly disappeared. In six weeks she could pick up a pin and even sew with the right hand.

Speech showed no impairment, except during excitement, when it was impeded and slightly incoherent. Insomnia had remained since the attack. The iodide was stopped, but the mercury continued. After this, there were intervals of shooting neuralgic pains of the left side of the head and a succession of colds, each of which brought on a slight relapse of the aphasia.

Then, in spite of an earnest warning, the patient disappeared for two months. March 3, 1890, in response to an urgent summons, I found she had stopped taking the mercury and had suffered for some days, with an intense boring headache located just back of the right frontal eminence, at which point there was tenderness on percussion.

Iodide of potassium was again prescribed but not taken, as the druggist supplied the vehicle without it.

At four o'clock the following morning she had a severe general convulsion with complete unconsciousness, frothing at the mouth, and biting of the tongue. It came on during sleep so nothing could be learned as to an aura or as to part in which the spasm began.

When seen at 11 A. M. her mind was clear, but headache was intense. The grip of the right hand was slightly weaker than that of the left, and the tongue deviated a little to the right, remnants probably of the earlier paralytic condition.

The headache and convulsion were attributed to a syphilitic new growth on the inner surface of the cranium, or more probably in the meninges, causing cortical irritation. The iodide was given in half-drachm doses every four hours, with half a drachm of mercurial ointment to be used by inunction each night.

March 5. Slept better; headache persists. Same dose of iodide every two hours.

7th. Headache better; iodide every four hours.

11th. Headache gone; iodism. Iodide stopped; inunctions continued.

25th. No recurrence of epileptic convulsion or other nervous symptoms. Blue pill substituted for inunctions.

During the next three months the patient took mercury and remained well, but was afterward lost to observation, and has not been seen since.

This case furnishes an example of both of the common forms of syphilis of the brain—endarteritis and meningeal gumma. Syphilitic endarteritis always attacks a large number of arteries, and consists of a gummatous growth between the intima and the elastic lamina. By narrowing the lumen it interferes with the nutrition of the part supplied by the vessel. Thrombosis is then liable to complete the obstruction; and softening—that is, molecular death—will ensue, unless blood is quickly restored to the part by collateral circulation. The basilar arteries supplying the corpus striatum and internal capsule are most apt to be diseased in this way, and as they do not anastomose, softening is certain to occur when one of them is obstructed, usually accompanied by apoplectic symptoms and hemiplegia. Cerebral hæmorrhage from syphilitic arteritis is rare until after middle life. If it occurs it causes similar symptoms. Gowers[1] claims that the prognosis is no better in these cases of hemiplegia than in those not due to syphilis, except that recurrence may be prevented. He mentions cases in which favorable prognosis was given in anticipation of the results of anti-syphilitic treatment, only to intensify the disappointment of the patient upon finding his paralysis permanent. An area of softening, whether due to syphilis or not, is never restored. Subsidence of secondary inflammation brings about some improvement, and the corresponding parts on the opposite side of the brain may to some extent act in place of the damaged tract, but the primary effects of destruction remain.

This is apparently opposed to clinical experience, for it is well known that in syphilitics severe hemiplegia may occur, and in a few weeks, or even a few days, entirely disappear. But it is not to be supposed that softening has occurred in these cases. Vascular obstruction is often cortical as well as basilar, and the cortical arteries as they ramify in the pia anastomose freely.

If a large branch is obstructed a considerable area of the cortex may suddenly become anæmic and hemiplegia be correspondingly complete; and yet, as collateral circulation is restored in a short time, the anæmic part may gradually regain its

[1] Diseases of the Nervous System. Am. ed., p. 828. Also, in the Lettsomian Lectures for 1889.

function with little or no remaining softening. I believe the paralytic attack in the case just reported was due to cortical thrombosis. The prompt recovery alone makes this localization probable. The second lesion in this case was doubtless a new growth, probably of the membranes. Either the base or the convexity may be attacked in this way, the former more frequently. The first symptoms are usually severe headache, worse at night, and insomnia. If the disease is at the base, the next symptom will probably indicate the involvement of one of the cranial nerves. The third nerve is most frequently implicated, but the optic nerve, the fourth, sixth, seventh, and eighth are not infrequently damaged.

If the convexity be attacked, instead of cranial nerve palsy, signs of cortical irritation will appear, usually in the form of an epileptic convulsion. Should the process continue, signs of cortical destruction will replace those of irritation, the symptoms varying according to the area involved. Syphilitic disease at the base is very likely to cause choked disc; but this is not apt to occur if the disease is at the convexity, unless pressure is notably increased.

It will be noticed that the lesions in this case appeared earlier than usual, the onset being about a year after infection, as nearly as could be ascertained.

Syphilis is indicated with sufficient probability to determine the treatment, irrespective of other signs of the disease and the patient's history, in the following cases:

1. Sudden cerebral hemiplegia in patients under forty-five, in whom atheroma, high arterial pressure, and the causes of embolism, notably endocarditis, can be excluded.

2. Progressive multiple cerebral palsies.[1]

3. Insomnia and nocturnal headache, followed either by cranial nerve palsy or cortical irritation.

4. Sudden stupor or coma, without other assignable cause. Somnolence, resembling that of alcoholic intoxication, with pain in the head and aimless, automatic actions.[2]

5. Paretic dementia, in which syphilis cannot be excluded, especially with prodromal nocturnal headache, insomnia, or somnolence and early epilepsy.[3]

In all of these forms the prognosis is good, compared with the gravity of similar symptoms not due to syphilis, but it should be guarded on account of the possibility of irreparable damage having been already done, and the occasional impossibility of securing the absorption of a gumma.[4] The treatment should, of course, be vigorous, consisting in the steady administration of mercury for years and enough iodide of potassium to remove all threatening symptoms or exhaust the tolerance of the patient.

SOME REMARKS UPON THE TREATMENT OF CROUPOUS PNEUMONIA,

With Report of a Case.

By C. S. BRADFUTE, M.D.,
DEMONSTRATOR OF THERAPEUTICS, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

The successful management of croupous pneumonia is a problem that occupies to-day as prominent a position for scientific consideration and solution as it did years ago, notwithstanding our present superior knowledge of its morbid anatomy and the recent advances in general medical skill; and, indeed, medical thought is so varied and confused as to its proper treatment that it may be justly regarded as chaotic. Contrary to what was logically expected the discovery of the dependence of this form of pneumonia upon the inroads of a specific poison, has not materially changed the therapeusis, nor are the mortality lists less lengthy or more favorable than those of former years. In view of this disappointing, and it may even be stated with propriety, humiliating, acknowledgment of our inability to handle a disease with which we are so familiar in all of its manifestations, it is incumbent upon clinical observers to discuss frequently and unceasingly its therapeutic management until some method is at last discovered that, *cæteris paribus*, will insure the patient immunity against a fatal issue. The writer cannot present anything very new in this paper, nor can he express the confidence that the line of treatment he has chosen to consider and elucidate will be successful in a large percentage of the cases that are now regarded as necessarily fatal; but he hopes, by drawing renewed attention to the importance of duly considering the relation between the pathological condition present and the physiological action of the drugs administered, to throw more light upon the general plan of symptomatic treatment that is now adopted by the majority of the profession.

Croupous pneumonia is met with in three classes of subjects, viz.: the sthenic, asthenic, and diseased, and presents in each distinctive indications for medical interference. The ordinary or sthenic type will, however, here be treated of alone.

The first question that arises in the consideration of medical treatment, confronts the physician as a problem which may be difficult to solve. In order to relieve the over-acting heart and full, bounding pulse, that is promoting restlessness, keeping up pain

and favoring extension of the inflammation, should he employ some drug that by its sedative action may depress the circulatory apparatus, or is he to practice venesection? The writer fails to see the philosophy of depletion in any instance of so-called plethora, except where it is necessary to relieve the blood pressure for a few minutes, as in apoplexy or pulmonary hæmorrhage due to acute congestion. It is true, blood is very quickly renewed and the withdrawal of fifteen or twenty ounces apparently does no harm, but is it well to add additional labor to the blood-forming organs that are already disturbed in their circulation and nutrition, and are shortly to be more seriously damaged, if the same end can be attained in some other way? Some light may be had upon the proper procedure to adopt, if the causes setting up the peculiar condition of the circulatory system be considered, for why not remove the cause in preference to adopting a mere palliative measure? The violent inflammatory process that has attacked the lung structure produces a shock to the nervous system manifested by anorexia, sometimes nausea and vomiting, restlessness, headache, elevated temperature, irregular flushing of the surface, and spasmodic contraction of the smaller vessels. The latter causes a diminution in the total area of blood-space, which necessarily sends more blood through the heart at each cycle, thus not only abnormally stimulating its action, but increasing the total amount of cardiac work; hence, the heart labors, the bloodvessels appear over-full, and the pulse is full and bounding. The obstruction, *a fronte*, also adds to the cardiac work; more blood than is required is pumped into the sound lung or parts of the lungs not implicated by the inflammation. The interchange of respiratory gases is impaired, and the patient experiences mild dyspnœic symptoms, becoming severe in bad cases. The influence of the vasomotor nervous system over the blood-supply of the lung tissue not being as yet clearly understood in man, it is difficult to say whether the irritation due to the inflammation causes a dilatation, of the lung capillaries, or contraction. Analogous reasoning would point to contraction, but in either case dyspnœa would be present, and the treatment of the general systemic circulation would not be changed. If there was dilatation it would be fair to assume that the inflammatory process would spread much more rapidly than it does, whereas, *au contraire*, it shows a decided tendency to become localized.

Here is a morbid anatomical outline which calls for a drug having a depressing action upon organic life, or to express it more clearly, one which possesses the power of lessening the functional activity of the peripheral nervous system. Several remedies will be thus suggested and the two most important are aconite and veratrum viride, each one having many ardent and authoritative supporters.

Aconite lessens the contraction of the heart, chiefly through its influence upon the vagus centre (Brunton), increases the action of the skin (Ringer, Fothergill, and others) and kidneys (Bartholow), and depresses the functional activity of the spinal cord and peripheral nerve-endings, effects which serve to recommend it above other circulatory sedatives.

The greatest care is necessary in its administration, and the writer cannot but think that adverse reports from the use of aconite in pneumonia are mainly due to its improper employment. If it be given in too large amount the vagus centre is overstimulated, the cardiac ganglia paralyzed, and the general circulation becomes so depressed that it is unable to react when the drug is withdrawn. It must not be given with any idea of reducing the temperature: its influence in this respect being due to its action on the circulation and not to any direct antipyretic effect. One-half to two-drop doses every hour (Ringer) until the pulse falls to 90 is the safest method of giving it. As soon as the heart-beats reach this rate it must be at once stopped, or its powerful paralyzant action will produce damaging results. When the drug has acted sufficiently, the blood flows readily from the arterial into the venous system, the lungs are relieved of their mechanical engorgement, the dyspnœa lessens, and the patient feels less restless. If the movements of the heart can be kept at the normal standard nature may be depended upon to do the rest, so far as the circulation is concerned. The importance of not giving too much cannot be too freely emphasized, for very frequently it only requires a few doses to produce the desired effect. If the drug cannot be left in the hands of an intelligent person or nurse to administer, the physician should see the patient within four hours after the first dose, or send a competent assistant at this time. If it should act unduly and the pulse fall below 70, a hypodermic of the $\frac{1}{60}$th of a grain of the sulphate of strychnine should be given and repeated every two hours, or oftener, until the pulse returns to the proper rate. Aconite given in this way will quell the circulatory disturbance without producing any deleterious results, and entirely obviates the adoption of so questionable a procedure as venesection.

On the fourth or fifth day of croupous pneumonia there is a marked diminution in the albuminoid constituents of the blood, especially the globulin (Sciolla, of Genoa), and in view of this very vital change taking place so early in the disease, it constitutes a grave objection to depletion; and as it has been shown that anæmia tends to promote fatty degeneration of the heart muscle (Goodhart,

Handford), it can be seen that the withdrawal of healthy blood, at the beginning of a disease characterized by high temperature, could only favor this morbid metamorphosis.

Recently there appeared in one of the London journals a report of several cases of pulmonary congestion treated by drawing blood directly from the congested area by means of an aspirator. The largest canula of the apparatus was plunged, under strict antiseptic precautions, into the engorged lung tissue, and the author stated that no difficulty was experienced in removing the requisite amount of blood, and no bad results followed. Such a method is certainly more scientific than general depletion, but its utility is doubtful and the measure too heroic to be generally recommended.

Due attention should be paid to the condition of the alimentary tract, which is sometimes seriously disturbed by reflex influences. Five grains of calomel, rubbed up with an equal quantity of bicarbonate of sodium, should inaugurate the treatment, to secure free evacuation of the bowels, and may be repeated in twenty-four hours if necessary. The administration of such drugs as morphine, quinine, or chloral cannot fail to be reprehensible, unless there be special indications. Morphine upsets digestion by deadening the sensibility of the gastric and intestinal mucous membranes, thereby lessening the flow of the digestive juices, and unless there be severe pain is of questionable utility. Quinine will not reduce the temperature except in massive doses, and when there is nausea is apt to disagree and be rejected. That it exercises any practical influence over the limitation of the pulmonary inflammation is open to question.

Counter-irritation has long been used in treating pneumonia, and there can be no doubt of its usefulness. When small, localized spots of pneumonic infiltration exist "flying blisters" act well; but when large portions of the lung tissue are involved hot flaxseed-meal poultices, containing one-fourth as much mustard, applied until decided redness of the skin is produced, are much more effective. After this the patient's chest should be enveloped in a sleeveless jacket, made of cotton batting, to insure protection from atmospheric changes which necessarily occur in the daily attention to the toilet. While resident physician in the Pennsylvania Hospital the writer, under the direction of his chiefs, applied simple hot flaxseed-meal poultices every two hours during the acute stage of all his pneumonic cases, but the exposure of the patient in removing and putting on each poultice, the discomfort from their weight and bulk, and the extreme doubtfulness of the utility of such a method, are objections which render the simple cotton jacket much more desirable and reasonable. Should the temperature become elevated during the early period, phenacetin may be cautiously given, but never antipyrine nor antifebrin. Five grains every three or four hours will generally be found sufficient; but if the temperature continues to rise above 104° F., some other means should be adopted to combat it. Phenacetin will assist in maintaining the effect upon the circulation produced by the aconite, and will preclude the necessity of repeating the administration of this agent when the circulatory activity proves refractory.

The above measures in the usual run of uncomplicated cases, will answer every purpose for the first stage: aconite to quiet the circulation, calomel to renovate the digestive tract, phenacetin to reduce the temperature and maintain the effect of the aconite, and counter-irritation to assist in checking the inflammation and pain. The diet will be considered later.

As the disease approaches, and during the stage of red hepatization, an entire change in the treatment becomes necessary. The symptoms now manifest are a weak and rapid pulse, mental disturbance, congestion of the liver and jaundice, general nervous stasis, gastro-duodenal catarrh, increase in temperature, profuse sweating, albuminuria, due to congestion of the kidneys, and, in severe cases, threatening symptoms of a failing circulation. Now circulatory depressants are strongly contra-indicated. To stimulate the heart and promote liquefaction of the exudate one drachm of aromatic spirits of ammonia should be given every one or two hours until resolution is fully established, as this preparation of ammonia acts much more satisfactorily, is quickly absorbed, and agrees better with the stomach than the carbonate. The theory that the decomposition of the carbonate of ammonium increases the amount of carbon dioxide in the blood and promotes dyspnœa and imperfect oxygenation is not manifested clinically by any unfavorable symptoms, though this form of ammonia is very apt to be rejected by the gastric mucous membrane. When it is retained it answers the same purpose as the aromatic spirits. To promote nutrition, sustain the vital forces, and stimulate the liver, half-ounce doses of whiskey every two or three hours yield the best results. The *role* played by alcohol is that of an active, diffusible food, which is quickly taken up by the tissues and appropriated for the purposes of reconstruction and physiological change. To allay nausea and gastric irritation the following prescription has been most successful in the hands of the writer: R. Bismuth. subnitrat., gr. xv.; acid. carbolic., gt. j; mucil. acac., ʒss; aq. menth. pip., q. s. ʒij. M. Sig.: Take as required (Bartholow). To combat the high temperature during this stage no antipyretic measure is admissable, save that of hydrotherapy. If

the temperature be 104° F., cold sponging every hour until it falls; if 105° F. or above, the ice-pack. The writer has elsewhere (*N. Y. Med. Jour.*, March 8, 1890) spoken of the effectiveness of this method of reducing fever, and it is especially applicable to pneumonia. The reduction is accomplished in a normal way; that is, by heat radiation and by increased nutrition induced by a more rapid circulation, thereby enabling the system itself to combat the morbid process which is keeping up the temperature. The physiological changes produced in the system by the external application of cold in the form of cold water are: slight chilliness, contraction of cutaneous vessels, short and jerky respiration for a moment or two, increased action of the heart, stronger pulse, sensation of better feeling, and increased muscular activity, followed by a general feeling of surface warmth and increased strength, stronger cardiac contractions, more rapid circulation; regular, deep, and easy respirations, abated sensation of feverishness, improved appetite, and a general bodily calm which frequently induces sleep. A measure acting in this way is certainly more desirable and scientific than one depending for its effects upon the employment of such powerfully depressant agents as antipyrine or antifebrin.

In cases where the formidable symptoms of collapse appear, in addition to the above measures, hypodermic injections of the sulphate of strychnine are most effective; $\frac{1}{60}$th of a grain every hour or half hour may be given until there is a decided response. The following case, which the writer is enabled to report through the courtesy of Dr. John S. Miller, in whose practice it occurred, shows most conclusively the value of this agent. The line of treatment adopted was suggested by a paper of the writer's on the use of strychnine in such a condition (THE MEDICAL NEWS, January 3, 1891), and the result was most gratifying. The condition of the case was so grave as to cause the two physicians in attendance to pronounce death near at hand, and the ambulance surgeon of a prominent hospital refused to move the patient for fear of death occurring on the way to the hospital:

Patient (adult, male) found wildly delirious, with several persons holding him in bed. Examination very difficult. Temperature 105° F.; pulse flickering and so rapid that it could not be counted; respirations 55 and shallow; cyanosis extreme, and sweating so profuse as to have saturated the patient's garments and bed-clothes. Percussion indicated consolidation of both lungs posteriorly and the greater portion of the left lung anteriorly. The anterior part of the right lung was clear, save a few râles. Three vital indications were apparent: relief to the weak and depressed circulation, control of the delirium, and nutriment to the exhausted tissues and nerve centres. These were met by the administration of ¼ of a gr. of morphia sulphate and $\frac{1}{60}$th of a gr. of strychnia sulphate every half hour, with half an ounce of whiskey every twenty minutes. At the end of three and a half hours the temperature was 101.5° F., the sweating had ceased, the pulse had become regular and steady, the respirations had diminished in number and were less shallow, the patient was quiet, conscious, and able to converse.

It is interesting to note the mechanism of recovery in this case: morphine in large physiological doses increases the irritability of the spinal cord (Brunton), thus promoting its functional activity and at the same time obtunds the centres of conscious cerebration. Strychnine does not act upon the cerebrum, but the whole of its physiological force is expended upon the spinal cord and end-organs; hence, the combination of the two agents in the pathological condition present, could only be productive of the most favorable results, if recovery was possible. The strychnine restored the function of the spinal cord, reflex centres, and nerve-endings; the morphine checked the delirium and rectified the mental condition, while the alcohol was utilized as fuel and force to assist nature in recovering herself.

Six or eight dry-cups applied to the chest over the affected area are often very useful in relieving the extreme sense of pulmonary discomfort, and inhalations of oxygen during the period of crisis will improve the quality of the blood and relieve venosity.

It is thus seen that the treatment of the second stage, from a physiological and pathological standpoint, may be summed up as follows: Ammonia to stimulate the heart and remove the exudation, alcohol to supply material for force and reconstruction, hydrotherapy to reduce temperature, strychnine to combat circulatory failure, and morphine to control mental disturbance. Subsidiary measures will, of course, be adopted as the indications arise. Alcohol is to be given freely, commencing with it in the form of whiskey; if this disagrees, then give champagne, then koumiss, then whiskey hypodermically. The amount of strychnine given will depend upon the degree of response to the initial doses; it may with safety be run up to gr. $\frac{1}{20}$th every hour.

The diet is of the utmost importance. Nourishment should be administered every two hours, night and day, from the commencement of the disease. Milk, broths, soft-boiled eggs, raw or stewed oysters, egg-nogs, milk punches, etc., are the most suitable forms of aliment. If the patient becomes unconscious and swallows with difficulty, the milk, alcohol, and medicine may be administered through a nasal-gastric rubber tube without difficulty.

PERIODICAL ATTACKS OF SYMPATHETIC OPHTHALMIA FOR TEN YEARS, DUE TO A BULLET WOUND; REMOVAL OF THE EYE WITH THE BULLET, FOLLOWED BY CESSATION OF THE ATTACKS.[1]

By ROBERT L. RANDOLPH, M.D.,
ASSISTANT OPHTHALMIC AND AURAL SURGEON TO THE JOHNS HOPKINS HOSPITAL AND DISPENSARY; PATHOLOGIST AND ATTENDING SURGEON TO THE PRESBYTERIAN EYE, EAR, AND THROAT CHARITY HOSPITAL, BALTIMORE; OPHTHALMIC AND AURAL SURGEON TO THE BALTIMORE AND OHIO RAILROAD.

The following history concerns a miner who figured as a principal in a tragedy in the western part of Maryland ten years ago. The subject of the sketch killed his antagonist and was himself shot in the left eye. The history of the case is as follows:

M. M., age thirty-one, shot in the left eye with a 22-calibre pistol bullet nearly ten years ago. Immediately after the accident he went to an oculist, who advised him to let the eye alone and told him that his vision would in all probability be partially restored, as it was his opinion that the bullet had not penetrated the eye, but had simply glanced and struck it. The vision at this time was limited to light-perception. Since the accident the eye has been the seat of violent attacks of pain lasting for several days, but the patient would frequently be for months without any trouble. Three years ago he was seized with an unusually violent attack in the injured eye, and at the same time sympathetic disease appeared in the other eye, showing itself by sensitiveness to light and profuse lachrymation. The attack lasted for a week, leaving the good eye unimpaired in its functions. Two years later he had another attack of the same nature.

One month ago the patient came to see me during an attack. The vision in the wounded eye was absolutely lost, not even light-perception being present. The eyeball was exquisitely sensitive to the touch and had been so at every previous attack. The pupil was closed and anterior synechiæ were present. A large scar at the upper border of the cornea indicated the site of the wound produced by the bullet. The eye was mushy and had shrunken considerably since the injury, and of course it was impossible to see the fundus. The conjunctiva of the eyeball was very red, and the secretion of tears abundant.

The singular and at the same time most interesting feature of the case was the condition of the right eye. The ocular conjunctiva was very red, and a superficial keratitis, limited to a small part of the cornea, was present. No involvement of the iris. The lens and vitreous were clear and nothing abnormal was to be seen in the fundus. The eye was painful and very sensitive to light. Vision was necessarily much interfered with by reason of the corneal complication. I advised the patient to have the injured eye enucleated. He consented and I immediately performed the operation. Just within the angle formed by the junction of the eyeball and the optic nerve, on the temporal side of the latter, the bullet was found. It had gone through the eye and its point of exit was marked by a narrow band of cicatricial tissue at the point where it had lain for so many years. The eyeball was cut open and found to be so much disorganized that it was impossible to make out the relative positions of the parts.

It was a matter of regret to me that it was not practicable at the time to make cultures from the inside of the eye, to ascertain whether the pain and the disease going on within were due to the presence of microörganisms. These, if found, must have made their entrance into the ball many years ago, for the hole made by the bullet had closed very soon after the accident, since which time there had been no opening into the eye. Though I did not regard the trouble in the injured eye as one of infectious origin, still if the presence of organisms could have been proven, an interesting, and at the same time valuable, fact would be established, namely, that microörganisms can remain quiescent for a number of years in an eye and at intervals give rise to all the symptoms of an acute inflammation.

It may be well, however, to state in this connection that two years ago, while making experiments on sympathetic ophthalmia, I had occasion to examine a number of eyes which had been enucleated on account of the danger of sympathetic disease, and in one eye only—in which the injury was of two weeks' duration—did I discover organisms, a fact which has led me to think that the agency of microörganisms in the causation of sympathetic ophthalmia can be excluded if the sympathetic disturbance appears as late as from two to three months after the injury.

As soon as the injured eye was removed the other eye recovered without treatment. The disease here could not have been of a parasitic nature, or the deeper structures of the eye would probably have been first involved. That the trouble in the second eye was either caused, or, in part, kept up by the presence of the injured eye, together with the bullet which was near, was evident on account of the disappearance of the sympathetic disturbance when the injured eye and the bullet was removed. Such a case of sympathetic ophthalmia I would look upon as due to the ciliary irritation kept up by the presence of the injured eye, and not to the passage of organisms from one eye to the other. Indeed, the infectious origin of sympathetic ophthalmia, in my opinion, is far from proved.

The road along which sympathetic irritation travels is a most complex one. It is composed of

[1] Read before the Clinical Society of Maryland, February 6, 1891.

the short ciliary nerves, which come from the ciliary ganglion, and of the nerves which enter into the composition of this ganglion, namely, one from the nasal branch of the ophthalmic, another from the third nerve, and still another from the sympathetic. Among these the nerves which have most to do with the sympathetic irritation are the fibres derived from the fifth and from the sympathetic. It is evident, then, that the irritation must pass along an eccentric course before it reaches the second eye. In order to establish the *rôle* of the ciliary nerves in the transmission of the sympathetic process it should be possible to put a stop to this process by cutting these nerves. The theory would then be proved. I quote the two following cases, which occurred in the practice of M. Abadie:

In the first a wound of the cornea through which the iris protruded had been caused by a piece of broken glass. The hernia of the iris, however, was excised, and the eye recovered, when suddenly there appeared in the other eye all the symptoms of a sympathetic inflammation, photophobia, ciliary and pericorneal injection, and, finally, irido-cyclitis, with posterior synechiæ. At this time the fundus showed nothing pathological, and it was plain that the inflammation was provoked and kept up by a certain degree of ciliary irritation; the symptoms which indicated this more especially were the excessive vascular injection and the pain on pressure in the ciliary region. After closely observing the case for a few days, M. Abadie determined to make a section of the ciliary nerves, as he was convinced that they were concerned in the transmission of the disease. The operation was performed, and immediately afterward the pain disappeared, as if by magic, and though sleep had been almost impossible before, the patient slept well the first night following the operation. The injection of the eyeball soon passed away, and recovery was rapid and perfect.

The second case, which was not less instructive than the one just described, showed the speedy relief afforded by an operation. In this case there was a relapse which necessitated a second operation, this being followed by complete recovery. These two cases apparently show that the sympathetic process can be removed by section of the ciliary nerves.

It would seem, then, that we have two forms of sympathetic ophthalmia, first, a ciliary or reflex form, under which head the cases here reported would come; and second, a variety of the disease the pathology of which is still in doubt. Their points of difference may be summed up as follows: In the ciliary variety of sympathetic ophthalmia the photophobia, lachrymation, and ciliary pains are most intense; and then, too, a fact noted by many surgeons, there is a spot which is particularly sensitive to pressure, and which occupies the same locality in each eye, namely, some point in the ciliary region. Here the process commences in the iris and ciliary region, while the vitreous and fundus of the eye generally remain healthy and only become involved secondarily. In this variety the disease manifests itself at periods varying from two and three months to fifteen and twenty years after injury of the first eye. In the other variety the sympathetic process appears more promptly, generally in from two to six weeks, and though the subjective symptoms are less intense than in the ciliary form, the former variety goes on more rapidly to destruction of the eye.

In the latter variety the fundus is first involved, and we notice a papillitis, soon followed by opacities in the vitreous, deposits on Descemet's membrane, and, finally, irido-cyclitis. I do not call this latter an infectious form of sympathetic ophthalmia, for the existence of such a variety of the disease rests on too uncertain proof. Both varieties are, in the majority of cases, to be traced to wounds, all of which are more or less of an infectious nature; and though in the ciliary form of sympathetic ophthalmia there is less likelihood that infection plays a *rôle* than in the other variety, yet I do not think that experiments in this direction would warrant us in designating either variety of the disease as distinctively infectious. It is evident that had the disease in the two cases reported by M. Abadie been of an infectious character simple section of the ciliary nerves would not have given relief.

ON THE VALUE OF FÆCAL VOMITING AS AN INDEX OF ACUTE INTESTINAL OBSTRUCTION.

BY THEODORE A. McGRAW, M.D.,
OF DETROIT, MICHIGAN.

IN the treatment of intestinal obstruction the most common cause of failure is the inability of the attending physician to arrive at a positive and correct diagnosis before the time for operative relief has passed. This difficulty of diagnosis has become notorious.

Given a case of local abdominal pain, gradually becoming general, of soreness spreading over the abdomen, of tympanites, of vomiting and obstinate constipation, who can say positively whether it is a case of general or local peritonitis, of ulceration and perforation of the bowel, of abscess without the peritoneum, of bilious colic from gall-stones, of fæcal impaction, or of some form of acute obstruction which demands an operation. In many such cases the diagnosis may be impossible during life, or at least until a late stage of the disorder, but occasionally the symptoms may be so positive and unmis-

takable that the practitioner who fails to recognize them must be responsible for a fatal result. It is important then to recognize all of the symptoms met with in a case of obstruction at once; we must also remember that all of the classical symptoms are rarely met with in one case, and that occasionally the great majority, if not all of them, are absent.

Acute intestinal obstruction may cause local or general pain, vomiting, tenesmus, constipation, tumefaction of the abdomen, tympanites, colic, disturbance of respiration and pulse, increased or diminished temperature, and finally paralysis and collapse. The symptoms necessary to make a diagnosis are the pain and soreness, tumefaction and tympanites, tenesmus and constipation, and vomiting. I think the profession should get rid of the impression that pain, tenderness, and tympanites of the abdomen necessarily indicate peritonitis.

I have frequently operated upon ovarian tumors in cases where, from the previous occurrence of sharp agonizing local pain accompanied with tympanites, lasting several days, I had expected adhesions, and have been happily disappointed in not finding the slightest trace of an inflammatory process, either on the smooth wall of the cyst or on the parietal or visceral peritoneum. I have operated for intestinal obstruction in cases, in which the diagnosis of general peritonitis had been made, to find only a circumscribed local inflammation at the seat of obstruction. The occurrence of general pain and tenderness over the abdomen, in cases of strangulated hernia, are symptoms which no one accustomed to deal with these cases, would think for a moment of attributing to peritonitis.

I am at present treating a patient with a syphilitic stricture of the bowel, and am obliged to keep his bowels open with frequent doses of cathartic medicine. When I fail to do so his abdomen becomes tympanitic and very sore. Abdominal pain and tenderness and tumefaction may arise from a multitude of conditions and is pathognomonic of none.

Small circumscribed tumors may arise more or less suddenly from perityphlitis or other localized inflammations, from intussusception and more rarely volvulus, from impaction of fæces, from the presence of foreign bodies in the gut, and from the rapid formation of cysts or tumors. Tumors of long standing may not be discovered until attention is directed to the part by the presence of pain. Tympanites may result from peritonitis, septic poisoning, indigestion, hysteria, paralysis, and acute or chronic obstruction. Tumefaction in itself can not be regarded as a symptom of great diagnostic value. Tenesmus may occur as the result of obstruction, but as it is met with in a great variety of irritative conditions of the bowel, it becomes of importance as a symptom only in cases of intussusception where it is associated with the rapid formation of a well-defined tumor.

Obstinate constipation, which does not yield to the free and repeated use of cathartics, is too often accepted by many practitioners as a symptom of obstruction.

Nothing could be more delusive. Obstinate and unyielding constipation may be met with in peritonitis, perityphlitis, paralytic conditions, high fevers, in many obscure disorders of digestion, and in acute or chronic opium poisoning. In the last case of perityphlitis on which I operated there was obstinate constipation which had not yielded to drastic cathartics given prior to my arrival. I have seen badly wounded men in the army killed by the injudicious use of purgatives, given to overcome constipation due to high fever and irritation caused by severe wounds. I recall one case in particular of amputation at the shoulder-joint in which constipation lasted several days in spite of repeated enormous doses of purgatives. Finally, at the end of the fifth day, the fever subsided and was succeeded by a fatal diarrhœa which could not be checked.

I think the constipation in these cases is due to paralysis of the intestines produced by the severe shock, irritation, and fever caused by the wound. Recovery from the paralysis is followed by absorption of the purgatives which produces hypercatharsis. I cannot too strongly express my disapprobation of the indiscriminate and repeated use of powerful purgatives in cases in which constipation is associated with tympanites or tenderness of the bowels. Purgatives may occasionally do good, but in these cases are more frequently harmful, and when there is intestinal obstruction they are always contraindicated.

The peristaltic action excited by the drugs forces that part of the gut above the obstruction down and doubles it over the constriction. If it be a case of intussusception a still larger portion of the bowel is invaginated. In any case the congestion at the seat of stricture is greatly increased and the death of the bowel is hastened.

Vomiting is a common symptom in many diseases and is of diagnostic value in intestinal obstruction only when its cause can be detected, or when it assumes a stercoraceous character. Fæcal or fœtid vomiting is, however, a symptom of the greatest value and the gravest import. In my own experience I have never seen it except in intestinal obstruction. I regard it, indeed, as the only symptom which taken alone is always pathognomonic of this condition, I have become convinced of this from bitter experience. Within the last six months I have lost three patients, after desperate operations, undertaken too late for the relief of obstruction, every one of whom had vomited stercoraceous

matter for days before the operation. One of these patients, who had a strangulated hernia, had been dosed liberally with pills and salines. Another case, a young married woman, had had an attack of peritonitis some years before I saw her. When I was called she had been ill for more than a week and had vomited fæcal matter for five days. The operation was performed *in extremis;* her pulse was 110 and her skin was cold and clammy. During the operation her respiration ceased several times, and she was kept alive with difficulty. I found the small intestines bound down and bent by a firm whip-cord band of false membrane, which I could not break, but which I cut between two ligatures. The vomiting ceased after the operation, but she never rallied from her state of extreme nervous exhaustion, and died six hours after the operation. The third patient had suffered from *la grippe*, which was followed by cough and constipation, associated with chills and fever. On Wednesday, March 19, 1890, he had chills and fever, and again on the 20th, when the family physician, a very intelligent practitioner of medicine, was called. The patient's temperature was 103° and he had slight pain in the bowels and very severe headache. On the 21st, he had a chill, headache, and slight pain in the bowels. There was a subsidence in the fever on the 22d. Pills of aloin, strychnia, and belladonna were administered, followed by an enema, but they produced no effect upon the bowels. On the 23d, no change, except nausea and vomiting, which was checked by milk and lime-water. On the 24th, there was a free movement of the bowels after an enema; the nausea was not so intense. On the 25th, there was another fæcal movement after an enema; the patient vomited matter which emitted a foul but not fæcal odor. On the 27th, vomiting continued and I was called in consultation. When I saw him his pulse was fair but the skin was cold and clammy, and there was paralysis of the capillaries which is so often the forerunner of death. He vomited a brown fluid which had a horrible putrid odor, but could not be called fæcal. I operated as soon as possible and found the small intestine twisted on its axis and there was a quantity of fœtid matter in the folds produced by the volvulus. When untwisted the bowels were found to be paralyzed, and could not be made to respond to any stimulus. A part of the intestine which seemed to be almost gangrenous, was excised and the gut reunited. At the close of the operation there was no difference in the general condition of the patient, and he died at 6 P.M. of the same day. The family physician recognized the possibilities of the case as soon as the vomiting of foul matter occurred, but as its odor, though putrid, was not fæcal, he hesitated until the golden opportunity had passed, and the operation was performed too late.

Fœtid odor of the vomited matter has the same significance, under certain circumstances, as that of fæcal odor. It means that intestinal obstruction has reached a high degree and that relief or death must soon follow. But some of my colleagues will say that a fœtid breath is of common occurrence in gastric troubles in which there is no question of obstruction. This is doubtless true, but suppose that a man with a breath of ordinary sweetness is seized with pain, constipation, and vomiting, that the ejecta at first have only the sour odor of half digested food, or perhaps no odor at all, and that finally after the vomiting has continued for some time it assumes suddenly an extremely fœtid character, then it always means intestinal obstruction. Fœtid breath often comes from nasal catarrh, necrosis of bone, rotten teeth, or fermenting food in the stomach. In cases of caries, necrosis of bone, and rotten teeth, the odor of the breath might not be communicated to the vomit. In cases of gastric fermentation in which there is continued vomiting, the stomach would soon be emptied of all the fœtid material, and the later ejecta would be less fœtid than the earlier. In intestinal obstruction the reverse of this occurs. The vomit becomes more and more fœtid the longer it continues. While the occurrence of fæcal or fœtid vomiting positively indicates operative procedures it is unfortunate that in the majority of cases this symptom is not present. The surgeon, therefore, must not wait for this symptom before operating when other symptoms of obstruction are present. Although other symptoms, taken singly, may point to various disorders other than obstruction, their combination enables the surgeon to come at once to a correct conclusion. Abdominal pain, tenderness, and vomiting are of plain import, if associated with an irreducible hernia. Tenesmus, abdominal pain, and the rapid formation of a tumor in the rectum or abdomen is also diagnostic of intussusception.

Fæcal or fœtid vomiting indicates almost without exception obstruction of the bowels and warns the surgeon of the necessity of an immediate operation for the relief of the patient.

73 CASS ST.

"PRISM-DIOPTRE" vs. "CENTRAD" IN THE REFORMED NUMERATION OF PRISMS.

BY B. ALEXANDER RANDALL, A.M., M.D.
OF PHILADELPHIA.

IN the *Ophthalmic Review* for January, Dr. Swan M. Burnett contributes a recommendation of the "prism-dioptre" for the numbering of prisms in ophthalmology, and denies to the other units proposed any such accuracy, convenience, and valuable relations as he claims for Mr. Prentice's proposed unit. The endorsement by a vote of the American

Ophthalmological Society last year of the "centrad" proposed by Dr. Dennett is characterized as hasty and mistaken; so it seems not improper that, as the mover of that vote, I should make an answer to his criticism.

We need for the designation of prisms a system that shall be accurate, simple, and practicable; and it is exceedingly desirable that it shall be intimately related to our reformed numeration of lenses, to the effect of decentering lenses, and to the "metre-angle" of convergence which corresponds with the "dioptre" of accommodation. Dr. Burnett advocates, as furnishing the desired unit, the "prism-dioptre"—a prism deviating a ray of light falling at right angles upon one of its faces through the space of 1 cm., measured upon the tangent-plane 1 metre distant—and says, in the matter of prisms, "'approximations' cannot be long tolerated."

A prism produces an angular deviation of the rays of light passing through it, and the size of this angle of deviation measures the strength or the effect of the prism. This may be expressed in terms of angle, of arc, of tangent, or of sine; but only the first two, which are interchangeable, are uniform. The prism-dioptre, which is a tangent measurement, declines in value with each increase of the angle, until near the right angle it grows infinitesimal. Even at the starting point it is but an "approximation" to what we wish to express; and it condemns itself, since 10 prism-dioptres are less than 10×1 P. D., 20 P. D. $= 19.3 \times 1$ P. D., 40 P. D. $= 35 \times 1$ P. D. The unit endorsed by the American Ophthalmological Society is uniform, and represents 0.57295° of angle or arc at every part of the circle.

The important "metre-angle" varies with each individual variation in the distance between the centres of rotation of the eyes, and has in the past needed more calculation than was convenient in clinical work. Mr. Prentice deserves our hearty thanks for pointing out its relation to his prism-dioptre. He shows that approximately, within narrow limits, the value of the metre-angle is expressed by half the distance between the pupils measured in centimetres. Yet he admits that it is far astray for high values, since for an inter-pupillary width of 64 mm. (the average of the books, though wide for American faces) 20 m.-a. would correspond with 83.4 P. D., instead of 64; and, conversely, 64 P. D. would express less than 17 m.-a., not 20. Even for eyes as close as 50 mm. 10 m.-a. would be erroneously expressed in prism-dioptres by as much as 3 per cent. The metre-angle is measured accurately under all circumstances by the "centrad" system approved by the American Ophthalmological Society; and even in this off-hand statement, obtained from half the inter-pupillary distance in centimetres, the approximation is very close. For 64 mm. and 20 m.-a. the "centrad"-reading on the arc is 69.46, and this is the real value: neither the corresponding 83.4 P. D. nor the 64 cm., which is twenty times half the inter-pupillary distance, directly express it; the former is its tangent, the latter its sine—from either it can be derived only by calculation. Yet, assuming for convenience that we may state metre-angles directly in terms of inter-pupillary distance, the above figures show how far better an approximation the centrad is than the prism-dioptre. Dr. Burnett implies that the prism-dioptre value is accurate, while he denies any relation of the centrad to the metre-angle. In both points he is manifestly in error.

In the decentring of lenses a prismatic effect is obtained, which is much used (unconsciously or intentionally) in ophthalmic practice, and deserves wider and closer study. This, Mr. Prentice claims, is accurately expressed in prism-dioptres, if the centimetres of decentring be multiplied into the strength of the lens in dioptres. I question if this be correct, although I fail to detect the flaw in his argument: the relation seems a matter of sine not of tangent, in which case the centrad system would again be closer the approximation. Certainly a 20 D. lens decentred 1 cm. (this probably exceeds the limits in practice) gives 20 centrads of deviation, as accurately as I can measure with improvised apparatus. The difference is small—20 P. D. $= 19.75$ Cr.—so at the worst the error in the use of the centrad in this relation does not compare with the gain at the other points.

Yet the centrad is impracticable, Dr. Burnett claims, because "neither Dr. Dennett nor any other advocate of the centrad has offered or devised any really practical method of measuring prisms according to the radian system." Dr. Burnett has befogged himself by importing into the centrad system the "minimum deviation," which has no place there. Like the prism-dioptre, the centrad is a prism which, at 1 m. distance, deflects the ray of light falling at right angles upon one of its faces through the space of 1 cm., the only difference being that the centrad is measured on the arc and not on the tangent. It is not "curious," therefore, that at first their values agree; they diverge because 20 Cr. $= 20 \times 1$ P. D., approximately, while 20 P. D. $= 19.3 \times 1$ P. D. The centrad may be measured on the tangent-plane at any distance with as much ease and accuracy as the prism-dioptre; only we must use the tangent-projection of centimetres of arc instead of even centimetres. But this calculation, though simple, may be avoided by measuring on the arc of the perimeter, with which nearly every oculist is provided. If its radius of

curvature be 30 cm., as in my instrument, every 3 cm. of the arc is 1 "centiradian," "centirad," or hundredth part of a "radian," and corresponds to 1 centrad. Fix the scale of Mr. Prentice's prisometer at, say, 25 cm., and curve it to this radius, and it will measure centrads with all the accuracy with which it now expresses the specious prism-dioptres: only 100 Cr. will not have a nominal value of 157, as is the case with the prism-dioptre. The oculist needs but to add a prism-holder and a vernier to his perimeter, and he has no need for the additional instrument.

To the optician there will be no recognizable difference between the centrad and the prism-dioptre. He will buy from the wholesale manufacturer, or will grind for himself, prisms of 1°, 2°, 3°, 5° refracting angle as before, just as many still handle lenses ground to inches of radius. When they differ distinctly from the strength required, he will lay them aside to fill the orders of the hair-splitter who calls for hundredths of a centrad, or will polish them down to true strength. Dr. Burnett's assumption that the centrad is indivisible and that only exact whole numbers can be employed is gratuitous, to say the least.

Yet the advantages of the "radian" system do not end (as with prism-dioptres) in the designation of prisms. This is but a part of its value in ophthalmology as in most mathematical work. The radian can everywhere replace the degree in designating arcs or angles. The deviation of a squinting eye is best measured on the perimeter, and better in "centirads" than in degrees. The field of fixation can be given conveniently in the same terms and the extreme limits of the visual field also. All values relating to the directions of the optic axis and vision, central or peripheral, monocular or binocular, can be well expressed in this system, which is far from limited to questions of "velocity" only, as Dr. Burnett states in his special pleading. More: the position of the cylinder-axis may be expressed in the same notation, although 157 + Cr. may be less convenient than 90° to express the vertical. Yet as many ophthalmologists reject the trigonometric notation now generally accepted, and insist on taking the zero point anywhere except at the "three o'clock" used by all mathematicians, we might secure uniformity by abandoning all degree terms and starting fresh in centirads.

Therefore, in urging the American Ophthalmological Society to adopt the centrad as the unit, I did not lead them into a hasty mistake; but, with Mr. Prentice's prisometer on the table before us, and with recognition of his valuable suggestion as to the metre-angle, a better standard than his was endorsed. The centrad has practically every advantage claimed for the prism-dioptre, without its inaccuracies; it can hardly be called, like its rival, an arbitrary choice; and it is in accord, not only with practical and scientific ophthalmology, but also with the most advanced mathematical science.

CAMPHORIC ACID IN NIGHT-SWEATS.

BY H. A. HARE, M.D.,
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO ST. AGNES'S HOSPITAL.

WITHIN the last eighteen months Combemale has published the results which he has obtained from the employment of camphoric acid and the tellurate of sodium in the treatment of the night-sweats of phthisis, or those dependent upon some other severe systemic disorder. I have been so frequently misled by the enthusiastic reports of clinical observers both in Germany and France as to the value of some new remedy which they had tried, that I must confess to have taken up camphoric acid with a considerable degree of prejudice against it. I have studied its action, however, very carefully in the wards of St. Agnes's Hospital during the last six weeks, and I am now prepared to most thoroughly endorse everything which Combemale has said about this drug. I believe it to be of greater utility than any of the remedies which have heretofore been generally employed, such as atropine, aromatic sulphuric acid, and sponging with alum or sulphuric acid water, or similar preparations. Altogether I have given it to about ten cases, and in every one of them it has acted, even if given in moderate dose, most satisfactorily. The following history of two cases are about as good examples of these clinical facts as I can offer:

A man, aged thirty-five, was brought into the hospital in the early part of January suffering from advanced phthisis with a large cavity at the left apex and with numerous smaller cavities in both lungs. There was a good deal of expectoration of purulent matter and a loose, racking cough, rapidly progressing emaciation, with that peculiar flattening of the wrist which we so often see, so that the forearms looked like laths, and with such persistent and aggravated night-sweats that the occurrence of each sweat could be seen to increase very markedly his debility and asthenia. So severe was the effect of these sweats that I could always tell on entering the ward whether he had one the night before, and on one or two occasions I was shocked to notice what terrible changes had taken place during the past twenty-four hours. All the anti-sudorific remedies which I could think of were employed, without any avail or with only a slight decrease in the quantity of the sweat. Finally, in despair, I turned to camphoric acid and ordered that twenty grains of the drug should be administered stirred up in a little milk or placed upon the tongue and washed down with water one hour before the time at which the sweat generally came on, namely, at one o'clock in the morning. To

make a long story short, I can only add that during the remaining four weeks the drug absolutely controlled all sweating, although it was only given once in every twenty-four or forty-eight hours—thereby greatly increasing the patient's comfort and undoubtedly prolonging his life. It is also worthy of remark that this drug did not seem to decrease the other secretions, such as the saliva, or to cause the uncomfortable drying of the throat and feverishness of the skin so characteristic of full doses of belladonna.

The second case was that of a woman, aged twenty-five, suffering from pulmonary phthisis of a more chronic form than that of the case which I just detailed. In this case also the sweats were very annoying, producing insomnia and loss of strength, although they did not seem to be productive of as much debility as in the case of the man. In this instance, also, camphoric acid in the dose of 20 grains produced a most pleasing effect, completely controlling the sweating. I may also add that I have employed the drug in cases of nervous exhaustion and general debility accompanied with excessive sweating with considerable success.

When we consider that the dose of 20 grains of camphoric acid is only a third of what may be given in cases where this dose fails, namely, 60 grains, it becomes evident that the drug requires a more general trial by the profession, and that it will probably take a prominent place in the list of our materia medica. It is absolutely devoid of taste, insoluble in water, and comes in small micaceous crystals, which are soluble in alcohol. It does not produce the gastric irritation and burning produced by camphor, and in none of the cases in which I have employed it has it ever occasioned any distress or untoward symptoms.

As yet I have not had an opportunity to test the therapeutic activity of the tellurate of sodium, and I can say nothing, therefore, in regard to its value. Combemale states that while it is useful in night-sweats it is not equal to camphoric acid in power, and I am so well satisfied with the latter drug that I shall only try the tellurate of sodium when I find a case in which camphoric acid fails.

ORIGINAL LECTURES.

PREPARATION FOR ABDOMINAL SECTION—HERNIA AS A SEQUEL.

A Clinical Lecture.

By E. E. MONTGOMERY, M.D.,
PROFESSOR OF GYNECOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE AND OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL.

Gentlemen: I propose to spend a portion of the hour in the discussion of abdominal surgery and the preparation to be made for the operation. This is a comparatively new branch of surgery, and dealing as it does with the largest serous and absorbing membrane of the body it requires the greatest care and precision in the preparation for operation. It is a field in which we may justly feel proud of the accomplishments of American surgeons. In reviewing the literature of the subject we find it well established that the first operations for the relief of ovarian growths were done by that courageous backwoodsman, Ephraim McDowell, of Kentucky, in the year 1809. He performed nine operations. Although the operation was subsequently done in isolated cases by Nathan Smith, of this country, by Lizars and Clay, of England, it was not until Atlee, of this city; Dunlap, of Springfield, Ohio; Kimball, of Mass.; and Peaslee, of New York, entered upon their brilliant work that the profession recognized the importance of the procedure. When we consider what these men went through in braving public and professional opinion we cannot but admire their courage and feel that they deserve to be immortalized.

In the extension of this department of surgery we find the names of Battey, urging the removal of ovaries for diseased conditions and for the purpose of bringing about the menopause artificially; Marion Sims, urging the opening of the abdomen in all injuries in which the abdominal viscera are likely to be affected; seconded by the work of such men as Bull, Davis, Barrow, and others. In lauding the work of American surgeons we have no wish to discredit the work of Spencer Wells, Tait, Hegar, Schroeder, Keith and many others, who deserve to be mentioned for their original work. Of the intestinal work alone, Prof. Goodman has said that had our present knowledge of the mode of treating intestinal injuries been known and practised at the time of our civil war, many hundreds of valuable lives might have been saved. At present there is no portion of the abdominal cavity or its viscera that has not been the subject of operation.

In preparation for the operation we have first to consider the patient. Of course, it is understood that the patient has been carefully examined, that the conditions of the various organs of the body are known so far as an examination of the secretions and excretions can enlighten us; and the surgeon is satisfied that the operation is one which is for the best interests of the patient. It is exceedingly important that the secretions of the patient should be in as healthy a condition as possible in order to favor the elimination of the poisonous products that may develop during convalescence; hence, we exercise precaution with regard to the diet of the patient, that the food shall be nourishing, and yet of such a character as shall furnish the least amount of waste material; that the alimentary canal shall be thoroughly emptied by purgatives, preferably saline, which cause a free watery discharge. The skin of the patient, not only the parts about the site of the operation, but of the whole body, should be carefully bathed and cleansed with a view of increasing its action. The skin of the abdomen, the external genitals, and the pit of the umbilicus should be carefully bathed and repeatedly cleansed. This should be done with soap and hot water, using a nail or flesh brush freely, and in those cases in which there is much sebaceous material wash the skin with ether. For a few hours prior to the operation the abdomen should be covered with a cloth wet in a solution of acid sublimate (1 to 1000). In the majority of

cases it is advisable to shave the pubes and the lower abdomen. This should be done, preferably, before the last cleansing, as there is then less danger of having loose hair about the wound during the operation. This precaution is one that is not infrequently neglected. I have assisted gentlemen in operations, when to my astonishment I would find them all ready to make the incision without having given the abdomen any preparation, and have seen it covered with sebaceous material, exfoliated epithelium, and oftentimes with the remains of plasters and applications that had been made to the surface.

We must consider the room in which the operation is to be done, and in which the patient is to remain. It should be performed in a well-lighted, well-ventilated room, one which has been thoroughly cleansed, and is free from carpets and hangings. In it the preparations for the operation should have been made, so that when the patient is brought in under the influence of the anæsthetic, everything is at hand that may be needed during the progress of a complicated operation, as it is very unfortunate to have an operation interrupted to procure instruments or material, which may have been imperfectly prepared for use. The room in which the patient remains subsequent to the operation should also be well heated, ventilated, and lighted, and should be one in which the patient can be kept quiet and undisturbed. No stationary washstand should be present. It is not unusual to find operators exercising every care and precaution in the ways we have already mentioned, and yet failing in others which are equally important. I recently assisted a gentlemen in performing an operation in which he had cleansed the furniture of the room with carbolic acid, had the atmosphere so impregnated with it that it was difficult to breathe, yet when it came to preparation for the operation he was poorly provided with antiseptic sponges, had his suturing material placed upon a syringe box which had not been disinfected, and used silk fresh from the store without sterilizing to ligate the pedicle. I do not mention this instance with a view of discrediting the work of another, but simply to impress upon you the importance of exercising precaution in the minutiæ, and leaving nothing undone by which the interests of the patient may be promoted.

One of the most important subjects for consideration is that of sponges. These should be of suitable size for ordinary sponging, and where large incisions are to be made there should be in addition a number of large flat ones. These sponges as procured from the shops are usually filled with sand, dirt, and particles of lime, and require careful preparation. They should be first carefully pounded to break up the lime and particles of shell. This should be done by placing the sponge in a towel and beating it. They should then be immersed in a solution of dilute muriatic acid, one ounce to the quart of water, for several hours, after which they should be washed in water until the acid is removed and then cleansed by washing in green soap (sapo viridis), and then washed in water until the soap is entirely removed. After this place in a five-per-cent. solution of carbolic acid and keep until used. Sponges may be used repeatedly if properly cleansed. Recleansing may be done by washing in a solution of green soap or placing the sponges in a solution of hyposulphite of soda, one pound to the gallon of water, to which is added half a pound of oxalic acid. This produces a double decomposition by which sulphur and sulphurous acid are set free. By this change the fibrine and animal material is burned out, and the sponge is in addition bleached so that it presents a much better appearance than when treated in any other way. It will require repeated washing of the sponge to get rid of the sulphur deposited in it, but when it is removed, we are certain that the sponges are clean. They may then be placed in the carbolized solution and kept for use.

During the past year I have used catgut very largely for ligatures and sutures. The occurrence of abscesses in a few cases, however, has led me to feel that it was not a material upon which we could thoroughly rely. The difficulty, particularly in the thicker catgut, is that we are unable to know how carefully it has originally been cleansed and prepared. The manner in which I have prepared it, has been to place the catgut in ether, allowing it to remain for from twenty-four to forty-eight hours, in order to dissolve out fatty substances that may be present. Then it is placed in a five-per-cent. solution of carbolic acid in which one grain of bichromate of potash to the ounce has been dissolved, in which it remains for from twenty-four to forty-eight hours longer, according to the size of the catgut, after which it is placed in absolute alcohol and kept for use. Lately, I have returned to the use of twisted Chinese silk, having this either boiled for an hour or placed for a number of hours in a solution of acid sublimate (1 to 1000), after which it is placed in absolute alcohol to be kept for use.

Now, it is very important to watch carefully your assistant in the removal of the ligatures from the receptacle in which they have been placed. He should be instructed to carefully cleanse and disinfect his hands, to take the ligature out and place it in a vessel containing hot water, being careful not to permit any portion of it to come in contact with table, clothing, or extraneous material by which it may be infected with pathogenic germs. The sutures should be threaded into the needle from the hot water. Precautions should be observed as the sutures are introduced, that the surface with which they come in contact should be one that has been thoroughly sterilized. For this purpose we thoroughly surround the line of incision with towels that have been wrung out of an antiseptic solution, preferably the acid sublimate; after these have been soiled they should be replaced with clean ones before the sutures are introduced.

Now, in performing the operation, the operator stands on one side of the patient. In my operations you will notice that I prefer to stand on the left side. The principal assistant on the opposite side should be a person who is ready and willing to follow the directions of the operator, to anticipate his wishes, and yet not to be officious and attempt to do that which is the work of his superior. He should be a person who is cool and calm in an emergency. The second assistant administers the anæsthetic; he should be accustomed to its use, and be depended upon to keep the patient under its influence with as little expenditure of the agent as possible. The other assistant, who may be, ordinarily, a trained nurse, takes care of the sponges. She should have two basins for this purpose; into one the spoiled sponges are thrown,

washed out, and placed in the other, ready to be handed to the assistant. It is well to have an additional assistant, not to handle the instruments, but to be prepared for emergencies, to have ready Paquelin's thermo-cautery or other preparations that may be needed. The instruments are upon a table to the right of the operator where he can reach them without assistance. The patient, thoroughly anæsthetized, is placed upon a prepared table; the abdomen is exposed, surrounded and covered, except where the incision is to be made, by antiseptic towels. As a preparation for the operation, the instruments have been thoroughly cleansed, placed in pans, and covered with hot water.

The first step in the operation is the incision through the abdominal parietes; this is made as nearly as possible in the median line in order to reach the linea alba. It should be made with a scalpel through the skin and superficial fascia down to the aponeurosis, by the first, or, at most, the second sweep of the knife. The extent of this has been determined by previous examination of the thickness of the abdomen. The aponeurosis is opened, and the further incision made by probe-pointed angular scissors, by which the tissues can be cut quickly and safely through to the peritoneum. The peritoneum is raised up by forceps in order to prevent injury to the intestines or to any growth within its cavity. Then, after opening, with a finger introduced as a director, the incision is extended the length of that through the walls. I will not take time now to discuss the methods of operating after the abdomen has been opened, as I prefer to do this when I have before you a patient suffering from a condition requiring abdominal section.

I now bring before you a patient who has undergone an operation some eighteen months since. Her history previous to the operation is rather vague, as she is unable to give the reason for its performance. She, however, now comes to us she says suffering greater distress than before. The operation was performed for the removal of her uterine appendages. She did not menstruate for seven months after the operation, and during this time was quite comfortable. She now menstruates regularly, and suffers a great deal of pain and distress. Prior to and during the flow she complains of burning distress and pain in the inguinal region as well as over the pubes. In looking at the abdomen you will see the cicatrix of an incision some five inches in length. This is an unusually long incision to make for the simple removal of the appendages. One inch from the lower part you will see a slight protrusion, which is increased in straining or in coughing. As the patient now coughs you will see that this protrusion becomes considerably larger; and when I press upon this I can distinctly feel something disappearing before my finger as it is passed into the abdomen. I find an opening through the muscular walls into which the point of the finger can be introduced. This condition is one that is known as ventral hernia, and is not infrequent after abdominal incision where precautions have not been taken in the closure of the wound to carefully approximate the edges of the incised aponeurosis. In this patient the aponeurosis above and below this are firmly united. I find that she has suffered during convalescence from an abscess in the wound, probably a stitch abscess, which continued open for several months. To this is due, probably, the weakened condition of this portion of the ventrum.

This subject of closing abdominal wounds is so important that I feel that it is to your interest that I should speak particularly of the method of introducing the sutures. The mistake is commonly made of introducing the sutures at some distance, say one-half an inch, from the edge of the peritoneum on either side. If we grasp the incised surface between the fingers the sutures may be introduced without bringing up or passing through the muscular portion of the wall at all, simply involving the peritoneum, the superficial fascia and skin, and such an approximation must necessarily result in a weak ventrum. Then, too, where a large portion of the peritoneum is included in the suture and a large portion of the skin, the peritoneum may be everted, the skin inverted, and but very little tissue intervenes in opposition between the respective edges. The proper plan of procedure is to so introduce the sutures that the edges of the peritoneum are brought in apposition, the aponeurosis and muscular wall thrown well together, and the edges of the skin simply approximated. In this way we are certain to have a firm cicatrix, with but very little danger of hernia.

This patient entered the hospital with the expectation of undergoing an operation for the relief of this hernia, but upon careful inquiry into her history, I fear it would be necessary to perform an operation with a view of relieving the probable adhesions that have occurred in the abdominal cavity. If it had been simply the relief of the hernia, I should have endeavored to have made an incision to one side of the protrusion, dissected or pushed off the peritoneum without opening it, then pushed it back through the opening, and freshened the edges of the aponeurosis, and have brought these together with sutures. But finding that this would not be sufficient to relieve the internal distress, I have concluded to defer operation for the present. This is particularly on account of the condition of the hospital, which, as you know, is undergoing alteration, and does not afford us an opportunity to give this patient a room suitably prepared for a critical operation.

It is very important in performing abdominal operations to use care that adhesions may not result which may very much increase the distress from which a patient may suffer. In all cases in which there have been adhesions, or where the peritoneum has been denuded for an extensive surface, or in which there have been pus sacs removed, drainage is absolutely demanded. Where the adhesions have been extensive, and there is danger of their re-formation, the cavity should be treated wet rather than dry. The introduction through the drainage-tube at frequent intervals of a solution of boroglyceride prevents the decomposition of the fluid contained in the perineal cavity, permits the intestines to roll over each other with layers of fluid intervening between them, and favors the granulation of the denuded peritoneum, so that cases thus treated may recover without the development of any adhesions.

Commencements.—The commencement exercises of the Jefferson Medical College will be held April 15th, and of the University of Pennsylvania May 1st.

PREPARATION FOR LAPAROTOMY.

Extracts from a Clinical Lecture, delivered at the Cincinnati Hospital.

BY THADDEUS A. REAMY, M.D., LL.D.,
PROFESSOR OF CLINICAL GYNECOLOGY IN THE MEDICAL COLLEGE OF OHIO; GYNECOLOGIST TO THE CINCINNATI AND GOOD SAMARITAN HOSPITALS OF CINCINNATI.

GENTLEMEN: Two weeks since I removed the tubes and ovaries from this patient in your presence. Seven days after the operation she was again brought before you with all sutures removed from the abdominal walls and the wound united by first intention.

The next patient I bring before you is the woman from whom I removed a thirty-five-pound multilocular ovarian cyst. She has no fever or pain, and the abdominal wound is closed except where the drainage-tube was inserted, at which point there is slight suppuration. The sutures have all been removed and the woman is out of danger.

You have seen during the past two years the abdominal cavity repeatedly opened in this amphitheatre on my table, which stands in the same place occupied by the operating-table of my friends and colleagues, the general surgeons, with all classes of surgical cases. Moreover my clinics are attended by a large class, made up of students from the different colleges of the city, many of whom are probably just from the dissecting-room, and yet my patients suffer no infection.

You are probably anxious to know what special antiseptic methods are adopted to secure these results. The answer to this inquiry is *cleanliness*. The patient, operator, assistants, nurses, sponges, instruments, water, dressings, and everything used in connection with the operation must be perfectly clean.

Let me call attention to points which I regard as important in the preparation for an operation of the character under consideration.

First, the diagnosis having been made and the operation determined upon, the patient should remain in the hospital from five to ten days before the operation is performed. This is important in order that she may become acquainted with her nurse and her physician, and acquire confidence in them; also that she may become accustomed to her surroundings and that her bowels may be properly and thoroughly evacuated, and that in other ways she may be prepared for the operation.

At the time of her entrance to the hospital she should receive a thorough bath, including shampooing of the head, and thorough scrubbing of the external genitalia, and all parts of the body covered by hair. She should have each day before the operation a sponge bath, and her vagina should be syringed thoroughly with warm soap-suds, followed by a ten-per-cent. solution of carbolic acid, or a bichloride of mercury solution, 1 : 1000.

The day before the operation her bowels should be evacuated by sulphate of magnesia. On the morning of the operation, but several hours before it, the lower bowel should be washed out by an enema of warm salt water. Just before the operation the abdomen should be thoroughly cleansed and rubbed with a 1 : 1000 bichloride solution, or a five-per-cent. solution of carbolic acid.

When the patient is placed upon the table the lower extremities should be well wrapped in blankets, but the stockings should not be removed. Her chest and arms must be well protected, and only the field of operation exposed. Some surgeons place a piece of macintosh with a slit in it along the proposed line of incision, but I think this is objectionable. Warm towels protect the parts well above and below the line of incision.

The operator's hands should be washed thoroughly with a nail-brush and soap in warm water, the water being changed repeatedly until there is no possibility of uncleanness. The operator's assistant, and the nurse who is to handle the sponges, must observe the same methods of cleansing.

The water used in these ablutions, and that used for cleansing the sponges, instruments, and for irrigating the peritoneal cavity should either be filtered and boiled or should be distilled. The receptacles for the sponges and instruments must be thoroughly clean.

I have recently seen an operator use absorbent cotton instead of sponges, which is only mentioned to be condemned. Soft clean sponges of the Smyrna variety should be used. Ordinarily those cup-shaped are most suitable. No sponge that has been cut or torn should be employed. For protection of the omentum and the intestines from injury by the needle in closing the abdominal wall, as well as for receiving the blood caused by the penetration of the wall by the closing needle, the flat silky sponge, called the elephantine sponge because of its resemblance to an elephant's ear, is much to be preferred. Of course, I assume that your new sponges have been thoroughly cleansed and are aseptic.

I am in the habit of using the same set of sponges in six or eight laparotomies.

Immediately after an operation they must be thoroughly washed in warm water, then placed in a strong alkaline solution, soda being as good as any, which must be changed until all albuminous matter has been removed; several days are required for this process. They are now carefully washed in plain warm water, and must then be kept for a day or two in a five-per-cent. solution of carbolic acid. When taken from this solution they are to be placed in a clean linen bag and hung in a room where they remain until the next operation. Before commencing an operation the sponges are washed out in warm water and are ready for use. The odor of carbolic acid remains quite perceptible though they may remain in the dry bag a month.

Good silk thread is hard to obtain. The so-called Chinese silk is not very reliable and braided silk is objectionable. I have of late used exclusively silk obtained either in Birmingham or London, which gives perfect satisfaction. It is hard, twisted and contains no cotton. It is important that there should be no cotton in the thread, for a pure silk ligature will, in the course of six to twelve months, be absorbed, being an animal product; while if it contains cotton it may not be absorbed, and may give trouble.

The pedicle ligature should be of as small size as consistent with proper strength. The silk to be used, both for ligating the pedicle and for closing the abdominal wound, is boiled in plain water for half an hour and then dried, just before an operation, by artificial heat.

I have already stated that no chemicals of any character are to be placed in the water employed for

cleansing the peritoneal cavity. In simple tubal and ovarian cases no water is poured into the abdominal cavity.

After thoroughly cleansing and drying, oil the abdominal wound; long adhesive strips are applied, followed by pads of absorbent cotton and mosquito netting. Neither moist dressings nor antiseptics are used. The wound is not examined until the fourth day.

In closing this lecture I wish to reiterate that the main object in abdominal surgery is *cleanliness*.

MEDICAL PROGRESS.

Treatment of Psoriasis.—Fabry has employed hydroxylamine in the treatment of psoriasis with good results. The prescription is as follows:

℞.—Hydroxylamine muriate . . 3–5 grains.
Spirits of wine . . . . 1½ ounces.
Carbonate of calcium, a sufficient quantity to neutralize.

Or,

℞.—Hydroxylamine muriate . . 15 grains.
Pure water . . . . 1½ ounces.
Calcium carbonate, a sufficient quantity to neutralize.

Guttman is said to cure psoriasis in seven days by the employment of a ten-per-cent. ointment of hydracetin.—*Wiener medicinische Presse.*

Treatment of Acne.—Isaac recommends in the treatment of acne the following prescription:

℞.—Powdered chalk . . . 1 drachm.
Beta naphthol, Camphor, Vaseline } of each . . . 2½ drachms.
Green soap . . . . 4 "
Precipitated sulphur . . . 1½ "

Equally good results may be reached by employing a ten- to twenty-per-cent. ointment of resorcin.—*Wiener medicinische Presse.*

Treatment of Eczema.—The *Wiener medicinische Presse* states that Cerasi employs the following ointment or wash in the treatment of impetiginous eczema:

℞.—Picric acid . . . . 4 grains.
Sulphuric ether, enough to dissolve it.
Lanolin . . . . . 18 drachms.

Or,

℞.—Picric acid . . . . 7 to 15 grains.
Sulphuric ether, a sufficient quantity to make a solution.
Rose-water . . . . 5 ounces.

Transmission of Tuberculosis from Mother to Fœtus.—Csokar has recently presented to the Imperial Society of Physicians in Vienna a pathological specimen which he believes proves with certainty that the bacillus of tuberculosis may pass into the fœtus from a tubercular mother. A cow which was advanced in pregnancy suffered from pulmonary tuberculosis and died from this disease. The fœtus showed, in its hepato-duodenal ligament, lymphatic glands which were partly caseous and partly calcified. There were a large number of tubercles and round cells with the tubercle bacilli. The fact that infection occurs through the umbilical vessels Csokar thinks of interest.

Treatment of Diphtheria.—In St. Bartholomew's Hospital reports for 1890, which have just been published, may be found a paper by Ogle and Willoughby upon this subject. The patients upon whom the study was based numbered twenty-two and occurred in the wards of Sir Dyce Duckworth. The cases were all extremely grave and the operation of tracheotomy was only resorted to when other measures appeared unavailing. The importance of early recourse to this operation is emphasized; the main indication for it being cyanosis. Ogle insists very strongly upon the use of a spray of a solution of bicarbonate of sodium with borax, in the proportions of ten grains of each to the ounce of water, for the purpose of disintegrating the membrane. Its employment is usually followed by the expectoration of creamy mucus containing shreds of membrane. Papain solution also proved very serviceable. The value of free stimulation was marked in all the cases, brandy being given in a dose varying from one to three ounces mixed with milk, beef or mutton essence and yolk of egg every four hours by means of a soft nasal tube. Jelly and custard were the first articles of food given by the mouth. The medicines employed were perchloride of iron and strychnine in full doses. These observers think that the importance of feeding by the nose in the early period after tracheotomy is not as yet fully appreciated.

Injections for Gonorrhœa and Leucorrhœa.—According to *L'Union Médicale*, Lutaud recommends the following prescription in gonorrhœa and leucorrhœa in the later stages of these diseases:

℞.—Creolin . . . . . ½ drachm.
Extract of hydrastis canadensis 2½ drachms.
Water . . . . . 8 ounces.

Add two teaspoonfuls to a pint of hot water and use as an injection in leucorrhœa. In gonorrhœa in the male the following formula is useful:

℞.—Creolin . . . . . 10 drops.
Extract of hydrastis canadensis ½ drachm.
Distilled water . . . . 8 ounces.

This solution is to be employed without dilution as a urethral injection.

Treatment of Syphilitic Pharyngitis.—According to *L'Union Médicale*, Crequy has used with great success the following tablets of the protiodide of mercury and chlorate and iodate of potassium in the treatment of mucous patches in the mouth and pharynx:

℞.—Protiodide of mercury . . ¼ grain.
Chlorate of potassium . . 3 grains.
Iodate of potassium . . . ¼ grain.
Chocolate, a sufficient quantity to make a tablet.

One or two of these tablets may be taken each day after a meal. Care, of course, should be taken that severe mercurialism does not result.

CURRENT LITERATURE.

SATURDAY, APRIL 4, 1891.

TREATMENT OF PLACENTA PRÆVIA.

EVERKE says the cause of placenta prævia is to be found in the possibility of the ovum falling from the fundus to the cervix, and developing there. Hence it is more frequent in multiparæ with large uterine cavities, and especially when previous catarrh has made the mucous membrane smooth. Everke has observed placenta prævia in such a patient three times in succession.

Hæmorrhage constitutes the greatest danger to the mother. The open vessels at the seat of the placenta easily absorb septic matter, and hence women with placenta prævia are especially subject to puerperal septicæmia. The danger to the child, of course, is from asphyxia.

Bleeding may occur in two ways. In the latter months of pregnancy the lower uterine segment may be drawn upward, and the placenta, being unable to stretch as much as this part of the uterus, may be separated from its base of attachment. In labor the placenta is separated by the dilating pains.

Treatment must meet two indications, first to save the mother from death by hæmorrhage, and second, to rescue the child from its threatening position. The first must be achieved, if necessary, by the sacrifice of the child. The physician who pays least attention to the child's life will save the life of the most mothers.

If the pains are strong, the position of the fœtus longitudinal, and the mouth of the womb dilated to the size of a five-mark piece, the bleeding can usually be controlled by rupturing the membranes. As soon as the membranes are ruptured the tearing of the lower pole of the ovum ceases, and there is no further loosening of the placenta. The uterine contractions press the presenting part against the os and the placenta, and the bleeding surfaces are effectually tamponed. Birth is then usually spontaneous. Rupture of the bag of waters is contra-indicated when the pains are weak, and when the os is not sufficiently dilated, as then tamponing would not occur, and version would be rendered more difficult.

Version is performed in placenta prævia with the view of making compression upon the bleeding spot. If the os is almost or completely dilated, the hand can be easily introduced and either rupture the membranes at the side of the placenta, or perforate the placenta, and bring down a foot. In all such cases the bleeding usually ceases. If hæmorrhage still continues, gentle traction should be made upon the foot. When the fœtal heart-sounds are good, slow extraction should follow version, as rapid extraction is a source of danger to the mother by producing atony of the uterus.

If the os is sufficiently dilated to admit two fingers, the mother may be saved from her dangerous position by two procedures—*accouchement forcé* and combined version. The first is recommended by Spiegelberg, and consists in slowly stretching the os from below backward, which is generally yielding in these cases, using first two, then three, and then four fingers. The hand of the accoucheur thus acts as a preliminary tampon. After careful stretching of the os, the hand is introduced into the uterine cavity, the foot grasped, and the fœtus turned. This procedure is only to be undertaken when the os is soft and yielding, and is always dangerous, as the cervix may be torn, followed by death of the woman from cervical hæmorrhage after the child's birth. Hence this method has been generally superseded by Braxton Hicks's method of combined version. Everke thinks this method the best, as it permits of early intervention, and can be performed with only one or two fingers within the os. The woman, therefore, loses but little blood, and so has left greater resisting power. It is certain, also, to control the bleeding. Post-partum hæmorrhage and cervical tears are avoided, the uterus is evacuated gradually, and no uterine atony results, and, as subsequent tamponing to control hæmorrhage is no longer necessary, the danger of septic infection is obviated. By the old method, in which tampons were sometimes employed for days while the os slowly dilated, there was great danger of septic infection because of the proximity of the tampons to the large placental vessels. This explains many deaths which have occurred in the puerperium; nevertheless tamponing is still necessary in rare cases in which the os is not dilated sufficiently to admit one or two fingers, and in which the os is so rigid that it cannot be easily stretched. When tamponing is necessary it should be preceded by careful cleansing of the genitalia, evacuation of the bladder, and washing out of the vagina. Strips of iodoform gauze should be pushed in rapidly, being followed by pledgets of cotton, so as to fill the vagina as soon as possible. In a few hours the cotton is removed, by which time usually the os is sufficiently dilated to permit of the termination of labor.

If the physician does not feel sufficient confidence in himself to perform combined version, he may succeed by external version, if the membranes are intact, the child small, and the head not fixed.

Hæmorrhage after birth should be rare, if extraction is slow. If it occur, however, the cause should be sought for. If there are lacerations, these should be repaired, and if atony exist, tamponing, according to Dührssen's method, is the surest, simplest and safest way of overcoming it. In cases in which placenta prævia is recognized in pregnancy, Everke recommends the induction of premature labor, on account of the liability to sudden hæmorrhage, which may occur when medical aid is not at hand. Labor should then be induced by the gradual introduction of one or two fingers, and the foot seized and brought down. In one case Everke was unable to grasp the foot after the induction of premature labor and external version, as only one finger could be introduced. He thereupon inserted a Sims speculum, fixed the os with two bullet-forceps, and then grasped the foot with a pair of dressing forceps,

and, so, easily drew it into the cervical canal. No further bleeding occurred, and the fœtus was delivered in about twelve hours.

The dangers of anæmia are to be overcome by infusion of salt solution, either into the veins or into the cellular tissue, as recommended by Münchmeyer. —*Therapeutische Monatshefte*, February, 1891.

OBSERVATIONS UPON THE ETIOLOGY OF ACUTE ARTICULAR RHEUMATISM.

Waibel remarks upon the growing belief in the supposition, first expressed by Hirsch, that acute articular rheumatism is an infectious disease. The exciting cause of the disease, which is yet undiscovered, cannot affect individuals entirely healthy, but only such as are in a depraved state, or are under special or general injurious influences. The predisposing injurious influences of a general nature are: The season of the year, and the prevailing meteorological conditions, as well as various other unhygienic conditions. The predisposing factors affecting individuals are: Age, sex, vocation; whether the person lives in the city or country, or has passed through a previous attack of rheumatism; heredity, and diseases of the mucous membrane of the digestive tract.

Waibel admits that his experience is limited to one hundred and twenty-one cases of rheumatism, but as he has been able to study these in person and to follow the patients into their dwellings, and so study the etiology with greater care, these facts make up for the relative paucity of numbers. These one hundred and twenty-one cases occurred in sixteen years, from 1874 to 1889 inclusive. There were more attacks in January and March than in other months, and the fewest in September. As regards season, more occurred in winter and spring. So far Waibel's statistics agree with the general experience of other observers, and appear to indicate that cold and wet operate to produce rheumatism. The writer, however, denies that they have any direct influence, but says they may act by favoring the growth and development of the cause of the disease. He also thinks it very probable that meteorological conditions favor the spread of the exciting cause of rheumatism in the same manner as they do the microörganisms of other diseases.

He says the indirect influence of meteorological conditions are much more important than the direct. In very bad weather men remain more at home, and the result is the crowding together of a number of persons in badly-ventilated rooms, in which the air and the floors are foul, not only from soiled and wet clothing, but also because the lighting, heating, cooking, and washing are all done in the living-room. In addition to these causes there are often found in these houses decomposing animal and vegetable materials and excreta, which also vitiate the atmosphere and contribute to the development and growth of disease germs. The patient generally attributes the attack to cold, which belief is deeply rooted in the minds of both physicians and laymen, partly from ignorance and partly from long-established habit.

Waibel's investigations as to the position, moisture, and age of the dwellings in which cases of acute articular rheumatism developed, are surprising. He finds that more cases occur in the high, dry, and old houses. Of his one hundred and twenty-one cases, eighty-two occurred in houses in high situations, as opposed to thirty-nine in low-lying houses; ninety-three in dry, and only twenty-eight in moist houses; one hundred and fifteen in old, and six in new houses.

Sex has no influence; sixty cases occurring in men and sixty-one in women. As regards age, more cases occurred in the decades from ten to twenty and from thirty to forty, and fewer in the decades from sixty to eighty.

Seventy-four of the patients were hard laborers belonging to the agricultural and industrial classes, while forty-seven were not over-exerted by their work. No special calling, however, appeared to predispose to rheumatism. Waibel has observed very few cases in factory hands, notwithstanding the fact that they are poorly clad, and frequently have to travel long distances in cold and wet weather, and then stand long hours in wet shoes and clothing. This exemption is, in his opinion, due to the fact that they do not have to work very hard, and also because they are away from their dwellings during the whole day.

Kunz's statistics of the morbidity for the cities of Swabia and Neuberg for 1884 indicate that acute articular rheumatism affects about equally the industrial and agricultural classes, while the house servants are more affected. According to the same statistics for 1885, the industrial were more affected than the agricultural laborers, aud of the former more cases occurred among brewers, joiners, and millers. A large number of cases occurred among soldiers.

According to Professor Strümpell, servant girls, waiters, and coachmen are especially disposed to acute articular rheumatism.

As regards residence in city or country, seventy-nine of Waibel's cases occurred in city-dwellers and forty-two in people living in the country. His statistics give no information as to the influence of heredity, although he suggests it may have an influence through the transmission of a weakened constitution. A previous attack is a well-known predisposing cause. The greatest number of attacks observed in one patient was seven in fifteen years, two of them occurring in one year.

Waibel has frequently observed that disturbances of the digestive tract precede an attack of rheumatism, and he thinks it very probable that this favors the invasion of the disease-germ. His observations do not warrant him in expressing a positive opinion as to the contagiousness of rheumatism. He thinks it highly probable that the contagium belongs to the contagious-miasmatic class of infections. He has never seen anything which justified the belief that rheumatism is epidemic. There has, however, been an increase of the disease in the past ten years, a fact which has also been observed by Port, in the Bavarian garrison.—*Münchener med. Wochenschrift*, February 3, 1891.

PLEURISY IN CHILDREN AND ITS TREATMENT.

Simon, in *Le Progrès Médical*, January 31, 1891, says that typical pleurisy with well-marked symptoms is of extreme rarity in children. In them it is rare to observe other than secondary pleurisies, consecutive either to lesions of the lungs, pneumonia, broncho-pneumonia, tuberculosis, or to the infectious diseases, measles, whooping-cough, scarlet and typhoid fevers. Together with the pleural inflammation, there is nearly always a simultaneous inflammation of the bronchi and lung. The pleurisy presents a most remarkable tendency to encystment, which renders the diagnosis very difficult. Several of the symptoms which are prominent in the adult are absent in the child. Thus, in the beginning, instead of complaining of pain at some point in the side, the child complains of a pain in the abdomen, or in the flank. Its respiration is accelerated, the respiratory movements reaching the number of 30 to 40 per minute; the temperature rises to 38° or 38.5° C. The child coughs a little, and seems to suffer in coughing. On inspection, the affected side is more or less immobile, its movements being limited. A little later, when the effusion is increased, the side shows a slight bulging. Percussion, when the effusion is abundant, gives an extended dulness. On auscultating the chest, the friction—the important initial sign in the adult—is hardly ever perceived in the child. When it is heard, it is in the late period, that of resolution. An important symptom is the suppression of the vesicular murmur, a suppression which makes a strong contrast to the puerile respiration of the healthy side. The pain in the belly, the fever, the dyspnœa, the extended dulness, and the suppression of the vesicular murmur, are the prominent symptoms of the early stage.

The frequent association of the disease with an inflammation of the bronchi and lungs renders the diagnosis a matter of great difficulty. However, the duration of the malady will reveal its nature. A frank pneumonia will be recognized in some days; a broncho-pneumonia, even, does not persist during three or four weeks with this fixity of position. A pleurisy, however, remains localized for five or six weeks, or longer. The termination is usually by suppuration, the fever persisting with irregular oscillations; at no time, however, tending to exceed 38.5° C. It is important to note this relatively low temperature, which exists notwithstanding the suppuration. Pus, once formed, shows even a greater tendency to encystment than does a serous effusion. The seat of this encystment may be posteriorly or anteriorly, in the axilla, in the middle portion of the chest, or even under the clavicle. After its encystment it frequently discharges spontaneously, either toward the skin, or toward the bronchi, or simultaneously toward the bronchi and skin. The prognosis of pleurisy in the child is relatively very favorable. Its gravity at first depends upon the associated broncho-pneumonia. Later, when there is suppuration, death may ensue from cachexia, asphyxia, or opening of the abscess into the pericardium or mediastinum, if the effusion is unrecognized. But if the diagnosis is made, if proper treatment is instituted, cure ordinarily follows, even in the gravest cases, such as secondary pleurisies, pleurisies associated with profound cachexia, or even double pleurisies.

The treatment in the first stage should be hygienic and medical. Avoidance of chilling of the surface, and the use of hot drinks, with calomel one-sixth to three-quarters of a grain every two or three days to produce a slight laxative effect, and digitalis, ten to twenty drops of the tincture, as a diuretic and antiphlogistic. In the second stage, when pus has formed, it may be necessary to perform thoracentesis. The point of election for the puncture will usually be in front of the axillary line, instead of, as in the adult, at the union of the posterior third and the anterior two-thirds. Thorough antisepsis should be practised, to avoid further infection of the system. If necessary, an incision should be made and thorough drainage instituted, antiseptic precautions being observed.

REVIEWS.

Saunders's Question Compends: Essentials of Surgery. By Edward Martin, M.D. Fourth Edition. Illustrated, Revised and Enlarged, with an Appendix of Prescriptions, etc. Philadelphia: W. B. Saunders, 1891.

The fact that Dr. Martin's question-book upon Surgery has passed in two years through three large editions, and that the publisher has found it necessary to issue another addition at this season of the year, points to its popularity not only with students but with a certain number of physicians. It is useless for us to repeat the commendations which were called forth by the earlier editions, and it only remains to call attention to the exceedingly useful appendix which has been added to the present issue, which contains a large number of prescriptions applicable to many diseases, and in addition a list of drugs and materials used in antiseptic surgery, together with general directions concerning preparations for antiseptic procedures. The average practitioner and the student will find this last portion of the book equally attractive with the first, and we are convinced that the fourth edition will be as thoroughly appreciated as its predecessors.

Diabetes: its Causes, Symptoms and Treatment. By Charles W. Purdy, M.D. Illustrated. Philadelphia: F. A. Davis, 1890.

The subject of diabetes is one of such universal interest to medical men that any book which deeply yet clearly discusses the causes, symptoms, and treatment of this disease cannot fail to be popular with physicians. While many monographs have been published which have dealt with the subject of diabetes, we know of none which so thoroughly considers its relations to the geographical conditions which exist in the United States, nor which is more complete in its summary of the symptomatology and treatment of this affection. A number of tables showing the percentage of sugar in a very

large number of alcoholic beverages adds very considerably to the value of the work.

The Year-book of Treatment for 1891. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia: Lea Bros. & Co., 1891.

To most of the subscribers of The Medical News the *Year-book of Treatment* is a familiar publication, and well worthy of a place upon the desk of every practising physician. The present year-book differs from its predecessors in that it is almost twice as large, and therefore contains a more complete *résumé* of the therapeutic literature of 1890. Under the skilful handling of Dr. T. Mitchell Bruce, the first article in the volume, upon "Diseases of the Heart and Circulation," serves the excellent purpose of making one familiar with the latest studies concerning this important portion of the body when affected by disease, and it is only necessary to state that among the other contributors are such men as Malcolm Morris, Edmund Owen, Reginald Harrison, and James Ross, to make one feel that the princes of English medicine have gathered together for their medical brethren all that is good, to the exclusion of everything that is useless.

CORRESPONDENCE.

NEW YORK.

As might naturally be expected, this winter has witnessed the presentation of an unusual number of papers on the subject of tuberculosis; but even before the memorable announcement of Koch's great discovery of the lymph treatment, I had been struck with the value of some of the papers which have been presented here to some of our medical societies, showing the direction of current thought. Whatever may be said in the way of criticism of these investigations, and of the conclusions which have been drawn from them, it is certainly most refreshing to learn that a diagnosis of phthisis is no longer to be considered as necessarily synonymous with the death-knell of the patient. It is also encouraging to be told that these new and optimistic views are not based upon some recent and fantastic method of treatment, but are founded upon a patient study of Nature's methods of bringing about a cure of tuberculous processes under favorable conditions.

One of these suggestive papers was entitled, "Some of the Facts in the Etiology of Tuberculosis," and embodied the results of experiments which had been made by Dr. H. P. Loomis. In his communication, which was read before the Bellevue Alumni Association, he narrated the histories of a number of cases in which the bronchial nodes or glands were the primary seat of lesion. In one case, that of a vigorous man who died in an attack of acute lobar pneumonia, the autopsy, made a few hours after death, showed that the organs were normal, and no evidences of tuberculosis existed except in the enlargement of the bronchial nodes, and even these presented no gross lesions of tuberculosis. The existence of tuberculous material in these nodes was, however, proven by inoculation experiments. As the determination of the bacilli in the sputum in cases where these organisms are present in small numbers is a matter of considerable difficulty, and one into which the personal equation enters very largely, Dr. Loomis preferred to make use of inoculation experiments to ascertain the presence of tuberculous material. A series of thirty autopsies made upon persons dying of acute diseases, or as a result of violence, showed that eight had tubercle bacilli in the bronchial nodes, although none of them exhibited any evidences of tuberculosis anywhere else. In the discussion which followed the reading of this paper, Dr. H. M. Biggs said that there seemed to be no organ or tissue in the body which might not be primarily affected by tuberculosis. In the autopsies which he had made at the various charity hospitals of this city, he had found that 60 per cent. of all the deaths occurring in these institutions showed tubercular lesions, and yet less than one-half of these had died of tuberculosis. He had been informed that in the Vienna General Hospital such lesions were found in 85 per cent. of all the autopsies. That this was not simply a dead-house view of the subject was apparent when one recalled that Dr. Austin Flint's large clinical experience had led him to a very similar conclusion.

I mention some of the more important points brought out in this discussion, because it was a most fitting preliminary to the study of the treatment by Koch's "lymph," which only ten days later was made known to the world. This matter of the "lymph" treatment has been so fully set forth to your readers that doubtless they feel that it is time to cry "enough;" but I think it will not be without interest to them to read a statement of the results obtained so far in the use of this "lymph" by Professor A. L. Loomis. It is well known that this gentleman is not easily aroused to such a pitch of enthusiasm that it will prevent him from discussing dispassionately and scientifically the results obtained in any new departure in therapeutics. I have heard him speak of his cases from time to time, and he has fully sustained his reputation in this particular. A few days ago he exhibited to his students two men who had been under Koch's treatment for a period of five weeks. Both of them had unmistakable physical signs of phthisis at the beginning of the treatment, along with tubercle bacilli in their sputum. One of them had received in all thirty-two injections, the dose at first being one milligramme, but afterward it was increased to five. At first his physical signs were aggravated, but for the last three weeks he had steadily improved, and the physical signs were now very slight. The patient had gained eight pounds in flesh. The second patient received altogether seventeen injections in varying doses, the largest being ten milligrammes. A similar change for the worse was noticed in the physical signs in his case after the first injections, but the signs of consolidation had almost entirely disappeared, as had also the bacilli from his sputum, and he had gained twelve pounds in weight. Two plans of treatment—viz., small doses at short intervals and large doses at longer intervals—had both been tried, but there was apparently no great difference in the effect, except that the reaction after the small doses was naturally less severe.

I have been unable to learn of any deaths which have been considered, on good medical authority, to have

been directly due to the injections of the "lymph," but a number of deaths among patients in the advanced stages of tuberculosis who were undergoing this treatment have been reported. It is reasonable to suppose that in such debilitated subjects, the injections of this fluid, as Professor Loomis distinctly states, exerting so powerful a depressing effect upon the heart and system generally, may have hastened the fatal issue. Whether this be true or not, it is hard to say on what grounds one officious coroner has felt called upon to issue notices to the effect that he will investigate all deaths occurring in patients undergoing this treatment. There is certainly nothing in the law which defines the functions of the coroner which can be so construed.

There is, of course, much difference of opinion as to the effects of the injections, but it is significant that those who have had most to do with this treatment are in general most emphatic in stating that the method of Koch should only be employed in hospitals, where the cases can be closely watched and intelligently nursed.

It goes almost without saying, that special hospitals for carrying out this treatment will be speedily established, and I have to note that the first one of this kind in this city was opened on February 4th. It is called the Koch Institute, and is under the charge of Dr. Alexander I. Aronson. The building will accomodate thirty-five patients, but no cases of advanced disease will be taken, as they are obviously unsuited for this treatment.

I have had considerable to say in recent communications about the new building of our Academy of Medicine. The prosperity of the Academy seems to have fully justified the efforts made to secure this new and beautiful home. It was the scene of another pleasant gathering some weeks ago, to listen to the inaugural address of its President, Dr. Alfred L. Loomis. The property of the Academy is now valued at about $400,000, with a debt of only $30,000. The membership is rapidly increasing, and many of the more energetic members are anxious to concentrate and centralize medical thought and influence here. To aid in carrying out this wish, the President suggested in his address that the various private medical societies which now divert the energy of the profession into many different channels, should be taken into the Academy as sections, where they would be more honored and more influential.

The address also contained two other important suggestions as to the future work of the Academy, viz.—first, that it should establish a reliable nurse bureau, and, secondly, that it should issue a monthly bulletin of its "transactions," somewhat after the plan adopted in a similar publication issued by Johns Hopkins. These latter propositions, I think, are likely to meet with favorable consideration, but the first suggestion will more than likely provoke much opposition.

ST. LOUIS.

COMMENCEMENT season is as eventful a time for the colleges as for the graduates.

On the 10th inst. the St. Louis College of Physicians and Surgeons held its twelfth annual commencement exercises at Memorial Hall. Sixty-eight diplomas were awarded to representatives of thirteen different States of the Union and two foreign countries.

On the 12th inst. at the same hall were held the forty-ninth annual commencement exercises of the St. Louis Medical College and the twenty-fifth of the Missouri Dental College. The medical graduates, after a three years' graded course, numbered sixteen. There were twenty-seven dental graduates.

The thirty-second annual commencement of the Homœopathic Medical College of St. Louis was held the same evening (March 12th) at Pickwick Hall. There were fifteen graduates, of whom three were ladies.

Saturday evening, March 14th, the Marion Sims College of Medicine held its first annual commencement exercises at Memorial Hall, graduating a class of thirty-one members. Over one hundred and fifty students have matriculated at that school during the last year, the largest number, it is claimed, ever enrolled at any medical college during the first year of its existence.

Tuesday, March 17th, the examinations will be held of applicants for positions as assistant physicians in the City and Female Hospitals; three positions are to be filled at the latter and eight at the former institution. These examinations are held at the offices of the Health Department in the City Building, under the direction of the medical members of the Board of Health, and are written examinations.

Quite a sensation has been caused by the outbreak of a smallpox epidemic in our city hospital within the last few days.

A man named Campbell was sent to the hospital with what was supposed to be malarial fever, and had been there three or four days before his ailment was recognized as smallpox. By that time others in the ward had become infected, and in all there have now been taken to the Quarantine Hospital from the City Hospital ten cases, together with a half-dozen others from outside. The first case has terminated fatally. The physicians and officers of the Health Department are putting forth every effort to trace out the associations of the cases which have been brought in from outside, with a view of preventing further extension of the disease if possible.

An interesting case against an accident insurance company is now before the United States Circuit Court here, involving some elements of special interest to the medical profession.

In November, 1888, Dr. George Bernays, of this city, cut his finger while performing a surgical operation. Erysipelas set in, and he died within thirty days. Mrs. Bernays demanded of the United States Mutual Accident Association the sum for which the doctor was insured, claiming that his death was the result of accident.

The company admit the cutting, but deny that he was seized with erysipelas then, claiming that he had had the disease nearly all his life. They claim further that as "there was no visible mark on his hand at the time of his death" there is no liability upon them to pay the insurance by reason of a stipulation in the contract or policy.

The rulings of the court and the final decree in this case will be of interest to physicians throughout the country, and will have a material effect upon the readiness of physicians to take accident insurance policies.

COLORADO FOR CONSUMPTIVES.

To the Editor of The Medical News,

Sir: The question, Where should a consumptive go? was asked me by one of my patients some four months since, and his rapid emaciation—averaging one and a half pounds' loss every week for six months—warned me that an immediate answer was of pressing importance. I had heard and read a little of the favorable influences exerted on this class of patients by the sunny and dry climate of Colorado Springs. I received the impression that probably there was no more favorable spot for the consumptive known within the boundaries of this country; but before deciding a question of such importance, I asked the advice of Professor William Pepper, who replied that he considered the removal of the patient to Colorado Springs the best thing that could be done. Preparations for the journey were hastily made, and within ten days we left Oxford, Pa., for Colorado Springs.

After four months' residence at this place, the emaciation has been arrested, and for a month past there has been an increase in weight, and an improvement in the lung disease, thus cheering the patient and giving him promise of final recovery.

The tendency of this case was rapidly downward, and there seemed no reasonable hope for a favorable change in the climate of the East. It is scarcely worth while for me to fill your pages with an account of the beneficial influences of the climate shown in this case. It is simply a repetition of what has occurred in many hundreds of cases during the past twenty years. There is scarcely a family living at Colorado Springs that has not in it a similar example of a life saved and restored to health by the invigorating atmosphere of this place.

I am sure no one can yet say positively to what the cure of so many cases of consumption is due. We see healthful climate, soil, and surroundings combined here as they are nowhere else. First, the town is situated on a plateau, the elevation of which is six thousand feet, protected on the north by bluffs and the Great Divide, and on the west and southwest by the Rocky Mountains, which average ten thousand feet or more in height, and on the south and east there is an unbroken expanse of plains for many hundreds of miles. The high elevation of the place and the consequent rarefaction of the atmosphere is undoubtedly beneficial to consumptives by causing habitual deep inspirations, in order that the blood shall be sufficiently oxygenated. The surroundings protect the city from severe northwest winds, and insure a purity of atmosphere which is not excelled. The cool nights of summer give refreshing sleep and rest, and the unclouded skies and bright sunshine of every winter day permit daily outdoor exercise throughout the winter. Even when the patients are too weak to leave the house the windows can be opened on many days, and thus they are benefited by the sunshine and fresh air.

Colorado Springs has under it a stratum of gravel between fifty and seventy feet in depth, in consequence of which mud is unknown, and the drives and walks are as dry and smooth as if made of concrete. While showers are not uncommon in May, June, and July, the sun is seldom clouded for more than an hour or two at a time and dews are almost unknown.

Colorado Springs is strictly a health resort, and the authorities have always wisely kept this in view, and have endeavored, in every possible manner, to add to the reputation and value of the city as a place for the sick. The streets are one hundred feet and the avenues one hundred and forty feet wide.

The water supply, of the purity of which there can be no question, comes from streams fed by melting snow from the mountain peaks and is sufficient for a city ten times the size of Colorado Springs. The sewerage system of the city is complete.

Compared with other Colorado cities, such as Denver, Pueblo, and Trinidad, this city must always be in the lead as a health resort, as it can never be a manufacturing place of much importance.

The mining and manufacturing industries have made Denver a great city, and will also place Trinidad and Pueblo in a few years among the great mining and manufacturing cities of the United States. For these reasons Denver, Pueblo, and Trinidad are objectionable as health resorts. The winds are higher and the winters colder in Denver, and the summer nights are not so cool as they are in Colorado Springs. The ground also becomes muddy after rains.

Pueblo and Trinidad are very hot and dusty in summer, and there is considerable mud after rains. Among the cities named, Colorado Springs is the only one that can claim to have an abundant and safe supply of drinking-water.

It is an admirable place for homes. Colorado Academy and Colorado College, both of which occupy a high place among the academies and colleges of this country, are situated here. A splendid system of graded schools is maintained, and the public school buildings are magnificent. Almost every religious denomination is represented, and each has a handsome church.

Among the public buildings are two large sanitariums and the State institution for the education of the deaf and dumb. The managers of the Printers' Home have secured eighty acres of land near the city on which their buildings will soon be erected. New electric street-cars now run at intervals of from ten to forty minutes to Manitou, Cheyenne, Canons, Broadmoor, Roswell, and Austin Bluffs. The street railway will soon be extended to all other near places of interest.

Six railroads enter the city and more are to be built. The population is about twelve thousand, and it is said that no other city of this size contains a more intelligent and moral class of people. The sale of liquors as a beverage, within the city limits, is prohibited.

As a place for business: I would like to caution those contemplating coming here and expecting to find employment. Many are sadly disappointed. Small resources are soon exhausted, and funds must be provided by the kind people of the place for the return of many unfortunates to their friends. Others are able to secure some kind of employment by which they can live, and some are so fortunate as to get into a profitable business and become wealthy.

A severe struggle to keep the wolf from the door is not conducive to restoration of health, and invalids should carefully consider this question before coming. For the poor, however, who are able and willing to accept any kind of honorable employment, and are

plucky and not easily discouraged, there is health and work here yet for many thousands.

Medical Ophthalmoscopy.—Dr. George E. de Schweinitz has been appointed Lecturer on Medical Ophthalmoscopy in the University of Pennsylvania, in order that thorough instruction in the use of this important aid to diagnosis may be given to the students. In addition to his regular lectures, the class will be divided in such a way as to permit of individual teaching. The appointment is particularly appropriate, since Dr. de Schweinitz has for a number of years been greatly interested in this subject.

Meeting of the National Association of Railway Surgeons.—At the Kansas City meeting of the National Association of Railway Surgeons last year, it was decided to hold the next meeting at Buffalo, May 7th, 8th, and 9th of this year. But, on account of the meeting of the American Medical Association being set for the same time, it has been decided to change those dates, and to hold our next meeting at Buffalo, April 30th and May 1st and 2d, to which all railway surgeons are cordially invited. To all railway surgeons sending their names and addresses to the Corresponding Secretary, a copy of the constitution and programme will be sent. All those wishing to read papers should send in the titles of their papers without delay. For further information inquire of

A. G. GUMAER, M.D.,
Corresponding Secretary.

BUFFALO, N. Y.

Obituary.—DR. CHARLES T. PARKES, Professor of Surgery in the Rush Medical College of Chicago, and for many years one of the most prominent surgeons in the State of Illinois, died on March 28th, of pneumonia and pleurisy, after a very short illness. The beginning of his illness was an attack of influenza, which was ignored until it forced him to take to his bed.

Dr. Parkes was graduated from the University of Michigan in 1862, and was actively engaged in recruiting troops for some years. After this he took a degree in medicine from the Rush Medical College in 1867. In addition to having gained prominence as a medical teacher, he carried out a series of valuable experiments upon gunshot wounds of the abdomen. The scope of his clinical work was very wide, and a number of reports of his clinics have appeared in THE MEDICAL NEWS within the last two years.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 24 TO MARCH 30, 1891.

HOFF, J. VAN R., *Captain and Assistant Surgeon.*—The leave of absence for seven days, granted in Orders No. 61, *c. s.*, Fort Riley, Kansas, is extended twenty-three days.—Par. 3, *S. O. 36, Department of the Missouri*, March 27, 1891.

By direction of the Acting Secretary of War, CHARLES R. GREENLEAF, *Lieutenant-Colonel and Assistant Medical Purveyor*, will proceed to New York City on public business, thence to Boston, Mass., to represent the Army Medical Department at the American Association for Physical Education, and, upon the completion of the duties contemplated, will return to his station in this city.—Par. 3, *S. O. 67, A. G. O., Washington, D. C.*, March 25, 1891.

By direction of the Acting Secretary of War, EUGENE L. SWIFT, *First Lieutenant and Assistant Surgeon*, now on duty at Fort Thomas, Arizona Territory, will report by letter to the commanding officer Fort Grant, Arizona Territory, for duty at that station, or at Fort Thomas, Arizona Territory, as the commanding officer may direct.—Par. 7, *S. O. 66, A. G. O., Washington*, March 24, 1891.

By direction of the Acting Secretary of War, the retirement from active service this date, by operation of law, of HENRY JOHNSON, *Captain and Medical Storekeeper*, under the provisions of the Act of Congress approved June 30, 1882, is announced.—Par. 5, *S. O. 66, Headquarters of the Army, A. G. O., Washington*, March 24, 1891.

By direction of the Acting Secretary of War, the leave of absence granted ROBERT J. GIBSON, *Captain and Assistant Surgeon*, in Special Orders No. 232, A. G. O., October 3, 1890, from this office, is extended one month.—Par. 10, *S. O. 65, A. G. O., Washington*, March 23, 1891.

By direction of the Acting Secretary of War, JOHN H. BARTHOLF, *Major and Surgeon*, now on duty at Plattsburgh Barracks, New York, will proceed to Fort Wayne, Michigan, and report in person to the commanding officer of that post for temporary duty.—Par. 7, *S. O. 64, A. G. O., Washington, D. C.*, March 21, 1891.

TILTON, HENRY R., *Major and Surgeon.*—Is hereby granted leave of absence for one month, on surgeon's certificate of disability.—Par. 5, *S. O. 56, Headquarters Division of the Atlantic*, March 21, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 28, 1891.

AMES, HOWARD E., *Passed Assistant Surgeon.*—Promoted to Surgeon, March 19, 1891.

WHITE, STEPHEN S., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Baltimore."

PICKERELL, GEORGE MCC., *Assistant Surgeon.*—Promoted to Passed Assistant Surgeon, March 25, 1891.

MARTIN, WILLIAM, *Surgeon.*—Ordered to Naval Rendezvous, San Francisco, Cal.

WHITE, C. H., *Medical Inspector.*—Appointed Fleet Surgeon Pacific Station.

HARRIS, H. N. T., *Assistant Surgeon.*—Ordered to the U. S. Receiving-ship "St. Louis."

PICKERELL, GEORGE MCC., *Passed Assistant Surgeon.*—Ordered to Naval Hospital, New York.

RUSH, C. W., *Passed Assistant Surgeon.*—Ordered for duty with the Inter-Continental Railway Commission.

OGDEN, F. N., *Passed Assistant Surgeon.*—Ordered for duty with the Inter-Continental Railway Commission.

NORTH, JAMES H., JR., *Assistant Surgeon.*—Ordered to the Navy Yard, New York.

ON THE TREATMENT OF CHRONIC SUPPURATION OF THE MIDDLE-EAR.[1]

BY H. GRADLE, M.D.,
OF CHICAGO.

IN view of the frequency and danger of chronic suppuration of the middle ear, every practitioner ought to be familiar with its treatment. According to the experience of specialists, such, however, is not the case.

While every modern text-book on the ear gives the information of the method of treating this disease, to him who seeks it, still all the books do not lay down the general surgical principles underlying the treatment in a sufficiently impressive manner. On this account a discussion of the principles upon which the treatment should be based does not seem to me a useless repetition.

Suppuration of the middle ear is the result of infection. This statement, suggested by our knowledge of suppuration in general, is based on the special investigation of the secretion of the diseased middle ear by numerous observers.[2] These authorities all agree that in acute inflammation of the middle ear the most frequent microörganism is the diplococcus known as the cause of croupous pneumonia, either alone or in conjunction with other pus-producing microbes. In other instances one or the other or several of the varieties of micrococci which cause the more common forms of suppuration were found, with or without the proteus bacillus, and occasionally also the bacillus of blue pus. All these forms are known to possess pyogenic properties. Of the diplococcus of pneumonia it has been shown by Zaufal that when introduced into the middle ear of animals it can cause suppurative otitis.

In chronic suppuration of the middle ear (Kauthak) the diplococcus is no longer present. Indeed, we know that it can only lead a short life in the animal body. Its place has been taken by one or several of the other pyogenic microörganisms. Chronic suppuration of the middle ear is therefore very often a secondary infection, and quite commonly a mixed infection. Rohrer[1] claims that when the discharge is not fœtid in odor, only micrococci are present, while offensive odor indicates the work done by putrefactive bacilli.

The elimination of the pus producing microörganisms from the tissues is interfered with by stagnation of irritant pus. In general surgery it is a rule that suppuration ceases spontaneously when the pus can escape freely, at least where there is no complication with tuberculosis and where no mechanical disturbances interfering with the rest or nutrition of the parts exist. The irritation of foreign bodies prevents the onset of suppuration only in as far as it forms a lodging-place for germs. All this applies equally as well to the middle ear. We have here an irregularly-shaped cavity with various recesses. Among the latter the most important one is the attic of the tympanum separated from the main cavity by the ligaments of the ossicles or by adventitious membranes.

In all these nooks and corners pus can stagnate. As long as such retention is not prevented, the lining membrane cannot rid itself of the micrococci which have invaded it.

In practice we find that only a small proportion of the cases of acute suppuration of the middle ear heal spontaneously. The natural cure is most likely to occur in early childhood, and in those patients where the nasal or pharyngeal disorder which led to the ear disease was only transient. On the other hand, the more advanced the patient in age, the more permanent any co-existing naso-pharyngeal disease, and the more severe the infection, like scarlet fever, during the course of which the ear trouble occurred, the less favorable are the chances of a spontaneous cessation.

In order to aid the tissues in their elimination of the pus micrococci, it is necessary, *first*, to remove all stagnating pus; *second*, to render the pus which continues to form unirritating, and *third*, to correct any condition that either keeps up the infection or interferes with the nutrition of the ear.

Pus cannot be removed from the meatus in any more efficient way than by a syringe. Wiping with cotton, the dry method in vogue some years ago, is painful unless very skilfully done, and cannot clean out corners as does a stream of water. The syringe should have a thin nozzle which can be deeply

[1] Read before the Chicago Medical Society, January 19, 1891.

[1] Morphologie d. Bakterien d. Ohres, etc., Zürich, 1889.

inserted into the meatus, and no force should be used in syringing. Rubber-bulb syringes or the tube of an irrigator can be more easily steadied than a piston syringe. Many of the so-called ear syringes, especially those with an olive-shaped nozzle, are useless. Unless unavoidable, syringing should never be intrusted to the patient. With a fairly large opening, especially in the lower part of the drumhead, it is generally not necessary to syringe out the drum cavity itself by introducing within it any canula. Under such circumstances a forcible current of air sent through the Eustachian tube with a Politzer bag and proper syringing of the meatus are usually sufficient to remove all retained pus. Whether this has been thoroughly accomplished can be most easily told in those cases in which the discharge is offensive in odor. If by the time of the second treatment the discharge has lost its odor our purpose has been attained. It can be set down as an absolute rule that no otorrhœa ever heals so long as the pus retains any odor of decomposition. On the other hand I have never met with a case of chronic suppuration of the middle ear with inodorous discharge which could not be controlled by persistent treatment, accompanied, when required, by attention to the nose or pharynx. When there is no odor present the only criterion of the efficacy of the treatment is the diminution of the discharge.

When the opening in the drumhead is so small or so high up that a current of water thrown into the meatus cannot remove all the retained pus, we can cleanse the middle ear either by irrigation through the Eustachian tube or by means of a canula inserted through the perforated membrane. It is no more unpleasant to the patient to force a warm saline solution than air through the Eustachian catheter, but it is more difficult. Beside, it cannot be done in every instance. Where there is suppuration of both ears it is easier to irrigate at once through both tubes by means of the nasal douche employed as in the Politzer method of inflation. Occasionally tubal irrigation shows its efficacy by washing out inspissated pus which previous syringing through the meatus had not been able to remove.

Often, however, we can reach pus accumulations more thoroughly by means of a fine tube inserted through the perforated membrane. Indeed, when the opening is in Schrapnell's membrane this is the only efficient method. For in suppuration of the attic of the tympanum this space is commonly separated from the cavity of the tympanum by adhesions and false membranes, and cannot be reached through the Eustachian tube. The silver tubes fitting hypodermic syringes are quite suitable for this purpose, the point being slightly curved in order that it may reach in all directions. Sometimes it becomes necessary to enlarge the opening in the drumhead. The canula can be used with greater steadiness and efficacy, if attached, by means of a flexible hose, to a syringe which the surgeon does not himself manipulate. Of course, it is necessary to use the speculum and illumination with such a canula. If, by any or all of these means, the discharge cannot be freed of its odor, there exists either caries with inaccessible clefts, where pus is retained, or the suppuration has involved the mastoid cells.

With thorough cleansing alone many cases of chronic suppuration of the middle ear will heal, though not all. We can, however, decidedly hasten the cure by the judicious use of antiseptics. The pus which continues to form after syringing is still irritant, and it is by checking further decomposition of this fresh pus, until the next time of treatment, that we deprive it, to some extent, of its noxious properties.

The use of antiseptic solutions instead of pure water for syringing is of doubtful advantage, for we cannot remove retained pus any better with the former than with the latter. The continuance of suppuration is due to the presence of microbes in the tissues themselves, where antiseptic syringing cannot reach them.

Where the discharge, however, is very offensive, it is more agreeable to the surgeon to employ a deodorizer like the permanganate of potassium.

In order to accomplish anything by means of antiseptics they must be left in the ear in excess in order to render the fresh pus bland. Aqueous or glycerin solutions are either inert for this purpose if weak, or unnecessarily irritating if concentrated. Peroxide of hydrogen is frequently used by some surgeons, but actual trial has convinced me that it is not superior to thorough irrigation. It aids only by decomposing with effervescence, and thus reaching mechanically further than careless syringing. The best means of preventing decomposition of fresh pus is by the use of an antiseptic in the form of a bland, dry powder, especially the one first introduced by Bezold, viz.: boric acid. Comparative trial has shown me that this can be rendered even more efficient by adding thereto *one-sixth of its weight of salicylic acid.* The addition of more than one-sixth its weight is too irritating. Although boric acid is scarcely a germicide, it checks decomposition when present in sufficient quantity. Salicylic acid possesses this property even to a greater extent, but when used alone it is too irritating. I have experimented somewhat with subnitrate of bismuth triturated with one-half per cent. of corrosive sublimate. This is perhaps equal to boracic acid, but not superior, except in those rare instances in which the insufflation of boric acid

is followed by a watery discharge lasting a few hours. Iodoform powder is absolutely useless for the present purpose, but may be employed to protect denuded surfaces in caries or after operations in the ear.

I have seen no reason to experiment to any extent with other substances in the treatment of chronic suppuration of the middle ear. For when we can remove all retained pus thoroughly and there are no complicating conditions, we can obtain a cure by the use of boric and salicylic acids as rapidly as we can expect it in view of the existing morbid conditions. It is not rare to find the discharge practically checked by a single treatment. Whenever a discharge free from odor is not at once influenced by the treatment, we must look for complicating conditions. Lately there has been considerable protest from the school of Schwartze, especially by Staake,[1] against the use of insufflations of boric acid. It is claimed that the powder, by blocking small perforations, may lead to retention of pus and even fatal consequences. Undoubtedly there is some ground for caution. When the opening is small we should assure ourselves, by looking through the speculum, that it is not obstructed by the powder. The meatus should never be packed, and it is generally not advisable to give the powder to patients for personal use. However, in an experience of 7000 cases, I have never seen any untoward results from insufflation.

As the result of a fairly large experience, I have come to the following conclusions as to the best management of those complicating conditions which interfere with the cure of suppuration of the middle ear. Polypi do not in all cases require surgical removal, although this, when thoroughly done, is usually the speediest way of dealing with them. If they are not so located as to dam-up the pus, and are not coexistent with caries, they will sometimes disappear by shrinkage as the otorrhœa improves under routine treatment. More often, however, this is not the case. It has seemed to me that polypi, unless very large in size, are of importance principally as an indication of caries, rather than as mere pathological entities.

If a carious spot is detected in the wall of the meatus or in the middle ear, all granulation-tissue should be curetted away, and any loose spicula of bone removed with the forceps. If this procedure proves inefficient, the dissolution of the dead bone by means of hydrochloric acid, according to the suggestion of O. Bull,[2] may prove of service. He inserts pledgets of cotton saturated with a four per cent. solution of the acid, and leaves them in contact for twenty-four hours. This is to be repeated until the sequestrum can be detached.

[1] Deutsche med. Wochenschrift, No. 50, 1887.

[2] Archives of Otology, 1889, p. 123.

I have not had occasion, since the publication of Dr. Bull's paper, to remove any large spicula of bone, but for small carious spots which had interfered with the success of the ordinary treatment, I have employed the instillation of muriatic acid (5 per cent. of the acid, chemically pure, in water) with satisfactory results. I have left the fluid in the ear fifteen to thirty minutes according to the tolerance of the patient, repeating the application on successive days until I found the discharge diminished. Caries may be present, however, in such a position that the dead bone is inaccessible to the probe. An otorrhœa which persists under the usual form of treatment, and is not kept up by nasal or pharyngeal disease, always arouses a suspicion of caries. In such cases the use of hydrochloric acid will assure the probable diagnosis by means of its curative influence. Whether caries of the ossicles can be treated successfully in this manner I am not prepared to state, since I do not know how to recognize this condition, except by examination of the removed ossicles. When the carious ossicles are inaccessible, by reason of adhesions around them, as in suppuration of the attic with small perforation in Schrapnell's membrane, a cure of the otorrhœa can only be expected from surgical interference, which should not be attempted by any save an expert.

Finally, I wish to emphasize the fact that there are instances of suppuration of the middle ear which either do not heal at all, or else relapse very soon on account of naso-pharyngeal anomalies. There is either an obstructing lesion in the form of enlargement of the pharyngeal tonsil or thickening of the septum, or else a persistent suppurative rhinitis. Whether there is in these cases a constant reinfection of the Eustachian tube, or whether an injurious influence is exerted upon the nutrition of the middle ear, has not yet been determined. In these cases the successful treatment of the otorrhœa will depend upon cure of the nasal or pharyngeal disease.

PROPOSITIONS SUGGESTED BY THE FAILURE OF MERCURY AND POTASSIUM IODIDE TO CURE A CASE OF NERVE-SYPHILIS SUBSEQUENTLY CURED BY MERCURY ALONE.

Report of the Case.[1]

By D. D. STEWART, M.D.,

LECTURER AND DEMONSTRATOR OF DISEASES OF THE NERVOUS SYSTEM AT THE JEFFERSON MEDICAL COLLEGE.

I FEEL constrained to offer an apology for giving a single case the dignity of a special report. Although it has seemed to me one of distinct interest, I have refrained from publishing it until now, trusting

[1] Read before the Philadelphia Medical Coterie, February 24, 1891.

that. I might meet in current literature, if not in practice, a second case, or more, similar, and might thus be permitted to draw definite conclusions, where I can now only suggest indications, upon an obscure, though important, therapeutic point.

The features of interest presented by the case are these:

A man without discoverable preceding history of lues presented symptoms of disease of the nervous system suggesting a syphilitic origin. As far as could be ascertained by searching inquiry he had not been suspected of having had syphilis until he came under my observation, and had never received anti-luetic treatment of any kind. He was placed on full doses of potassium iodide in combination with the mercuric chloride for some time, absolutely without benefit. He was afterward rapidly cured by mercury alone. The following is the history:

H. M. B., male, aged forty three years, dentist. First seen November 15, 1888. For the past nine years has had occasional attacks of migraine, chiefly affecting the right side, with accompanying gastric disturbances; apart from this he has always been in fair health until the trouble for which he sought advice began.

About November, 1887, he first noticed that his gait was becoming a trifle clumsy, and that the legs had a tendency to stiffness and heaviness. This gradually increased until it became quite perceptible to others about April, 1888. His gait then began to be decidedly spastic; the legs were stiff, and easily wearied by walking short distances. On May 2, 1888, right-sided headache appeared, and soon became intense and continuous, with daily remissions and very decided nocturnal exacerbations. The ache, from the first, grew very severe on the approach of night, and continued so unbearably so that it absolutely prevented sleep. He stated that he had spent, for several months, most of his nights walking as best he could about the floor of his bed-chamber until sheer fatigue, or a very free use of anodynes, induced sleep. On examination the head pain was found to be strictly limited to the right side, and greatest in the temporal, inferior, and superior anterior parietal regions. The skin in these situations was hyperæsthetic. Deep, continuous pressure seemed to relieve the pain, while sharp percussion over the temporal region much aggravated it momentarily. There was also aching in the nucha, and muscular soreness relieved by pressure. With the onset of headache there had also appeared slight right-sided deafness, and soon after tinnitus.

His speech was a trifle thick, and there was decided tremor in the tongue, without noticeable paresis. The tongue presented ulcerations closely resembling mucous tubercles. His lower limbs exhibited the symptoms of spastic paraplegia. He walked with difficulty by the aid of two sticks; the legs were stiff and the soles of the feet dragged the floor as he progressed. The deep reflexes were exaggerated. The limbs had a tendency to jerk spasmodically at night, and the muscles to cramp. Spasticity and loss of power were greater on the right. Dorsal flexion of the toes and foot on both sides was incomplete. Coördination was unimpaired. He walked as well by night as by day, and with eyes closed as when open. Muscular sense was also carefully tested in other ways, and found unaffected. Tactile, pain, and temperature sense were tested a number of times in the extremities and trunk, and always found normal. There had never been any pains in the limbs, and no tenderness could be elicited by pressure on the nerve-trunks. No electrical examination was made, as at that time I had no portable batteries, and he was unable to come to my office. The pupils responded normally to light and accommodation. There were no ocular paralyses; eye-ground was found normal. The bowels were constipated. He had lost considerable flesh since the illness began.

I made a diagnosis of local cortical meningitis; spastic paraplegia, due to specific disease of the lateral columns; perhaps beginning bulbar paralysis. I looked upon the case as one of probable nerve-syphilis, but though the patient was seemingly very anxious to assist me in discovering the cause of his ailment, he absolutely denied any knowledge of specific infection, though I repeatedly questioned him. On stripping him during my first visit I found about the trunk a number of variable-sized, somewhat coppery-looking, cicatrices, that suggested the remains of a luetic eruption, the history of which, however, he informed me apparently in good faith, he could not recall.

He had been under the care of some seven or eight physicians since the head trouble began. Headache being by far the most trying symptom, he had preferred to be treated rather for it than for the paraplegia, trusting to obtain relief from the latter afterward. As he had had all prescriptions filled by the same druggist, I was readily able to obtain copies of them. Syphilis had evidently not been suspected. The treatment had been quinine alone, and in combination with morphia, bromides, bromides and morphia, gentian and sodium bicarbonate, and occasionally calomel and jalap to act on the bowel. Mercury (except as a purge) or the iodides had not been prescribed, and he assured me that at no time in his life had he been treated for syphilis. I placed him upon twenty-grain doses of potassium iodide in combination with one-twentieth of a grain of mercuric chloride three times daily, and at night at first full doses of potassium bromide alone, and later in combination with cannabis indica. In a few days the dose of potassium iodide was increased at first to thirty, then to fifty grains, and the mercuric chloride to one-fourteenth of a grain. There was absolutely no improvement on this treatment at the expiration of a month.

Bromides in very large doses had not influenced the distressing headache and insomnia. Hyoscine and morphia were also used ineffectually. It then occurred to me that as the patient in the past had, in all probability, never been subjected to a mercu-

rial course, it might be well to administer mercury alone, as it was not unlikely that the full doses of potassium iodide ingested were eliminating the mercuric iodide before it could exert any effect. I therefore placed him on one-third of a grain of the mercurous iodide in pill form, combined with a little opium and belladonna, four times daily, discontinuing the potassium iodide. The effect was quite astonishing. In three days there was noticeable improvement. Nocturnal headache, insomnia, and restlessness had distinctly lessened. From this time improvement was decided and continuous, and so rapid as to surprise me. In three weeks the headache had entirely disappeared. His tongue grew clean and normal in appearance. He became able to walk about without a cane, the spastic and paralytic condition having diminished materially. Two weeks later he was able to return to his vocation; he was eating and sleeping well, and had gained considerable flesh. He now drifted out of my hands, though he still continued the mercury. I hear from him occasionally. The amelioration in the spastic condition continued to a certain point and then ceased, as might be expected, anti-specific treatment having no power to replace lost tissue or to remove the secondary ordinary lesions. His gait is still noticeably paralytic, especially in the right leg, though he can readily get about without a cane.

So far as I know, the advisability of the conjoint administration of mercury and potassium iodide in lues has never been questioned. The majority of practitioners are, I believe, in the habit of so treating the late lesions of syphilis. And yet we know that the iodides of potassium and sodium, especially the former, are very active eliminants of mercury as of other metals. It is by some considered almost criminal to neglect to follow a prolonged mercurial course by potassium iodide to prevent the retention of the mercury in the system.

In this case I cannot but think that had mercuric iodide been administered alone, in the same doses in which it was prescribed in conjunction with the potassium iodide, an effect analogous to that produced by the mercurous iodide would have been obtained.[1] It may, therefore, I think, be justly inferred that the inefficiency of the combination was due to the fact that mercury, and not potassium iodide, was indicated in this case; why, it is difficult to explain. Althaus[2] states that he has found that mercury acts as a true specific in all primary luetic nerve lesions just as it does in all the earlier manifestations of the secondary period, and that it is infinitely superior to any other drug. He relates a case where epileptiform seizures were present, with intense headache, vertigo, insomnia, tinnitus, paralysis of the left leg, and specific ulceration of the tongue, in which, after a thorough trial of large doses of iodide of potassium, without benefit, recovery resulted from the use of mercury. He, therefore, regards potassium iodide secondary in usefulness to mercury. This opinion, however, is not general.

Gowers,[1] in reply to the question, whether there are late syphilitic lesions on which iodide has no influence and which yield to mercury, states that he has never met a case of intracranial syphilis in which there was reason to believe mercury was successful while the iodide failed. He, however, relates a case of luetic peri-adenitis of the neck, compressing the brachial plexus, and causing paralysis of the arm, in which full doses of potassium iodide, administered for a period of six weeks, exerted no effect, and which was subsequently removed by mercury. It has occurred to me that in those cases in which mercury, and not potassium iodide, is distinctly useful, a mercurial course in the past has never been instituted. It is well known that in many cases of nerve-syphilis, primary and secondary luetic symptoms have been so slight as to pass unnoticed by the patient, while the nervous symptoms are the first that distinctly appear. In these, of course, there has been no specific treatment. May it not be that in these cases the syphilitic virus still retains the contagious and transmissible qualities of its earlier stages, and is only capable of being brought into subjection by mercury.

In conclusion, a consideration of the foregoing suggests the following propositions:

1. Does not the fact that the success of mercury administered alone, immediately after the failure of full doses of a mercurial administered in combination with large doses of potassium iodide, indicate that potassium iodide probably eliminated the mercury too rapidly to exert any effect, and, therefore, that it is better not to give these drugs at the same time? or, if they are coincidently administered, should not the mercury be given in a somewhat larger dose than when it is prescribed alone?

2. That, in a case of disease of the nervous system the cause of which is suspected to be syphilis, though no history of specific infection is obtainable, it is unwise to exclude lues because no result accrues from a thorough course of potassium iodide.

3. In such a case, in all probability, no mercurial treatment, or, at least, no thorough course, has ever been tried. Will this fact, granting it, account for the failure of potassium iodide, and the subsequent success of a mercurial administered alone.

[1] When mercuric chloride and potassium iodide are combined mercuric iodide results.

THE PEROXIDE OF HYDROGEN—ITS USES IN ABDOMINAL SURGERY.

By CHARLES P. NOBLE, M.D.,
SURGEON-IN-CHARGE OF THE KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

The importance of the peroxide of hydrogen as a germicide, and more especially as a pus-destroying agent, is becoming firmly established by rapidly accumulating clinical evidence. A very considerable experience with the drug has made me enthusiastic concerning its remarkable qualities; and I find myself extending its application almost daily. In general, in order that antiseptic or germicidal agents may be used effectively, it is absolutely essential that all foreign material, discharges, etc., be first removed, so that the agent may be brought in direct contact with the surface or tissue to be acted upon. It is also true that the power of penetration of the antiseptics in common use is slight, so that they are reliable only in combating strictly superficial septic processes. This is particularly true of corrosive sublimate solution, which, by its action on albuminous discharges, forms an inpenetrable covering which prevents the solution from coming in contact with the tissues to be acted upon. In this respect the action of the peroxide solution is essentially different. It attacks, disintegrates and oxidizes all discharges and dead tissue with which it comes in contact, thus favoring its contact with and action upon underlying tissues. Moreover, the products of its activity escape as water and carbonic acid gas. At this time I do not propose to discuss the relative value of the peroxide of hydrogen as a germicide. I believe that our knowledge upon that subject will be far more exact after a little time than it is at present. The fact, however, that this agent has the power to oxidize dead organic matter suggests to my mind a wide field of usefulness for it in preventing sapræmia or ptomaine poisoning, in the treatment of suppurating tracks and cavities in which dependent drainage cannot be had, and in which free irrigation with water is impracticable.

In my work in abdominal surgery I have found peroxide of hydrogen of positive value.

In cleaning the hands preparatory to operation I have found it very useful, especially when the skin about the finger-nails has become somewhat horny or roughened from too much use, or from frequent washings, or from prolonged contact with antiseptic solutions. Its power to loosen and to remove dead epithelial cells, and to soften the skin about the nails, is quite remarkable. Moreover, all foreign material about the nails is either oxidized and removed or is made more accessible to the sublimate solution which is used later. In practice I have used the peroxide after scrubbing my hands through three waters with soap and the nail-brush, then soaking them in turn in saturated solutions of permanganate of potassium and of oxalic acid, and before soaking them in corrosive sublimate solution.

Bacteriological examinations have shown that even this method (omitting the peroxide solution) does not make asepsis certain, as germs have been removed from the subunguial spaces after it has been faithfully carried out. I have not been able to test the value of the addition of the peroxide of hydrogen solution in securing asepsis by bacteriological experiments, but practically I feel convinced that it is of service in securing that end. The settlement of the question authoritatively will be of great interest to all those who believe in satisfying an antiseptic conscience.

In the management of the drainage-tube after abdominal section, under special conditions, the peroxide solution has been of signal service. In typical cases, in which the drainage-tube is removed after from one to three days, there is no indication for its use. But when from any cause the drainage-tube must remain in longer, it is useful in keeping the tube and drainage track sweet and free from pus. On a number of occasions after a tube had been in place from a week to ten days, and the discharge had become slightly purulent, I have been able to combat successfully the tendency to suppuration, to shorten the tube gradually, finally to substitute a gauze plug for the glass tube, and to secure rapid healing of the drainage track; when otherwise a sinus would have resulted. One such case was one of a ruptured large ovarian tumor, having contents of a jelly-like consistency, which had become distributed throughout the peritoneal cavity. Jelly-like material was discharged through the tube for two weeks, and yet by the use of the peroxide solution rapid healing was obtained. Another case was one of post-operative intra-peritoneal hæmorrhage. Tarry blood was discharged through the tube for ten days, yet the same care secured the same result. Another striking case was one of fæcal fistula which formed after the removal of a dermoid ovarian cyst—presumably caused by the growth of a small bunch of hair from the cyst into the bowel. The track was kept clean and the peroxide was used freely. The fæcal fistula closed in three weeks, and the remaining sinus closed within two months from the date of operation, being kept open for a time by an infected omental ligature, and closing promptly after its discharge.

The peroxide solution has been applied to the drainage track and to the inside of the tube by saturating absorbent cotton, held in a slender long-handled forceps, and passing this down the tube. The peroxide solution has been used pure or diluted (one to two or three).

I have not used the peroxide solution within the

peritoneal cavity during operation, but believe it will prove useful in disinfecting infected pedicles. In removing pus sacs rupture frequently occurs, deluging the broad ligaments with pus. Under these circumstances the ligature applied to secure the pedicle necessarily becomes infected. Heretofore I have washed away septic material with boiled water, and later applied bichloride solution on a sponge to the region of the ligature. In such cases it seems probable that the peroxide solution will be of real value.

In cleaning the abdominal wound preparatory to removing the sutures, the peroxide solution has proven very efficient; especially if a dry dressing—boric acid or iodoform—has been used. Finally, if any pus has formed in the track of the drainage tube or of any of the sutures, the peroxide solution will remove it more efficiently than any other agent.

TWO CASES OF TRAUMATIC HYSTERIA.[1]

By HENRY HUN, M.D.,
PROFESSOR OF DISEASES OF THE CHEST AND NERVOUS SYSTEM IN THE ALBANY MEDICAL COLLEGE.

The study of injuries resulting from accidents is of peculiar interest, inasmuch as in them other important questions besides that of treatment are presented. Accidents are usually the result of negligence, and injuries caused by such accidents usually involve suits for damages, in which the physician or surgeon must state in court how seriously the patient is crippled by the accident, for enjoyment and usefulness in the world. This, in the present condition of expert evidence in this country, is an extremely unsatisfactory process. In the case of injuries to the bones and muscles this question concerns the surgeon alone, and can generally be definitely answered. When any portion of the nervous system is injured the answer is more difficult, and concerns not only the surgeon, but also the physician, and especially the neurologist. When the injury occasions, as it sometimes does, an organic disease of the nervous system, such as a cerebral tumor, a myelitis, or a neuritis, the diagnosis and prognosis of the case is not difficult, except that these diseases are often of very slow development and it may take months or years before the tumor attains sufficient size or the myelitis sufficient extent to give rise to definite and diagnostic symptoms. Therefore, in many of these cases the full extent of the injury done to the nervous system is not manifested until long after the question of damages has been settled. But besides these organic diseases it has been recognized for a long time, and is now being recognized more and more clearly, that not infrequently there result from accidents functional diseases of the nervous system which are very obscure, both in their symptoms and their pathology, and which depend in their etiology probably quite as much on the fright as on the physical injury.

These cases of functional nervous diseases are not apt to occur associated with severe injury of the bone and muscle. Probably because the long stay in bed which these latter injuries require and the concentration of the patient's attention upon these forms of injury are very favorable factors in the treatment of the functional neuroses and probably prevent their occurrence; although these neuroses do sometimes occur associated with severe injuries of the bone and muscle. Many of these cases of traumatic functional nervous diseases were described by Erichson under the name of spinal concussion, or railway spine, and were considered by him, as the name implies, to be due to a concussion of the spinal cord. But the more the symptoms of these cases were studied, the more difficult it became to regard them as due to any diseases of the spinal cord, and it became more and more clear that the symptoms were of cerebral origin, and the term spinal concussion, or railway spine, was replaced in turn by the terms railway brain, traumatic hysteria, traumatic neurasthenia, and traumatic neuroses. As these diseases are of a functional nature, their symptoms are such as can be simulated voluntarily or involuntarily; and as the temptation to voluntary simulation is great, on account of the damages claimed, the question of deception is to be considered a most important one. These cases have been the subject of many discussions in various neurological associations during the past few years, but on account of their wide interest I need no apology, I think, in calling the attention of this Society to two cases belonging to this class which present many of the points of interest common to all such cases:

Case I.—An unmarried dressmaker, aged nineteen years, was sitting in the last car of a railway train standing before the station and saw another train on the same track approaching rapidly from behind. Every one in the car shouted, "Jump for your lives!" and ran to the forward door. She got through the door, and, as the platform of her car was crowded, she stepped on the platform of the forward car and was about to jump to the ground when the two trains collided and she was thrown upon the track. A young woman who had stood beside her on the platform was thrown off and instantly killed. She was carried into the station and did not think she was much hurt, but soon became unconscious. When she regained consciousness and was helped on board the train she found that the right leg was numb and paralyzed. When she

[1] Read before the New York State Medical Society, February 3, 1891.

arrived home she presented a few slight bruises and complained of a numbness and weakness of the right leg and of pain in the lumbar region, which, during the ensuing weeks, grew steadily worse, and was associated with severe pain in the occiput. About a month after the railway accident she had an attack of convulsions, and again ten days later she had another similar attack. After she had been lying about twenty-four hours in this second attack, I saw her for the first time in consultation with her attending physician, Dr. Melick, of Fort Edward. She was then in a typical hysterical convulsion, her head being strongly retracted. Her movements were very violent, but though she threw herself from one side of the bed to the other, she did not throw herself out of it, nor did she hurt herself against the wall. In her convulsive movements all parts of the body moved. There were exaggerated knee-jerk and traces of ankle-clonus present in both legs. The pupils were equal and reacted to light. She was constantly shouting and raving that she was in a lunatic asylum and begged not to be sent upstairs among the noisy ones, whom she heard shrieking. She also saw knives and blood on the walls of her room. The attending physician stated that she did not feel pin-pricks in her right leg, but did in her right arm. Before examining her I stated in her presence that it seemed to me that the arm must be anæsthetic as well as the leg, as hemianæsthesia was usually present in such cases. She responded well to my suggestion, and when I examined her I found that the right arm and leg were absolutely insensible to pin-pricks, and the right side of the face very nearly so. Ovaries somewhat tender, but deep and continued pressure on them did not arrest the attack. Great tenderness over the spinous processes of the lumbar vertebræ, not over the others. Toward the end of my visit, as I made a feint of leaving to return to Albany, she ceased her convulsions and raving and talked rationally enough, complaining only of pain in the head.

After my visit the patient remained in about the same condition, making very slow progress toward recovery. She continued to have convulsions at irregular intervals and complained of numbness and heaviness of the right leg, which she seemed to be utterly unable to move. She showed marked tenderness of the spine. The right side of the face was very slightly anæsthetic, the right arm was slightly more anæsthetic, the right leg was completely anæsthetic. She was unable to walk or bear any weight on her right leg, principally because it caused such a severe pain in her back. There was no increase of the reflexes in the leg. She was unable to sit upright, but reclined during the day in an invalid's chair. The railway accident occured in November of 1888. In March, 1889, without litigation, the railroad company paid her $8500 damages, and after this the gradual improvement in her condition which had been taking place did not seem to be in the least accelerated. She remained a cripple, unable to use the right leg, and suffering from frequent attacks of hysterical convulsions during the next year.

Many times during this year she was urged to come to the hospital for treatment, but could not be persuaded to do so. Finally, after months of waiting, in April, 1890, she entered St. Peter's Hospital. At that time she complained of some headache in vertex and occiput and of paralysis of the right leg. She also complained of severe pain in the left ovarian region shooting around to the back. This pain was worse during and before menstruation. She was having from three to six attacks of convulsions each month, was well nourished, walked with the aid of crutches, and in so doing dragged the right leg. There was complete paralysis of all the muscles of the right leg, and complete anæsthesia and analgesia of that leg. Passive motion of the right leg was painless, but showed much muscular resistance, and the muscles could be felt firmly contracted, certainly with enough power to move the leg. There was no muscular atrophy nor fibrillary contraction. The movements of all the muscles except of the right leg were normal. Exaggerated knee-jerk and trace of ankle-clonus were present and equal in both legs. There was slight anæsthesia and analgesia of the right hand and arm, but not of the face, and there was ovarian tenderness on both sides, most marked on the left.

After entrance into the hospital the patient was given fifteen grains of quinine every night for the first three nights and a very strong faradic current was daily applied to the right leg. This strong current was scarcely at all painful, but caused active muscular contraction, and the patient was urged to increase the movements of her leg, which were occasioned by the muscles contracting under the application of the electricity. She was confidently assured that a rapid recovery would take place, and was encouraged in every way. Each day the leg moved more freely during the application of the electricity, and the patient found that directly after the electric current had been applied she could herself move the leg a little. Improvement having once commenced was rapid. At the end of five days she could walk better, the leg felt less numb, and the application of the faradic current, which was at first almost painless, had become extremely painful. Ten days after entrance into the hospital the patient walked with only a slight limp, and the right leg was only slightly analgesic; and in less than a month after entrance she was entirely well, and has remained so ever since, and has never had any return of the hysterical convulsions.

There are many things about this case which make it seem not impossible that the whole thing was assumed for the purpose of obtaining money from the railroad company. After the railway accident the patient did not seem to be particularly hurt, but went home, where she was surrounded by a sympathetic family and sympathetic friends, who undoubtedly suggested to her the possibility of obtaining damages from the railway company. After this had remained in her mind for a month or more, she began to develop symptoms of a severe nervous disorder, which symptoms might have been feigned.

She seemed to be unconscious, but in that state she was capable of receiving suggestions, as, for instance, that "the whole of one side of her body was anæsthetic instead of the leg alone," and acting upon this suggestion the whole side of her body became anæsthetic. Also, when I told her that I must go back to Albany and she would lose the benefit of my visit, she very promptly came out of her attack of unconsciousness and talked to me quite rationally. Then, too, the long-continued paralysis of motion and sensation in the leg was evidently a mental one purely, because under purely mental treatment—that is, isolation in a hospital and the application of the faradic current—this paralysis rapidly and entirely disappeared. And yet all these symptoms and conditions are what we frequently meet with in ordinary cases of hysteria, and it is no longer maintained that hysteria is assumed simply for the purpose of troubling relatives, friends, and doctors, but that it is a real disease, although exaggeration and involuntary simulation are prominent symptoms in it. If we had seen this patient without having obtained any history of a railway accident, we should have regarded her as simply a case of hysteria, such as often results from a sudden shock or long-continued worry or mental strain, and which recovered promptly under appropriate treatment.

We have, then, the alternative of regarding this case as one of functional disease of the nervous system dependent on fright, and either hysteria or very closely allied to it, or to regard it as a case of malingering pure and simple. With the first supposition the symptoms and course of the case correspond exactly, and it resembles cases of hysteria which are of frequent occurrence. Under the second supposition, however, the case is not so easily explained. The patient has not complained of some simple symptom like vague neuralgic pains, dizziness, general weakness, or loss of memory, in regard to the reality of which we must depend merely on her word; but she has simulated an actual and very complicated disease, and has simulated it accurately, which is no easy thing, even if she had abundant opportunity of studying such cases, which is not probable. Moreover, it seems altogether probable that if it were a case of malingering, she would have shown sudden, or at any rate more rapid, improvement, after having been given the large damages which she obtained. Undoubtedly in many cases of hysteria there is a decided element of exaggeration and deception, and both of these elements may have been present in this case; but the prospect of damages did not tend to diminish these factors. On the other hand, it certainly seems true that as the basis of this case there was really functional disease of the nervous system consequent upon the fright and shock of the accident, and that the diagnosis, traumatic hysteria, is justified.

Case II.—A woman, aged thirty-six years. On the 1st of October, 1885, while walking in the street her foot caught in a hole in the pavement, and, as she struggled hard to pull it free, it was suddenly released, and she was thrown some distance, her head and the left side of her body striking the ground violently, so straining and bruising herself that she had to be carried home. She did not lose consciousness, but during a month she remained in bed, vomiting everything that she swallowed and having pain in her head, throat, abdomen, and the left side of the body. The same symptons continued during the next month, but she got out of bed and then found that her left leg seemed shorter and weaker than the other, so that she could not lift it from the floor.

She entered the Albany Hospital March 7, 1887, stating that since the accident she had suffered from nausea, vomiting, pains in the head and in various parts of the body, and had had two attacks of general trembling. During the thirteen months previous to entrance she had taken nothing to eat but peptonized milk, except that on two occasions she had tried solid food with disastrous results. On entrance the patient was anæmic, the spine was tender, and there was some hyperæsthesia of the left side of the body and great tenderness in the left ovarian region. The left side of the pelvis was drawn up by muscular contraction, so as to cause an apparent shortening of the left leg. There was ankle-clonus and exaggerated patellar reflex in the left leg. She could walk only with a crutch and cane. The most urgent symptom in the case was the persistent vomiting, and to relieve this she was given a quarter of a grain of hydrochlorate of cocaine in a half-teaspoonful of water five minutes before eating. This method of treatment, which I have never known to fail in cases of simple irritable stomach, acted well in this case also, and the vomiting ceased and did not return. About two weeks after entrance, during which time she had taken three meals of solid food daily, she was etherized and the left leg was moved about violently in all directions. Before the etherization she was assured that under treatment and while under ether the leg would be restored to its proper length. Since that time the left leg has seemed to her to be as long as the other. Her back was cauterized several times. She remained in the hospital six weeks, her treatment consisting of frequent cauterization of the back, the application of electricity, and encouragement. When she left the hospital she could walk without cane or crutch and limped but very slightly. She ate well and had no nausea nor vomiting, although she still had some pain in her back and in different parts of her body. She herself said she felt like a different woman.

In July, 1890, she received, after long litigation, the sum of $6500, and on December 11, 1890, I saw the patient again. She walked freely about the house with a slight limp, but in the street carried a cane, because she frequently felt as if her legs were

collapsing under her, and as if she would fall if she did not sit down or have some support. She limps because her left leg feels awkward and seems short, as if the cords at the knee and ankle were contracted and drew the leg up. The shortness of the leg is entirely relieved when her back is cauterized; after which, during a few days, she does not limp. The cauterizations are made every two or three weeks, on account of attacks of vomiting associated with intense pain about the waist, and in all the upper part of her body, and with great hyperæsthesia of the skin—all of which symptoms are entirely relieved by the cauterization. She also has dizzy spells in which she sometimes falls to the ground, but in which she never loses consciousness.

In this second case the symptoms are in many respects quite different from those of the first case, and yet there can be no doubt that it is a clear case of hysteria, such as we are constantly meeting with in practice, and under appropriate treatment the hysterical symptoms almost completely disappeared. In this case the great improvement was obtained more than three years before the damages were awarded, instead of afterward, as in the first case. In both cases hospital treatment was necessary, and I doubt not that a stay in the hospital now of some months would make a complete cure in the second case as well as in the first. Just as in the first case, in this second case also the receiving of large damages did not favorably modify the disease, the patient being in the same condition now as she was for a year before the damages were received. In regard to the question of malingering, the same thing may be said concerning the second case as was said concerning the first, and the fact that the second case improved so much under hospital treatment several years before the damages were awarded to her, makes the question of simulation extremely improbable, because if the disease were simulated, the simulation would almost certainly continue until the damages were received.

In conclusion, I would say that in this short paper I have not attempted to exhaust the subject of the traumatic neuroses, but I have merely wished to present to the Society two cases of well-marked functional nervous disease belonging to such a clear type of disease as hysteria, which were the result of accidents. Similar cases have been reported by many observers, so that I think the occurrence of hysteria following and occasioned by accidents cannot be doubted.

If these cases of traumatic hysteria, as well as the other forms of traumatic neurosis, were, in their early stage, isolated from their family and friends and given special treatment in a hospital, there can be no doubt that they would recover much more rapidly, and would obtain a much smaller sum of damages from those responsible for the accident. Of course, these cases cannot be confined against their wills in a hospital; but if, when a suit for damages on account of traumatic functional nervous disease was commenced, the defendant were to make the offer to pay all expenses of the treatment in a hospital, in the hope of obtaining a rapid and complete cure, I think that in many cases the offer would be accepted, and in the other cases the fact that the offer had been made would put the defendant in a better light before the jury, for no expert could deny that had such a course of treatment been adopted the case would have stood a better chance of recovering. Finally, in estimating the amount of compensating damages it should be remembered that a considerable number of these cases are easily and rapidly cured under proper treatment, and especially so after the question of damages has been definitely settled.

HYPEREMESIS GRAVIDARUM.

BY STANLEY M. WARD, M.D.,
OF SCRANTON, PA.

THE paper on this subject by Professor Hirst, of the University of Pennsylvania, before a recent meeting of the Philadelphia Obstetrical Society, together with its discussion by some of the leading members (*Annals of Gynecology and Pediatry*, November, 1890), has constrained me to give my personal experience with two cases, and in connection therewith my views on the subject formed by that experience—somewhat brief, it is true—and the perusal of a great deal of the modern literature on obstetrics.

There seems to exist no doubt in the minds of obstetricians, that if the life of a pregnant female suffering from hyperemesis can be saved only by interrupting the course of pregnancy and sacrificing the life of the fœtus, such a course must be pursued; but there does evidently exist a grave doubt in the minds of many, and these, too, men whose honesty and capability none will gainsay, whether such a question need ever arise. There is such a wide difference of opinion, that should the practitioner consult authorities for a solution of the problem in a given case, the chances are that he would find himself much bewildered. He would find an author like Playfair teaching that "there is abundant evidence that every now and then women do die of uncontrollable vomiting, whose lives might have been saved had the pregnancy been brought to an end;" while, on the other hand, Braüne, whose experience is probably equalled by no other living obstetrician, states that he "has never observed a lethal issue in consequence of the uncontrollable vomiting of pregnancy," and speaks of abortion as only permissible from a "scientific point of view."

In discussing the paper before alluded to, Dr. J. Price also states that he never knew of a death from this disorder, though he had made inquiries, not only at home but in rural localities, of practitioners of large experience. Dr. Jaggard, in his article in the *System of Obstetrics*, edited by Hirst, goes a step further, and questions the diagnosis of "death from uncontrollable vomiting of pregnancy" in the absence of post-mortem proof. Indeed, were it my object to strengthen either side of the question, quotations could be easily multiplied.

It ill becomes anyone to dogmatize in this matter where so many able men differ; nevertheless, the outcome of the cases I have seen—the histories to be hereafter given—and what seems to me to be the *rationale* of the disease, force me to agree with Professor Hirst, who, in closing his remarks before the Obstetrical Society on the occasion referred to, said: "If a pregnant woman becomes the subject of a disease which has its origin in the condition of pregnancy, or which is much aggravated by the existence of pregnancy, and if by this disease the woman's life is placed in danger, then it is not only justifiable, but it is incumbent upon us to terminate the pregnancy, thus saving one life, and that by far the more important one, when, otherwise, two would be sacrificed." Physicians do not like to bring about premature evacuation of the uterus. Our profession is maligned and slandered in this respect altogether too freely. I do not believe any body of men is so often tempted, by money and influence combined, to commit an overt act, with so little yielding, as is the medical profession—and, though perhaps foreign to the subject, I wish to say emphatically, that I believe physicians often permit their patients to die rather than end a life only just begun. I do not defend this course; I believe it to be difficult to justify it, but that it is true no one with a knowledge of the facts will deny.

In the treatment of hyperemesis gravidarum it is only up to a certain time, in the majority of cases, when abortion is at all indicated, that the question of producing it ought to be considered. While a few instances are recorded of its having brought about cures almost miraculous, yet, as Playfair says, "when it has failed it seems to be on account of undue delay." Let not the practitioner, therefore, ease his mind altogether by the thought, that after failing to relieve the vomiting by the use of all the various drugs recommended, the local applications and mechanical procedures, he can still interrupt the pregnancy at will. The drugs are legion: cerium, ingluvin, cocaine, arsenic, opium, and so on through the list—"stomachics," "alteratives," "tonics," "sedatives,"—one and all have been used for the relief of the "vomiting of pregnancy," and besides these there remain ether spray, blisters to the spine, correction of uterine displacements, applications of nitrate of silver, electricity, and dilatation of the os uteri. A fair trial of all these measures, with many more which space forbids mentioning, would consume, I think, the whole nine months of utero-gestation; and while it is true that vomiting may cease spontaneously or as an effect of one or all of these agents, it is altogether likely—if the case has arrived at that pass when abortion as a means of relief was being seriously thought of—that Nature will empty the uterus during the death-throes of the patient, leaving the physician two deaths to ponder over instead of one. Without pretending to possess an infallible judgment or powers of discretion above the average, my deliberate opinion is that after a few days' use of oxalate of cerium, of Fowler's solution of arsenic alone or combined with the deodorized tincture of opium, morphine, with or without cocaine (hypodermically or not), restricted diet, pop-corn (a homely remedy, but one I have seen used with good effect), absolute rest in bed, rectal feeding, correction of uterine displacements, should such exist, with local applications—I say, after using each of these for a few days, and failing to relieve the patient, I would then dilate the os uteri, and this likewise failing, would stop treating symptoms and proceed to attack the disease at its headquarters, viz., in the uterus, and before a great febrile rise, before the brown tongue, the glazed and reddened buccal cavity, the anxious facies and delirium warn us of the rapid approach of the "grim monster," this must be emptied, or so treated that it will empty itself, always providing that one of our former procedures—dilatation—has not already brought about such a consummation.

Case I.—Mrs. E., a well-developed brunette, of excellent family, was married when about thirty-four years of age to a gentleman many years her senior. Four or five years before her marriage she suffered a severe shock by falling on her back against the back of a car-seat from the jolt caused by two trains colliding. She developed "railway spine," probably, and was invalided for some time, though for a year prior to her marriage and for some time afterward she was better than before, and able to walk and to travel to some extent. About a year after her marriage she had a miscarriage at two and a half months, the cause of which is unknown. She was then in Florida, and her physician there said she had cellulitis, and metritis thereafter. Nausea and vomiting were not pronounced symptoms. While at the seashore in August, 1887, she failed to menstruate; but that function not having been performed regularly for some little time, it was thought of no importance, and it was not until late in the month, when sickness at the stomach manifested itself, that she thought herself pregnant. A physician was consulted, who failed to relieve her, and she came home. On September 5th her family physician was consulted, who

diagnosed pregnancy, but who, from what I can learn, made no particular investigation of the case. For a month Mrs. E. was under his care, with no improvement. In fact she was confined to her room most of the time, and was becoming nervous and somewhat hysterical. Early in October the gentleman with whom I was then associated was called in consultation. His note at that time was: Patient somewhat thin, and vomiting almost continually, retaining nothing, apparently. Believes herself pregnant, and is in good spirits over the fact. All efforts to introduce the finger into the vagina are followed by so much pain and nervous excitement that I desisted for the nonce. A condition resembling vaginismus obtains. Ordered vaginal injections of hot water; glycerin also, as a lubricant. Bowels to be cleared out with an injection of soapsuds, and minute doses of calomel in milk-sugar to be dropped dry on the tongue every fifteen to twenty minutes for six doses.

October 4. Has had several movements of bowels. With much difficulty, and in spite of strong protests on the patient's part, a digital examination of the vagina and uterus was made. Great resistance of the vaginal walls; os tincæ hard; uterus not apparently enlarged, but hard, and firmly fixed by adhesions. Very little displacement. This examination, though conducted with the greatest care, annoyed the patient very much, and she became more excitable after it, and vomited with much exertion several times thereafter. The next day she was salivated, and there was also very marked gingivitis, whether due to the mercurial or not it is impossible to say. With this exception there was no change in her condition. No attempt to feed her in the usual way was hereafter made. Instead, nutrient enemata were used four times during the day and night. Vaginal suppositories of cocaine and belladonna were also employed. There being no improvement following this treatment, a few days afterward an attempt to dilate the os by the finger was made. This being found impossible, we endeavored to introduce a rubber bougie as far as the internal os; this likewise resulted in failure. Like all the other vaginal manipulations, these were followed by excitability and vomiting. A resort was now had to morphine, and a sixth of a grain was administered hypodermically twice daily with an apparent good effect. This respite, however, proved but temporary, and the patient again began losing ground.

13th. Another attempt was made at dilatation, which was likewise unsuccessful, and was followed by renewed vomiting and excitement. The patient protested loudly against further vaginal or uterine manipulation. She averred that the pain was most excruciating, and insisted that nothing should be done to interrupt the pregnancy. Some doubts were now expressed by her husband as to her condition, and the physicians began questioning themselves as to her real condition. Marked emaciation, fever, and mild delirium now became prominent symptoms, with the temperature partaking of the "typhoid type," as did likewise some others of her symptoms. The vaginal injections and suppositories, feeding *per rectum* every six hours, with the hypodermic use of morphine twice daily, together with small quantities of dry malted milk—which her stomach seemed to retain—were now the measures relied on, though little perceptible effect was obtained, and on the 16th a last attempt at dilatation was made; this was also unsuccessful. On the 19th and 20th it was thought there was a slight amelioration in her symptoms, though when the writer saw her on the 21st, in the absence of my associate, I saw little hope unless, under slight anæsthesia, say to the obstetrical degree, the uterus was forced to part with its contents. I was overruled, however, and nothing was done, save as above mentioned. Neuralgic pains came on during the night, with pain in the eyes, ears, and throughout the entire body. Delirium became more marked, and she sank rapidly, dying of exhaustion during the forenoon of October 23d. In adjusting the bedclothes a few minutes after death, a fœtus of nearly three months was found between the limbs of the patient.

I think comment is unnecessary. It seems to the writer that this case carries its own moral with it.

CASE II. Mrs. A., mother of one child born in 1884, failed to menstruate in May, 1888, from which fact she believed herself pregnant. She was a nervous, excitable woman, about thirty years of age. During her first pregnancy nausea and vomiting, though present, were not severe. She felt much chagrined and displeased at her present condition. During June she began to suffer from "morning sickness," and shortly became so bad that her physician was called. He treated her for a week with the usual remedies, but no relief being obtained, the patient retching and vomiting almost continually, recourse was had to morphine and cocaine hypodermically, and an examination *per vaginam* made. In this case, as in the former one, the vagina was small, and objections were made to the examination. Nothing of any value was learned. The os uteri was tightly closed. A peculiarity about this case was, that though the patient might be nauseated, and complaining most bitterly of her "sick" feeling, the introduction of the finger into the vagina was sufficient to stop all bad symptoms for the time. Acting on this discovery, vaginal injections were ordered, and twice daily glycerin tampons were introduced into the vagina well up against the cervix. This respite, however, lasted only a short time, and in a few days the patient utterly refused food, retched and vomited nearly all the time, became restless, slept but little; her tongue was becoming brown, and her breath offensive; she was slightly delirious at times, and there were evening exacerbations of fever.

Our therapeutic resources were about exhausted. It is not necessary to mention all the drugs used; local applications and counter-irritation had also been tried. In the condition in which this patient now was, with the result of Mrs. E.'s case before us, would we be justified in giving Nature a further chance, and in the meantime wait? This was the question that came to the minds of the attending physician and myself, as we talked over the case. We agreed that the worry and grief under which our

patient labored probably had a great deal to do with her condition, but a knowledge of this fact failed to assist us in our efforts to combat the symptoms. She herself had not even intimated that an interference with the pregnancy was what she desired. Her husband was very much distressed, and feared for her life. We agreed to wait twenty-four hours longer before deciding on further measures, and ordered the nourishment *per rectum* to be continued, and administered a sixth of a grain each of morphine and cocaine hypodermically. The vagina was also washed out and a suppository of cocaine and belladonna inserted. As long as she was under the effect of these drugs she rested quietly; but their effect was transient, and late that night we found her again vomiting, and rolling from one side of the bed to the other, groaning and moaning with the feeling of indescribable sickness. Her family were now most thoroughly alarmed, and urged that any means, by which her life might be saved, be adopted. More on account of our own fears for the patient's safety than in accordance with their demands, we introduced a bougie into the os uteri the next morning, and packed the vagina. She was kept gently under morphine all day. Her bad symptoms ceased almost entirely; but dilatation had proceeded too far for the safety of the fœtus, and a faint "show," with occasional pain, warned us to expect what soon happened; in forty-eight hours the uterus was empty. Mrs. A. had slight abdominal tenderness, accompanied with some rise in temperature for a few days thereafter, but these soon subsided, and her recovery was complete. Nearly a year afterward she became pregnant, and in due time gave birth to a healthy child. Early in this pregnancy her stomach threatened to make trouble again, but it was only for a short time, and her pregnancy pursued thereafter the usual course.

While any remarks on either case may appear entirely superfluous, I cannot forbear calling attention to a few facts connected with each. In Mrs. E.'s case it is probable that had it not been for unknown and uncertain factors, viz., the old spinal trouble and the "fixed" condition of the uterus, forcible dilatation under an anæsthetic would have been done. Whether dangerous pelvic diseases might not have been lighted up, had this been attempted, and the ultimate outcome been just what it was, is a question I am not able to answer. In the case of Mrs. A., while fully cognizant of the fact that the unwelcome pregnancy had much to do with her condition, yet our efforts had proven unavailing either to calm her mind or to check the vomiting, and it was felt that she was rapidly passing into a condition in which, perhaps, even the most radical measures would be of little use.

417 Adams Avenue, February 11, 1891.

A CASE OF RUPTURE OF THE SHEATH OF THE ADDUCTOR LONGUS MUSCLE.[1]

By JOHN B. HAMILTON, M.D., LL.D.,
of Washington, D. C.

A case of rupture of the sheath of the adductor longus muscle lately came under my observation, and, as the injury is an unusual one, I thought it worthy of record. I am indebted to Assistant Surgeon Geddings for the compilation of the clinical history:

Wm. L. Marshall was admitted into the surgical ward of Providence Hospital, Washington, D. C., February 7, 1891, suffering with a tumor upon the upper and inner aspect of his right thigh.

The patient, who had been an enlisted man in the United States Army, gave the following history: About two years ago, upon an alarm of fire being sounded, he ran down a steep flight of winding stairs and slipped and fell, with his leg and thigh in a position of extreme extension. He suffered considerable pain and was confined to bed for several days. Shortly after this he noticed the formation of a tumor upon the upper and inner aspect of his right thigh. The tumor, which increased in size, incapacitated him for duty, and he was discharged from the service by the Examining Board for physical disability.

The records of the Adjutant-General's office show the following:

"Private Wm. L. Marshall, Battery 'B,' First U. S. Artillery. Discharged at Fort Columbus, N. Y. H., August 12, 1890, because of disability produced by a tumor on the inner aspect of his right thigh."

Major J. R. Gibson, surgeon, U. S. A., reports the case as follows:

"An enlargement of the right femoral canal, ... which is complicated by a swelling or enlargement (muscular) on the inner aspect of the thigh."

On admission to the Providence Hospital, Washington, D. C., six months after his discharge, there was found upon the inner side of the right thigh, below Poupart's ligament and the sartorius muscle, a hard, non-fluctuating tumor, about the size of a hen's egg, and which varied in size, according to the patient's statement, being increased after exercise in the erect position and diminished after rest in the recumbent position. The tumor was movable and reducible, there was no gurgling upon taxis, and only a very indistinct impulse upon coughing. The patient being anxious for relief, and the diagnosis being somewhat obscure, an exploratory operation was determined upon. I operated Sunday, February 8th, in the presence of the hospital staff and class of the Georgetown Medical College. The integument was divided and the layers of tissue were incised upon a grooved director. Upon reaching the tumor it was found to have no connection with the abdominal cavity, but to consist of a portion of the adductor longus muscle, which had pro-

[1] Read before the Medical Society of the District of Columbia, March 18, 1891.

truded through a rupture in its fascia. The swelling was divided parallel with the muscular fibres. A rubber drainage-tube was introduced, the wound was closed by silkworm-gut sutures, and an antiseptic dressing was applied. The drainage-tube was removed in twenty-four hours; the wound healed by first intention, and the sutures were removed by the tenth day. The question of removal or excision of the tumor was not considered. A microscopical examination of a section of the tumor was made by Dr. Geddings, who found it to consist of striated muscular fibres. The patient made an uninterrupted recovery from the operation, the temperature at no time exceeding 38° C. It is now very noticeable that the tumor increases in bulk upon flexing the leg upon the thigh and the thigh upon the abdomen. Patient being anxious to resume his trade as a tailor, was discharged at his own request March 5, 1891, but was cautioned to avoid the use of the sewing-machine, and to keep constant elastic pressure applied to the tumor for some months.

I could easily have removed the projecting portion of the muscle, but I considered it better policy to allow it to remain, as the removal of the muscle might have resulted in permanent lameness; whereas he can now walk without limping, if his thigh is bandaged.

One naturally inquires what course should be adopted if such a case should fall under observation immediately after the accident. The answer is that the swelling should be cut down upon and the fascia united by sutures. The diagnosis may easily be made by observing the changes that take place during flexion and extension of the limb.

PERITYPHLITIS.[1]

By HUGO PHILLER, M.D.,
of Waukesha, Wis.

It seems strange that the description of the cæcum, the vermiform appendix, and the ileum, is, in certain respects, different in the several text-books on anatomy. All agree that the cæcum, or caput coli, is a blind pouch about three inches in diameter, two and a half inches in length, which forms the widest part of the intestine. It varies much, however, both in position as well as in shape. It is most frequently found, not in the iliac fossa, but on the psoas muscle itself, or in the pelvis.

According to Treves, who also denies the existence of a meso-cæcum, it is entirely surrounded by peritoneum from the ileo-cæal valve to its apex, and no areolar tissue is behind it, as described by the older anatomists.

Bardeleben[2] came to this conclusion as early as 1849, from an examination of one hundred bodies. Ransohoff, in a paper read before the Section on Surgery of the American Medical Association, May, 1888, found in sixty-three examinations (only twice in adults) that the cæcum was invested only in front and laterally by peritoneum, and he is convinced that perforations of the cæcum, or appendix, without involvement of the peritoneum, are "physical impossibilities."

Drs. E. W. Lee and J. B. Murphy, of Chicago, in an article entitled "Early Operations in Perityphlitis,"

"try to account for this discrepancy of opinion by different interpretation of these observers as to the manner in which the peritoneum is reflected around the vermiform appendix at its base; for while it appears to be within and completely encircled by peritoneum at its mesenteric attachment, about one-eighth of its entire circumference is not covered by that membrane."

The appendix vermiformis is a blind diverticulum of the cæcum, round, tapering and hollow, subject, however, to a great variation in size, shape, and situation, its general direction being upward and backward behind the cæcum. According to Fitz, the usual position is behind the ileum and its mesentery, with the tip pointing toward the spleen. Its walls contain but a small amount of muscular tissue, so that solid contents are not easily extruded into the cæcal cavity. It is for this reason very properly called "the death-trap of the intestines." In embryonic life the cæcum and appendix form one continuous pouch. Toward the fifth or sixth week the cæcum appears at the side of the rudimentary intestinal loop, in the form of a short and broad dilatation. While it grows in length, its width does not continue uniform, it being widest at the base, where it joins the colon. The differentiation between the upper third and lower two-thirds of the cæcum does not commence until the tenth week, and as it progresses the former rapidly widens, while the latter does not greatly increase in calibre. The appearance is thereby presented of a long, narrow tube hanging from and continuous with the apex of the projection from the intestinal loop. The cæcum and the appendix are thus formed. They are continuous with each other in the axis of the former, and, in the first half of embryonic life, are cylindrical like the small intestine. It is only at the sixth or seventh month that three ampullæ in the cæcum form the longitudinal muscular fibres in bands or tæniæ. They descend from the colon and meet at the apex of the cæcum—that is at the root of the appendix; one lies on the side of the bowel into which the ileum enters, a second is placed on the postero-external aspect of the colon and cæcum, while the third runs along the anterior aspect of the gut. By the equidistant disposition of these bands in the fœtal cæcum, it is divided into three parts. Uusually the part of the cæcum to the right of the anterior band grows quite out of proportion to that

[1] Read before the Brainard Medical Society.
[2] Virchow's Archives, Bd. 2, p. 584.

on the left, and the anterior wall of the cæcum becomes more developed than the posterior. As a result, the true apex of the cæcum is turned more and more to the left, until at last it is placed in close proximity to the ileo-cæcal junction, and can only be recognized by noting the point of origin of the appendix. The highly-developed part of the anterior band becomes so dependent and prominent that it forms a new or false apex to the cæcum, and it is to this projection that the anatomical term *apex* is usually applied.

Judging from the absence of the appendix vermiformis, which J. T. Whittaker[1] calls a relic or rudiment of a subsidiary stomach in lower forms of life, in the greater number of omnivorous animals except man, ourang-outang, and a species of rodent, the wombat, it seems physiologically to have no influence on digestion, except that it may act as a lubricator (like the tonsils), as it always contains a thick, glairy mucus. The normal appendix is, with very few exceptions, found completely surrounded by peritoneum and having generally a distinct mesentery, by which it is attached to the under layer of the mesentery of the ileum, and for this reason the peritoneum is necessarily involved in every perforation of the appendix.

The appendix varies in size, in the character of its walls, and in its contents. It may vary in length from one and a quarter to nine inches. In the museum of the Pennsylvania Hospital an appendix nine inches in length is described by Wistar. It lay behind the colon, reaching the under surface of the liver.

A long appendix generally takes an upward direction. Sometimes it lies on the psoas muscle with or without its tip in the pelvic cavity. It may stretch across the pelvis and become adherent to the sigmoid flexure of the colon, and has been seen in one instance, by Dr. J. H. Musser, of Philadelphia, in the inguinal canal, associated with a hernia. The character of its contents is also pathologically of importance. Various articles have been found in the appendix, such as fæcal masses or fæcal concretions, chiefly; but there have appeared, also, seeds of various kinds, buttons, bristles, worms, shot, pins, and gall-stones. Haeckel and Buhl even found concretions of meconium in the appendix of a newborn child.

There are certain anatomical points which favor the occurrence of local inflammation in this region:

1. The fixed position of the cæcum, restricting the amount of its peristaltic action.

2. Its deep transverse sacculi, affording great opportunity for the lodgment of hard fæcal matter or foreign bodies.

3. The arrangement of the ileo-cæcal valve preventing relief to the distended cæcum by crowding backward its contents.

4. The vertical direction of the ascending colon, along which the contents of the cæcum must be moved onward.

5. The existence of the vermiform appendix, so admirably adapted for catching and retaining small foreign bodies.

Morbid Anatomy.—On section of the abdominal walls there is found, especially in the right iliac region, an œdematous state of the tissues—either serous œdema or infiltration of pus due to the burrowing of the primary abscess. The peritoneum exhibits an intense degree of general or limited inflammation, and serum, pus, and sometimes blood, are found in the peritoneal cavity. In severe cases large flakes of lymph cover the intestines, the parietal peritoneum, and the abdominal organs; the intestines are more or less adherent to each other, according to the duration and degree of the inflammation.

The location of the abscess, usually circumscribed, depends upon the position of the cæcum; it is either in the right iliac fossa, just above Poupart's ligament, or behind the cæcum, or in the pelvis. Its size also varies, as it contains sometimes only two to three ounces, and in other instances more than a pint of pus. The appendix is found always in the abscess, and has generally undergone some changes. There is either inflammation and ulceration of the mucous membrane, serous infiltration of the walls, or perforation discovered. Such a perforation varies in size, sometimes surrounding the appendix entirely, sometimes only large enough to admit a probe. In the canal near the cæcum a foreign body is found in about sixty per cent. of the cases, but some authors think this percentage is too small.

The following conclusions must be drawn from the morbid anatomy:

1. Peri-cæcal inflammation is due to the inflammation, ulceration and rupture of the appendix vermiformis, with the secondary formation of an abscess.

2. The position of the abscess depends entirely upon the position of the appendix.

3. The larger number of cases of inflammation and ulceration are due to the presence of a foreign body occluding the canal—called by Ransohoff "retention inflammation."

4. There is no evidence of the existence of infiltration of the walls of the cæcum, other than that caused by a catarrhal infiltration or ulceration of its mucous membrane, the most common forms of ulcer being stercoral, typhoid, tubercular, and perhaps syphilitic.

5. The symptoms of a catarrhal infiltration of the

[1] Pepper's System of Medicine, vol. ii.

mucous membrane of the cæcum are those of a colitis rather than those of a typhlitis, and ulceration of the cæcum does not give rise to symptoms of typhlitis, unless the peritoneal covering becomes involved.

6. Very few cases terminate fatally, for resolution takes place, or the abscess either becomes encysted or ruptures into some neighboring organ.

Causes and Diagnosis.—While external violence, such as a fall, or blow, or the effort made in lifting a heavy weight, may be the exciting cause, the presence of a foreign body, however, or of a small mass of dried fæcal matter, is, in a great majority of cases, concerned in the production of perityphlitis.

Age and *sex* appear to have a causative relation. According to Fitz, who made a careful analysis of 257 cases, 80 per cent. occurred in males and 20 per cent. in females; 76 per cent. were under thirty years of age, and 50 per cent. under twenty years of age. Congenital or acquired irregularities in the position and attachment of the appendix may also influence attacks of inflammation. Ransohoff calls attention to another clinical feature or cause for perityphlitis, in the occurrence of marked symptoms of intestinal obstruction. This may occur from pressure by the thickened appendix upon the ileum from below and behind. Twelve cases have been collected by him, in which perforative appendicitis produced all the manifestations of internal strangulation.

The question as to the exact seat of the several lesions, which may be embodied under the name of perityphlitis, is still under discussion.

According to Israel T. Dana,[1] inflammation *in and about* the cæcum presents itself in three clinical varieties, viz.:

"1. The body of the cæcum is the primary and essential seat of the inflammation, the appendix being invaded, if at all, only secondarily, by simple extension of inflammation along the continuous mucous membrane (typhlitis). But this, I think, should be called more properly *cæcitis*.

"2. The vermiform appendix is the primary and essential seat, the body of the cæcum often escaping altogether (appendicitis or paratyphlitis).

"3. The inflammation early invades the post-cæcal tissues, and produces a burrowing abscess (perityphlitis)."

Dr. C. Eisenlohr takes exception to a division of the several lesions in the right iliac region generally characterized by inflammation and eventual perforation of the appendix. I quote his own words:

"We must admit that the appendix is the most frequent seat for these lesions, also that obstruction and necrosis are the most frequent causes. But even the nearest sequelæ of a partial necrosis of the appendix are not explained in all their phases, either on the post-mortem table or in the living subject. Notwithstanding the fact that the researches of French and American observers during the last few years have endeavored to distinguish appendicitis from other primary perityphlitic lesions (Bucquoy and Dantel), notwithstanding that Porter has shown the effects of a perforation of the appendix into its mesentery or outside of it, a precise differentiation of all these modifications cannot be made by clinical observations."

Dr. Graser, who has made extensive studies on this subject in the clinic of Professor Heineke, at Erlangen, claims that most of the processes formerly described under the titles of typhlitis, perityphlitis, and paratyphlitis, take their origin from the vermiform appendix. The process begins by ulceration about fæcal calculi, and results in the formation of pus, with perforation; the whole process is intraperitoneal, since the vermiform appendix is entirely surrounded by peritoneum.

Dr. R. H. Fitz, in an elaborate paper, makes the attempt to define clearly the anatomical relations of pathological conditions occurring in connection with the cæcum, which have heretofore been described under terms that fail to express accurately the origin of the lesion. Ulceration and perforation of the vermiform appendix have been found, in the vast majority of cases in post-mortem examinations, to have been the origin of the perityphlitic abscesses, the cæcum being intact. He, therefore, applies the term *appendicitis* to all these lesions, to express the primary conditions and to define their origin.

Dr. William Pepper,[1] in an article read before the Philadelphia County Medical Society, divides all cases of peri-cæcal inflammation into two distinct classes:

"1. Cases where the affection is limited to the walls of the cæcum and peri-cæcal connective-tissue, with a comparatively slight affection of the appendix. Those cases are marked by pain as the initial symptom, not excruciating in character nor associated with the evidences of collapse, but often accompanied with nausea and vomiting and elevation of temperature, which continues to rise until decided fever is present. The pulse also is considerably accelerated. There exists tenderness in the right iliac fossa, a sense of fulness and induration, with dorsal decubitus and flexed thigh, generally due to a considerable fæcal impaction in the cæcum. Those cases generally end in resolution and complete recovery by the proper treatment, to wit: absolute rest, abstinence from food and strict avoidance of interference with the state of the bowels, local depletion, counter-irritation followed by the application of the ice-bag or warm fomentations, the internal use of opium and mercury, and by watching closely the convalescence and insisting on the above restrictions until the over-sensibility of the part is entirely removed.

"2. Cases which commence with a catarrhal appendicitis. Here the patient may have been apparently in almost perfect health, perforation of the appendix taking place without any perceptible previous symptoms. The fæcal matter, which is present in nearly every healthy

[1] Reference Handbook of the Medical Sciences, vol. iv.

[1] Journal of the American Medical Association, December 14, 1887.

appendix, is no longer able to circulate and escape, because the outlet is partially closed by the swelling of the mucous membrane (partial stenosis); the pent-up secretions and the irritating fæcal matter excite serious inflammation in the walls of the appendix, ulceration is established, and perforation occurs. In such cases the first symptom is excruciating, intense pain, followed by the rapid development of the signs of peritonitis. The pulse becomes frequent, there is marked tenderness, not in the iliac region only, but also toward the middle line of the abdomen, sometimes extending into the genitals, especially into the right testicle and spermatic cord. The abdomen becomes distended, though evidence of dulness or induration may be present or absent. Vomiting is rare, and only induced when the stomach is taxed. For two or three days these may be the symptoms after the subsidence of the initial pain, and there may be only a moderate febrile reaction for several days, associated with continued moderate pain, simulating an ordinary catarrhal attack with intestinal colic. The bowels are quiet; not so constipated as in typhlitis, and with less impaction of the fæces in the cæcum. After a time there appear the symptoms of a rapidly-spreading, general peritonitis. The abdomen becomes greatly distended and tender, vomiting becomes frequent, the temperature rises, the pulse becomes thready and rapid, and death from exhaustion ends the scene in five to ten days."[1]

The most important question to be considered is, When is the earliest moment that we can establish the diagnosis between these two forms of cæcal inflammation?

The initial symptoms may give us some indication as to the seat and the gravity of the attack.

Typhlitis and perityphlitis soon offer demonstrable symptoms; but as the appendix is hidden under the intestine, the symptoms of perforative appendicitis are often obscure for several days. The most careful palpation may fail to show the slightest fulness. The patient may complain of pain over the cæcum, or over the hypogastrium, and external examination may not aid us in the diagnosis.

Pepper and Loomis speak highly of early and oft-repeated rectal examinations as the most important diagnostic means. I quote Pepper's own words:

"In such cases, if rectal digital examination should give a sense of distention of the right side of the pelvic roof, might not a puncture be made with a curved exploring-needle introduced through the rectum? In this way we might demonstrate the presence of pus, when it could not be possible to do so through the external abdominal wall."

Loomis holds, as a matter of theory, that by the careful examination of a patient, previously anæsthetized, with the index-finger of the right hand in the rectum and the left hand pressing into the right iliac fossa, evidence may be obtained to establish the diagnosis in the early stage, and so aid in determining the question of a laparotomy.

According to Joseph Ransohoff, the anatomical relations of the cæcum and the appendix alone suffice to explain certain clinical differences between inflammatory conditions of either part. The cæcum being comparatively superficial in position, and its peritoneal coat continuous with that of the iliac fossa and anterior abdominal wall, an abscess about it will speedily manifest itself by the presence of a tumor. The appendix, on the other hand, being deeply seated behind the cæcum and below the mesentery of the ileum, abscesses about it may continue for a considerable length of time without the appearance of a tumor in the right iliac fossa. The fixed position of the ileo-cæcal junction and the mesentery will often direct the progress of such an abscess toward the pelvis. Hence the great importance of rectal exploration as a diagnostic measure in cases of suspected inflammation of the appendix.

Treatment.—Fully concurring with the opinion of Dr. Murphy, that perityphlitis belongs, in the great majority of cases, to the province of surgery, I will not spend any time in recapitulating the so-called expectant, conservative plan of treatment, which consists of rest in bed, restriction of diet to nourishing liquids, hot poultices or fomentations frequently placed upon the parts, with local depletion, and hypodermic injections of morphia to control pain, to allay tenderness, to reduce abnormal peristalsis, to restrain hypersecretion, and to exercise an anti-inflammatory influence. According to Morton, the bowels should be kept open and free from accumulation of gas and fæces by the administration of salines and non-iritating enemata with the addition of some turpentine. I quote his own words:

"I would ask of those disposed to cavil at this advice, Shall we keep the bowels in liquid condition, and so prepared to best resist peritonitis, should it occur, whilst at the same time the mere draining of fluid from the intestines and surrounding parts would influence for the better the peri-cæcal inflammation? Or, shall we paralyze, and congest, and inflate the bowels by the old-fashioned 'splinting' treatment, and thus beckon on peritonitis?"

Wyeth,[1] while admitting the usefulness of laxatives in stercoral typhlitis and the early stages of typhlitis, warns us againt their use in the early stage of perityphlitis.

Thomas G. Morton,[2] in an article read before the Philadelphia County Medical Society, December 14, 1887, urges the division of the disease into a *pre-purulent* and a *post-purulent* stage. In the first, the conservative medical treatment above mentioned is resorted to; in the second, operative measures must be employed, and the perityphlitic abscess, or the post-purulent stage of perityphlitis, passes from the domain of internal medication into that of modern surgery.

The question then naturally arises, When shall we operate? Unfortunately, the acuteness or mildness

[1] Keating: Diseases of Children, vol. iii.

[2] Journal of the American Medical Association, January, 1888.

of the local or general symptoms is not an invariable index of the ultimate gravity of a given case. Sometimes fatal cases will set in with a very deceptive mildness of appearances; on the other hand, a very alarming beginning may be followed by resolution or a tractable state of affairs. According to A. G. Gerster, all therapeutic advice has only a conditional value, to be weighed and accepted or rejected by the sugeon in each separate case.

In view of the impossibility of foretelling whether, in a given case, spontaneous evacuation of the contents of an appendix or perforation will take place, and, in the latter case, whether a superficial or a deep-seated abscess will develop, and considering the fact that laparotomy followed by the excision of the appendix has yielded uniformly good results, if done before the access of perforation, it is safe to follow McBurney's advice, which consists in the performance of laparotomy and removal of the appendix, whenever severe symptoms persist and increase for more than forty-eight hours. The operation is indicated when an abscess has formed and threatening symptoms of collapse seem imminent, or when threatened perforation or intestinal obstruction appear. In most cases the operation is performed too late, or the patient is unnecessarily exposed to a long and exhausting illness. Sudden illness, with high fever, radiating pains, and increased resistance, are reliable signs for surgical interference. According to the time-honored maxim, "*Ubi pus, ibi incisio*," the lateral method, as first done by Professor Parker in 1843, is to be adopted under the strictest antiseptic measures.

When the abscess is found and opened, and the bulk of its contents has escaped, a gentle exploration by the index-finger is advisable to detect recesses or a foreign body. But all rough treatment of the walls of the cavity by scraping, tearing, or rude squeezing, is to be avoided, as it may lead to inward rupture. If the appendix is easily found, and appears necrotic or ulcerated, it should be removed. Two drainage-tubes are slipped into the cavity and fastened, for facilitating irrigation without causing undue distention. Daily change of dressings will be required for the first seven or ten days, until the discharge becomes serous and allows the removal of the tubes.

Dr. H. Kummel, of Hamburg, speaks of the treatment of a third form, the chronic relapsing form of perityphlitis. A patient who has once passed through a siege of perityphlitis is always in danger. The least error in diet, or a trauma, is likely to cause new trouble. Those which are most susceptible to relapses are the cases which do not result in the formation of abscess, but have an exudate around the appendix. The operation of removal of the appendix, as a lasting, radical cure, is to be performed after the acute symptoms have subsided, and the exudate around the appendix is resolved under the influence of ice and opium, the sheet-anchors of medicinal treatment.

The incision is made along Poupart's ligament or in the median line, the appendix being ligated close to the cæcum, and the stump closed with peritoneal suture. Only a few operations of this kind are published, so far, in literature; two have been reported by Senn, one by Treves, and two by Kümmel.

The three male subjects who fell victims to this disease in our community, a village of about 6000 inhabitants, during the past summer (May, July, September), were twenty-four, twenty-six, and thirty years old relatively, all robust and well-nourished workingmen. The disease came on in each case suddenly, and the patients and their respective relatives were rather reluctant in believing that the illness was grave and would need early surgical interference. All three consented rather late to be operated upon, after symptoms of peritonitis had fairly set in, and the cases ended in death, two dying from septic peritonitis four days after operation, the remaining one from shock six hours after operation. The appendix was found in each case perforated, and in a more or less necrotic state. The two cases which died from sepsis might have terminated in recovery, if the necessary antisepsis in all its details could have been carried out; but this is sometimes rather difficult in private practice.

Under such disadvantages, I, for my part, have concluded to remove, under all circumstances, as soon as I have established the diagnosis, any further case of perityphlitis to a well-regulated hospital for operation and treatment, and where the chances for recovery are above *par* on account of surgical cleanliness.

ORIGINAL LECTURES.

ICHTHYOSIS.

A Clinical Lecture,
delivered at St. Luke's Hospital.

BY I. N. DANFORTH, A.M., M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE CHICAGO MEDICAL COLLEGE; PROFESSOR OF RENAL DISEASES IN THE WOMAN'S MEDICAL COLLEGE OF CHICAGO.

GENTLEMEN: The first case I show you to-day illustrates a very rare variety of skin disease. I have only seen one other case like it. From the history-sheet we gather the following data: The child is twelve years of age, father living, and mother dead. Cause of mother's death unknown. She has two sisters living; one has some affection of the kidneys, the other is perfectly healthy. Two years ago last September the child had scarlet fever, from which she recovered, being sick about one month. A month or two ago she began to have epileptic seizures. In order to control the paroxysms the bromides were given. During the last two weeks

she has had only one seizure. It is not on account of epilepsy that I have brought her into the clinic, but because her case is a typical illustration of that rare form of skin disease which has been called by English writers "*ichthyosis*." It is a good case for you to study. It has been called by Wilson "*xeroderma*." The scales resemble those of a fish. The surface of the skin is dry, rough, and pearly in color. The cuticle exfoliates in fragments. The affection involves the extensor surfaces of the hands. On the flexor surfaces of the lower extremities it is quite well marked. Sometimes the skin is so peculiar in appearance that there is very little difficulty in making the diagnosis. The only mistake you are liable to make in regard to this affection is in winter time. When the skin is moist or weather cold, there is likely to appear an eczema of the skin, which we are told was present in this case when the patient was admitted into the hospital, but has disappeared under treatment. The general appearance of the lesion, however, extending, as it does, over the whole body, is enough to establish the diagnosis without any difficulty.

There are two varieties of this affection, viz., *ichthyosis diffusa*, and *ichthyosis follicularis*. These two varieties are subdivided by some English writers into *xeroderma follicularis*, *xeroderma diffusa*, *xeroderma pigmentosa*, and a half dozen others, which practically amount to nothing. There are only two varieties, and these are based upon the morbid anatomy of the disease. One variety is where the lesion begins upon, and is for a long time limited to, the surface of the skin. It does not involve the follicular structures of the skin. This is called *ichthyosis diffusa*, meaning a diffusion of the affection over the surface of the body, and this is a typical case of it. After a time it may affect the follicles of the skin. It develops usually during early infancy.

The other variety of the primary lesion is usually in the follicular appendages or hair follicles, and this variety is known as *ichthyosis follicularis*.

It is invariably a congenital affection. The child may be born with it, but if not, it develops within two to six months after birth. Hardly ever does it appear after that time. I do not think there is a case on record of the development of this disease after puberty, hence it may be regarded as congenital.

In ichthyosis the cuticle may be said to be more abundant than natural. There is an over-development of the epidermal layer.

The disease is invariably hereditary, being transmitted from parents to children. In this case, it is inherited directly through the mother, but *she* inherited it in turn from *her* mother. Another child, a sister of our patient, also has the disease.

Again, it prevails more extensively in certain regions, as, for example, South America. It is quite common in Patagonia, as well as in some of the islands of the South Pacific. Although the affection is said to be *endemic*, it is still *hereditary*, as seen in these cases.

As I have already told you, it almost always begins a month or two after birth. Sometimes the disease may remain latent for a year or two. It usually begins at the flexor surfaces of the joints, and the mother is very apt to pay little or no attention to it, supposing it to be some ordinary skin disease, such as chapping. The pearly scales fall off. The disease gradually spreads until it involves nearly the whole body. In some cases, however, only a certain area of the body is affected. It is always attended with dryness of the skin, for the reason that there is an arrest of development of the physiological power of the epidermal cells. The glands fail to secrete, so that the skin remains dry and apparently unnourished. When these lesions of the skin are once established, they are permanent.

This is the second case I have seen of the disease. The first case I saw was that of a lady, now forty years old. She has always been fairly well with the exception of this skin affection. I have known her for the past ten years, and she told me that she has never known her skin to be moist during the hottest weather. It always remains in that dry condition characteristic of the disease. The result is, that double work is thrown upon the kidneys. You are aware that there is a physiological relation between the skin and the kidneys. The skin is an adjunct to the kidneys. The skin in this case is entirely inactive, and it is not to be regarded in the light of a secretory gland. Ordinarily we look upon the skin as an active eliminating organ. Here the results are different.

In the case of the lady I speak of, the urine is constantly loaded with urinary salts or lithic acid. Five years ago she had an attack of neuralgia, hæmaturia, fever, extreme pain, etc., and was laid up in bed for two weeks. At the end of that time she passed a small calculus. These attacks have recurred every few months. She has pain, constant hæmaturia, and other symptoms indicative of calculus in the kidney. She is at present considering the advisability of an operation for the removal of the calculus. Life has become a burden to her.

This condition of things is largely due to the inactive and undeveloped condition of the skin. There is no possibility of restoring its functions.

If you take a section of the skin, and place it under the microscope, you will notice that the follicles are either undeveloped, or are dilated by the presence of a great number of dry, shrivelled, epithelial cells. In a word, these follicles are imperfectly developed.

The skin you notice in the patient before us is very dry and branny, and scales are constantly falling off. There seems to be a deficient development of the pigmentary layer, so that English writers recognize the pigmented variety where pigmentation is excessive. In the follicular variety the skin feels rough, like a nutmeg-grater; that is, the follicles become filled with a mass of dried cells which project like little horns above the surface of the skin. This peculiar appearance disappears as the rest of the skin becomes affected, but during the early stages the skin has a roughened appearance with a peculiar feel.

There are no subjective symptoms peculiar to the disease, so far as I am aware—no pain, no itching, except during very hot and oppressive weather. The lady, to whom I have referred, complains bitterly during hot weather. She cannot perspire. She gets no relief from the action of the perspiratory glands.

The history of cases like this is simply a continuation of the disease in one direction. It remains as it is. If neglected it gets worse, if treated it improves to the extent that there is some comfort afforded the patient. As

far as curing the disease is concerned, it cannot be done. We have, as yet, no therapeutic measures at our command which can restore the congenital defects of the skin.

The prognosis, so far as I know, is this: A patient is likely to live as long with ichthyosis as without it, provided no acute disease carries him away. But there is no question but what this affection increases the danger of pneumonia, rheumatism, fevers, bronchitis, etc., because we cannot thus have the benefit of the skin as an organ of elimination. You know that in patients affected with pneumonia, there is always more or less danger of nephritis, and in ichthyosis there would be the added danger due to the condition of the skin. If the skin does not act as an eliminating organ, a great deal of its work is thrown upon the kidneys, and there is constant danger of nephritis. Other than the dangers which naturally follow an arrest of development of the skin and the absence of its physiological functions, a patient is likely to live as long with this form of skin disease as without it. I do not know that it predisposes to lesions of any other organs of the body except the kidneys.

I will now say a few words with regard to the treatment. It is an incurable affection. There are no remedies which will cure a case of this kind, for the reason that we have no therapeutic measures which can develop an undeveloped organ. All we can do is to take care that other organs do not suffer or become involved.

I advise you, for one thing, to watch the condition of the kidneys. The urine of the patient should be examined every now and then, to see that the kidneys are not over-worked, for they are constantly in danger.

As to the skin, the first thing is to employ soap-and-water baths, or frictions with green soap, for removing the dead scales which are constantly accumulating. You can also keep the skin moist by the use of inunctions of some bland ointment. In my cases I have used inunctions of the oil of sweet almonds. It is a bland and mild oil, and odorless. It keeps the skin moist and supple and thereby adds to the patient's comfort.

If the skin becomes very dry it will sometimes crack about the joints, so that there will be longitudinal and transverse fissures. It is necessary to guard against this by the application of some simple inunction. Almond oil, lanolin, benzoated lard, or any other of the fat preparations which are bland and unirritating, may be employed with benefit. Vaseline is of little use. It remains a gummy mass upon the skin. Then, again, occasionally you might give the skin a bath with frictions of green or some other alkaline soap. The inunctions of ointment or oil should be as bland and unoffensive as you can make them.

A point of importance for you to remember is this: If a patient with ichthyosis has pneumonia, rheumatism, bronchitis, pleurisy, or any other acute affection, you must prognosticate accordingly. In a word, the prognosis would be more unfavorable than if the skin were in an entirely healthy condition, for reasons to which I have already alluded.

SYPHILITIC ECTHYMA.

Here is a case, gentlemen, which perplexed us a little in the matter of diagnosis. The patient was admitted into the hospital about three weeks ago as a gynecological case. At that time it was decided to have an operation performed on her, but before the operation was done she had a febrile attack, followed by an eruption on her face, mouth, body, arms, etc., which assumed very much the appearance of varioloid or chicken-pox. A physician from out of the city diagnosed the case as smallpox, so that it was for a time isolated. One or two days elapsed before I saw the case. It then had some of the characteristics of smallpox. It broke out in the form of pustules. Now and then these pustules had an umbilicated appearance, being depressed at the top. The case illustrated the fact that one who makes a diagnosis too rapidly might very easily mistake it for smallpox.

But what are the facts in the case? The patient had a vesiculo-pustular eruption with an elevated temperature, which would be hardly sufficient ground for making a diagnosis of smallpox. The girl stated that she had had smallpox or varioloid once. That statement may or may not be true; at all events, if it were true it would interfere somewhat with a diagnosis of smallpox.

In smallpox the temperature always runs higher, so far as I have been able to observe, than it did in this case. In smallpox there are rigors, headache, cough, soreness of the throat, marked bronchial irritation, and, more than all, there is pronounced lumbar pain, which, in many instances, is the first symptom of which patients speak. In all my experience with smallpox the first symptoms they complain of is an intense backache. I have seen cases repeatedly where an intense backache, not preceded by any eruption, has led me to suspect smallpox, and further investigation has proved it to be so. Pronounced backache, then, may be regarded as one of the diagnostic symptoms of smallpox. If a patient has an eruption, and that symptom is absent, you may be reasonably certain that it is not a case of smallpox with which you are dealing.

If you examine closely the pustules you will find that they are not typical of smallpox. In smallpox the pustules are nearly all alike, but in this case they differ in size, form, height, appearance, and termination, and they do not pursue the same course. The absence of backache and the atypical character of the eruption are against smallpox.

The subsequent history of the case led me to the conclusion that I had to deal with a specific eruption. I will not go into the details of that history at the present time. A diagnosis of syphilitic ecthyma was made. It is a rare case, and a typical illustration of the disease. It is an interesting case to study.

The treatment would be the same as for any other specific lesion.

HOSPITAL NOTES.

WOMAN'S HOSPITAL OF PHILADELPHIA.

SURGICAL CLINIC OF DR. JOHN B. ROBERTS.

Reported by MARY E. ALLEN, M.D.,
DEMONSTRATOR OF SURGERY.

Radical Operation for Scrotal Hernia at the Age of Four Months.—L. B., a boy of four months, was admitted to

the Woman's Hospital of Philadelphia December 19, 1889, on account of a very large congenital scrotal hernia, complicated with phimosis. The scrotum, when the hernia was forced down by crying, was about as large as a fist, and the penis was buried in the mass, looking like a sort of dimple on its surface. At other times the hernia was not quite so large, but was unusually bulky for so young a patient. The child's family history was good, both parents being living and healthy. The patient was also in good condition, with the exception of the trouble mentioned. Dr. Roberts stated that he was not inclined to attempt the radical cure of non-strangulated hernia as often as some surgeons, because he believed the slight risk of operation was unjustifiable in many of the troublesome hernial protrusions; and because the radical cure was often radical in name only. As there was every prospect that this enormous hernia would still further increase in size with age, it was decided to undertake an operation which, if it did not produce a radical cure, would at least diminish the size of the ring and permit subsequent treatment with a truss. The phimosis was to be operated on at the same time, as the straining in urination was evidently a cause tending to increase the hernia, if indeed it was not the original exciting cause of the intestine being forced down through the unsealed inguinal canal. The hernia was evidently of the congenital form—no true hernial sac, but the intestine lay in the tunica vaginalis testis.

On December 20th the patient was etherized for operation. He took the ether poorly, but without any bad effects. The incision for the herniotomy was made in an oblique line over the scrotum, the external abdominal ring and inguinal canal, and was nearly three inches in length. This was done while the tip of the forefinger of the operator's left hand was held in the external ring, having been placed there by invaginating the integument of the scrotum. This was done to prevent the reduced intestine from descending through the ring. The ring was half an inch in diameter—enormous in an infant of four months. After the hernia was thus reduced and retained by the finger, and the primary incision made, the canal was opened up to the internal ring. As there was no hernial sac proper here, the operator had nothing with which to plug the external ring and canal, and had to be content, therefore, with attempting occlusion of the passage, through which extrusion occurred, by simply suturing the walls of the canal and margins of the rings together. This was done as thoroughly as possible with sutures of catgut and silk, carried by means of a curved cervix needle. Obliteration of the ring and canal, so far as could be done without injury to the cord, was accomplished; and the hernia thus well retained within the abdomen. Some sutures were also applied to the upper part of the vaginal tunic of the testicle where it was continued upward as a patent canal, communicating with the peritoneal sac, in which the hernia had lain. The fascia and integument were sutured separately, and a few strands of catgut laid in the lower angle of the wound for drainage.

The phimosis was then operated upon by slitting the prepuce up on the dorsum and subsequently cutting away the redundant integument and mucous membrane, and suturing these two structures together with catgut around the circumference of the glans penis. Dry antiseptic dressings were then applied, both to the hernial wound and to the penis. The temperature after the operation was 101°, and remained elevated for the first three days. Two and a half grains of quinia sulphate in suppository, and five drops of sweet spirits of nitre were given every four hours to lower the temperature. This treatment was discontinued on the sixth day.

The dressings required frequent changing, because it was impossible to prevent access of urine to the region of the herniotomy, though vigorous attempts were made by covering the dressings with rubber tissue. Everything went well until the seventh day after operation, when the child began to show the first symptoms of influenza, which was then prevailing as an epidemic in the city. He had a slight diarrhœa and some coryza. On the eighth day, the temperature being still normal, the stitches were removed from the site of the hernial operation, when union was found to be good, and but a single drop of pus appeared, at the upper angle. Subsequently there was a further discharge, but it never occurred in any considerable quantity. The influenza, however, went on increasing, until by the tenth day severe bronchitis developed, and threatened the life of the child. The chest was rubbed with a liniment of yolk of egg, turpentine and vinegar; and 1 grain of chloride of ammonium, 5 drops of syrup of ipecac, 5 drops of sweet spirits of nitre, and 10 drops of syrup of senega were given every two hours as a cough mixture. The 2½ grain suppositories of quinia were also resumed, and a jacket poultice of wool placed upon the chest. By the eleventh day symptoms similar to those of meningitis developed, and added to the gravity of the case. The pupil of the right eye was markedly contracted and brows drawn; there was constant motion of the head and extreme restlessness, with a cry of pain. The temperature by this time was 104.4°. A warm bath was given, and cold water dashed on the breast to deepen the breathing, and cold was applied to the head. This was repeated several times during the day, and after the bath mustard was applied to the spine, behind the ears, and around the ankles. Two grains of bromide of potassium was given every two hours in anise water. The temperature was still high, 105.4°. The child continued very ill for nearly a week longer. One grain of iodide of potassium was added to 3 grains of bromide of potassium every two hours, and continued until improvement commenced. Later, 5 drops of syrupus ferri iodidi, three times a day, were administered, and the child rapidly convalesced. The hernial wound did well, and by January 9th, when the patient had recovered from the influenza, was entirely healed, retaining the bowel perfectly within the abdominal cavity. The wound made by the operation of circumcision did well also.

When the child was last seen, a week or ten days after leaving the hospital, the hernia was still undescended. Dr. Roberts advised that a spica bandage of the groin be continued until the firmness of the cicatrix was greater. He spoke of the probability of the hernia recurring, but believed that even in such a case the tumor would be small and manageable by a truss. The recovery of the child after such a severe attack of epidemic influenza, superadded to the operations was, in his opinion, principally due to the unremitting efforts of Dr. Fullerton, the physician in charge of the hospital.

MEDICAL PROGRESS.

Stricture of the Urethra.—J. WILLIAM WHITE reaches the following conclusions:

1. Strictures of large calibre, that is, of more than 15 French, situated at or behind the bulbo-membranous urethra, are to be treated, almost without exception, by gradual dilatation.

2. Strictures of large calibre occupying the pendulous urethra are to be treated by gradual dilatation when very recent and soft, and by internal urethrotomy when of longer standing, distinctly fibrous in character or non-dilatable. It is to be remembered that the great majority of so-called strictures of large calibre of the pendulous urethra are merely points of physiological narrowing.

3. Strictures of the meatus and of the neighborhood of the fossa navicularis should be divided upon the floor of the urethra whenever it is evident that they are real pathological conditions producing definite symptoms and not normal points of narrowing.

4. Strictures of small calibre (less than 15 French), situated in advance of the bulbo-membranous junction, unless seen very early and found to be unusually soft and dilatable, furnish the typical condition for internal urethrotomy, which should be done preferably with a dilating urethrotome and, invariably, with all possible antiseptic precautions.

5. Strictures of small calibre (less than 15 French), situated at, or deeper than, the bulbo-membranous junction, should be treated whenever possible by gradual dilatation. In a case of resilient, irritable or traumatic stricture in this region, or of stricture which, for any reason (as the occurrence of rigors), is non-dilatable, external perineal urethrotomy is the operation of choice.

6. Strictures of the deep urethra, permeable only to filiform bougies, should be treated by gradual dilatation when possible, the filiform being left *in situ* for some time, and followed by the introduction of others, or used as a guide for a tunneled catheter. If the stricture be not suitable for dilatation, external perineal urethrotomy should be performed.

7. Impassable strictures of the deep urethra always require the performance of perineal section.—*University Medical Magazine*, March, 1891.

Ointment for Acne.—*L'Union Médicale* states that ISAAC uses the following prescription in acne:

℞.—Resorcin		½ to 1 drachm.
Powdered oxide of zinc Powdered starch	}	of each 1 drachm.
Vaseline		2 drachms.

This is to be applied day and night to the affected part. If it is not desired to apply it during the daytime, it may be removed by the aid of olive oil and soap and followed by an inert absorbent powder.

Treatment of Alopecia.—MONIN recommends the following treatment of alopecia:

℞.—Gallic acid	45 grains.
Olive oil	6 drachms.
Vaseline	1½ ounces.
Essence of lavender	15 drops.

This is to be made into an ointment and applied with friction to the part affected morning and night for the arrest of the disease.—*L'Union Médicale.*

Treatment of Laryngitis.—MOURE recommends the following to be used in the treatment of laryngitis:

℞.—Crystallized carbolic acid	7–15 grains.
Hydrochlorate of cocaine	7 "
Opium	1½ ounces.
Distilled water	10 "

This may be applied by means of a brush three times a day, or

℞.—Boric acid	1 drachm.
Crystallized resorcin	½ "
Cherry-laurel water	1½ ounces.
Distilled water	10 "

This mixture may be used in an atomizer for from three to five minutes morning and night, or three or four times a day if the condition of the throat is subacutely affected.—*La Tribune Médicale.*

Treatment of Acne.—CAPOZI recommends in the treatment of acne the following solution:

℞.—Washed and precipitated sulphur Powdered glycerin Carbonate of potassium Cherry-laurel water Alcohol	}	of each 2½ drachms.

After thoroughly washing the part which is affected this mixture is to be applied at night, and may be replaced by an application of oxide-of-zinc ointment or glycerin.

Treatment of Diarrhœa by Salol.—MONCORVO has published an interesting paper concerning the use of salol in infantile diarrhœa. He considers it an exceedingly useful agent in the production of intestinal antisepsis in infants who are affected with enteritis or entero-colitis. The passages rapidly diminish in number under the influence of the drug and lose their disagreeable odor a few days after administration. The flatus which arises from intestinal fermentation is decreased by the action of the salol. He thinks that the drug may be used with advantage in infants of all ages, and that it is very rare for it to produce any untoward effects. The dose which he employed was from 2 to 30 grains in twenty-four hours, according to the age and gravity of the case.—*Revue Internationale de Bibliographie Médicale.*

The Treatment of Cardiac Asthma.—*The Journal de Médecine de Paris* gives the following treatment of FERRAND for cardiac asthma, which is divided into several parts. The general treatment consists in the administration of 2 teaspoonfuls of the following solution every morning:

.—Iodide of sodium	6 drachms.
Infusion of inula	10 ounces.

At night, after supper, two tablespoonfuls of a solution

of bromide of sodium and aconite are to be given, made as follows:

℞.—Bromide of sodium . . 6 drachms.
Tincture of aconite . . . 16 drops.
Infusion of hops . . . 8 ounces.

The treatment of an attack of asthma is to inspire steam arising from a vessel of hot water, and if possible containing the fumes of ammonium. 5 drops of the following mixture may be given every five or ten minutes:

℞.—Laudanum . . . . 1 drachm.
Cherry-laurel water . . 1½ drachms.

At the same time a subcutaneous injection of the following will be found of advantage:

℞.—Sulphate of atropine . . . $\frac{1}{10}$ grain.
Sulphate of morphine . . 3 grains.
Cherry-laurel water . . 2½ drachms.

Twenty minims of this may be injected at a time. After the attack has passed by, the following may be given:

℞.—Extract of stramonium, Valerianate of zinc } of each 1 grain.

Treatment of Coryza.—In the treatment of coryza Kola recommends that a teaspoonful of powdered camphor be added to a pitcher of boiling water, and that a cone of paper be placed over the mouth of the vessel, the other end of the cone being placed over the nose and mouth of the patient. The vapor which arises from the water is charged with the camphor, and may be inhaled for from five to ten minutes. Three inhalations are usually sufficient to arrest the most rebellious coryza. These inhalations provoke a most abundant secretion from the nasal and pharyngeal mucous membrane, and exert a favorable effect upon the inflamed parts.—*L'Union Médicale.*

Hæmoglobinuria from the Use of Quinine.—The *Revue Internationale de Bibliographie Médicale* states that Coromilais has recently observed six cases of hæmoglobinuria due to the ingestion of sulphate of quinine, thereby confirming the earlier observations of Beretas regarding the so-called hæmaturia produced by this drug.

Trichloracetic Acid as a Caustic.—This acid has been largely employed by Ehrmann in the treatment of maladies of the nose and throat. A crystal of the acid may be applied to the part affected, when it forms a white scab, which is rapidly detached. From an experience with 140 cases Ehrmann concludes that this acid occupies the first rank in the treatment of maladies of the nose and pharynx. It may be used with great advantage with an astringent, and the following formula is recommended by the writer:

℞.—Iodine . . . . . 4 drachms.
Iodide of potassium . . 5 "
Trichloracetic acid . . 4 to 8 "
Glycerin . . . . . 8 "

Apply to the part with a tampon.

One drop of this solution is not disagreeable, and it is followed by very little pain. In the treatment of follicular tonsillitis Ehrmann found it to produce a cure after three applications, and in two cases of ozæna the effects were very good indeed. Among fourteen cases of chronic pharyngitis there were eight cures and six notable ameliorations. A number of other instances are given in which equally good results were obtained —*L'Union Médicale.*

Pills for Dysentery.—The following pills used in the treatment of dysentery have given satisfactory results:

℞.—Powdered ipecac . . . 4 grains.
Calomel . . . . . 1½ "
Extract of opium . . . 1 grain.

Make into three pills, and give one each hour, in the treatment of diarrhœa or dysentery due to exposure to heat.

Treatment of Sciatica.—Jaccoud gives the following treatment for cases of sciatica. During the acute period severe counter-irritation or local depletion may be resorted to over the affected limb and hypodermic injections of morphine are to be given. If anæmia is present to any great degree severe vesication is not to be applied. If the disease is due to rheumatism it should be treated by the internal administration of salicylate of sodium given in the dose of from ½ to 1 drachm a day. Other cases may require large doses of quinine. Jaccoud prescribes the hydrobromate of quinine in the dose of 15 to 30 grains a day, and continues it until the symptoms of its physiological action become manifest. In this case the treatment is suspended for one or two days and then begun again. When sciatica passes into a chronic state in which it recurs, it is best to administer a mixture containing iodide and bromide of potassium in the dose of from ½ to 1 drachm each to be dissolved in a suitable vehicle, such as sarsaparilla. Externally resorcin may be resorted to and simple vapor baths or turpentine vapor baths may be used. The pain may be relieved by morphine.—*L'Union Médicale.*

The Treatment of Phthiriasis Pubis.—Fournier in *L'Union Médicale* gives the following applications for the treatment of this troublesome condition:

℞.—Distilled water . . . . 12 ounces.
Alcohol . . . . . 3 "
Corrosive sublimate . . . 15 grains.

Or,

℞.—Vinegar . . . . . 9 ounces.
Corrosive sublimate . . . 15 grains.

Add to double this quantity of water and apply as a lotion. Sometimes applications of oil with beta-naphthol may be employed.

Iodo-carvacrol, a New Antiseptic.—This preparation, which is isomeric with thymol, is formed from carvol, a derivative from caraway, dill and mentha crispa. Just as thymol, treated with iodine and iodide of potassium in the presence of an alkali yields aristol, so carvacrol similarly treated forms a yellow-brown precipitate which can be reduced to the form of a powder. This is called iodo-carvacrol and is available for the same therapeutic purposes as aristol.

Antiseptic Application for Diphtheria. — LE GENDRE recommends the employment of

℞.—Borate of sodium Chlorate of potassium	of each	1 drachm.
Carbolic acid		3 grains.
Glycerin		2½ drachms.
White honey		1 ounce.

The mixture is to be applied to the portion of the throat which is involved in the disease by means of a camel's-hair brush.—*La Tribune Médicale*, February 5, 1891.

Abortive Treatment of Herpes.—In those persons in whom herpes occurs periodically and produces much pain and discomfort LELOIR recommends the employment of resorcin, thymol, or menthol in one of the following solutions:

℞.—Resorcin	30 grains.
Alcohol	3 ounces.

Or,

℞.—Menthol	30 grains.
Alcohol	4 ounces.

If the pain following this application is very severe, the following formula may be employed in place of the other two:

℞.—Hydrochlorate of cocaine	15 grains.
Extract of cannabis indica	2½ drachms.
Essence of peppermint	2½ "
Alcohol	4 ounces.

It is also well to cover the sore spot with some impermeable dressing, in order to protect it from the air.—*Gazette Hôpitaux de Paris*, December 18, 1890.

Treatment of the Vomiting of Pregnancy.—The *Deutsche medicinische Wochenschrift* recommends the following treatment for vomiting of pregnancy:

℞.—Creasote	10 drops.
Acetic acid	20 "
Sulphate of morphine	1 grain.
Distilled water	1 ounce.

A small teaspoonful every half-hour until four doses have been taken.

Treatment of Effusion in the Knee-joint.—In the London *Practitioner* for February, 1891, OWEN describes his treatment for effusion into the knee-joint. He says:

In some instances the aspirator was employed, but in others the distended joint was dealt with by a hydrocele canula of about the gauge of a No. 1 English catheter. In the use of either instrument the surgeon must take care that it is aseptic, and that the skin through which it is to be introduced is not only "cleansed" but clean. Moreover, he must not operate with "unwashen hands." Another point to be attended to when using the canula is that just as the fluid is ceasing to flow the surgeon should block the end of the instrument with his finger, and so withdraw it that he does not introduce air into the joint.

A canula thus used is as safe as an aspirator, and it has this recommendation, that it is sure to be in working order. If an ordinary canula and trocar cannot be used with security, peritoneal cavities, ovarian cysts, and vaginal tunics should have been in the habit of suppurating. This we know is not the case. It is very much the fashion now, however, to drop the simple word "tapping," or its equivalent "paracentesis," and, with a homage to euphemism, to employ the term "aspiration."

To the practitioner it matters not whether the fluid is blood or sero-synovia. He has merely to obey the indication. If the joint has begun to swell up directly after the injury, the distending fluid must be blood; but if a day or more have intervened between the hurt and the swelling, the fluid has been poured out by the inflamed synovial membrane. Such fluid is a mixture of synovia with serum; often it is stained with blood.

Dr. Owen has never known any trouble to follow the tapping of a joint; he adopts it as a routine treatment in the case of fracture of the patella as well as in the more simple variety of distention.

As a rule, the puncture is made to one side of the patella. When withdrawing the canula the track is obliterated by firm pressure with the finger. The skin puncture is covered with a scrap of lint dipped in collodion, or by a little pad of dry wool. The knee, together with the upper half of the leg and the lower half of the thigh, is then enclosed in lateral splints of house-flannel and plaster-of-Paris. The limb is fixed in the extended position, the foot being slightly raised. The firm pressure which is made around the joint is comforting, and it effectually prevents further effusion into the synovial membrane.

Having watched the effect of this method of treatment, Dr. Owen can honestly say that, should he have the bad luck to be the subject of acute traumatic hæmarthrosis or sero-synovial effusion of the knee, he would most certainly have the joint treated in the manner described. And he should ask that the site of puncture might be first numbed by the application of a piece of ice and some salt.

Treatment for Gonorrhœa —

℞.—Opium	7 grains.
Acacia	7 "
Saffron	15 "
Boiling water	5 ounces.

Make an infusion, filter, and add

℞.—Acetate of lead	20 grains.
Sulphate of zinc	45 "

Use as an infusion in the later stages of gonorrhœa. In place of this the following may be employed:

℞.—Pyridine	6 to 8 drops.
Distilled water	2½ ounces.

Use three to four injections of this a day.

Treatment of Seborrhœic Eczema.—DUBREUILH states that this affection, which is difficult of treatment, will yield to the following application, if made twice a day:

℞.—Oxide of zinc	2 drachms.
Washed sulphur	1 drachm.
Salicylic acid	15 grains.
Vaseline	1 ounce.

Current Literature.

SATURDAY, APRIL 11, 1891.

SYRINGO-MYELIA.

Charcot and Brissaud (*Le Progrès Médical*, January 24, 1891) report a case of peculiar interest. The patient fifteen years ago, at that time twenty-five years of age, visited Professor Charcot for a nervous affection giving rise to an incoördination in the gait and a feebleness of the entire left side of the body. There was an incoherence in his movements, together with great increase in the patellar reflex, and associated with these were painful cramps in the lumbar region, extending across the abdomen in the direction of the psoas muscle and down the inner face of the thigh and the anterior surface of the leg. The action of the adductors of the thigh and extensors of the foot was so exaggerated that the patient walked upon the external border of the foot. The limb was absolutely rigid and his gait resembled an infantile hemiplegia complicated with a certain degree of athetosis. The patient came of a family whose male members were in robust health, and from this fact, together with the symptoms he presented, it was evident that his disease had nothing in common with tabes. Charcot decided that he had a spasmodic spinal affection, the origin of which he could not determine, but that the affection was certainly not tabes. Hydro-therapeutic treatment was instituted and followed with some regularity for six months. Then the patient, who was an officer in the army, rejoined his regiment, and Charcot lost sight of him.

Fifteen years later, in September, 1890, the same man again consulted the Professor. To the spasmodic hemiplegia, which had formerly been his whole complaint, were now added various nervous manifestations which formed a very complex condition. The contracture due to the spasmodic condition was very pronounced in the arm and leg, but more so in the leg. While walking the forearm was semi-flexed, the leg stiff, moving as one piece, and oscillating from side to side, and the foot rested upon the external border rather than upon the sole. The toes were elevated, the plantar surface facing internally. There existed a slight lumbar scoliosis, with the concavity turned to the left. The patellar and olecranon reflexes were greatly exaggerated. The spinal epilepsy once provoked, persisted indefinitely. The plantar reflexes were also exaggerated. The movements of the left arm and shoulder were very limited, the member, with the exception of the hand, being almost completely impotent. The entire right side was normal. Upon neither side did a muscular atrophy, properly speaking, exist, but the muscles of the left side were not so well developed as were the right. There were no fibrillar tremblings. The cutaneous sensibility was intact upon both sides, while the thermic sensibility, both for heat and cold, was almost totally abolished *upon the entire left half of the body, including the face, the tongue, and the pharynx.* The patient was unable to perceive very high or very low temperatures. The sensorial sensibilities were intact. The analgesia and thermo-anæsthesia dated from 1882, and only had therefore eight years of existence. The left hand in its entirety was much more voluminous than the right—it was large, thick, and flat, without having increased in length. The fingers were voluminous and bloated; the skin rugous; the folds of the palmar surface deepened. The whole appearance of the hand approached the type of acromegalia. The metacarpo-phalangeal and phalangeal articulations were sensibly hypertrophied, the fingers not being uniformly cylindrical. These multiple unilateral arthropathies, limited to the left hand, were of trophic origin. Such was the condition of the patient at the time of his second visit in 1890.

The significance of this case is very important. It would appear from this history that syringo-myelia may, during a long period of years, present itself under the form of a *pure and simple spasmodic hemiplegia*. Such a condition has not, as yet, to the author's knowledge, been noted.

THE RECENT RESEARCHES IN DIPHTHERIA.

Among infectious diseases diphtheria is the one which during the last two years has been most thoroughly investigated. The specific cause of the disease has been discovered, its biological properties studied, the poison isolated, and its mode of action determined. Klebs, in 1883, was the first to note the existence of a specific bacillus in the diphtheritic false membrane and upon the surface of the subjacent mucous membrane; but it was not until 1884 that Löffler studied the bacillus and its actions most completely. He, however, did not pronounce himself in favor of the specificity of the bacillus, for three reasons: the absence of paralysis after positive inoculations, the presence of a similar bacillus in the mouth of a healthy child, and the absence of the specific bacillus in several typical cases of diphtheria. Such was the state of the question when it was taken up by Roux and Yersin (1888 to 1890), who have definitely demonstrated the specificity of the Klebs-Löffler bacillus. As to the existence of the pseudo-diphtheritic bacillus, these investigators pronounce in favor of an affinity between the two bacilli, one of which becomes virulent only under certain conditions. The reasons upon which they base their belief are the following: The pseudo-diphtheritic bacillus exists in the mouths of healthy individuals and of those who have non-diphtheritic angina. But this non-virulent bacillus, which is very rare in fatal diphtheria, is most abundant in benign diphtheria, becoming more common in proportion as severe diphtheria approaches a cure, and in the latter case is more numerous than in the mouth of a healthy person. These facts show, then, that there is a direct relation between the two bacilli, of which the one does not exist in the attenuated form of the other. This hypothesis appears much more probable, since the cultures of the pseudo-diphtheritic bacillus possess certain pathogenic properties, and provoke œdema more or less considerable, according to the nature of the animal.

The bacillus of Klebs is ordinarily found upon the free surface of the false membrane; but in some cases the most superficial layer of the membrane is covered by divers microbes, rods, micrococci, and chains, mixed with masses of the Klebs bacillus, which are, on the contrary, predominant immediately below. These bacilli are colored blue by methyl, rapidly coagulate serum at a temperature of 33° C., and more slowly nutritive gelatin, where they take a characteristic appearance. The bacillus is nearly the length of the bacillus tuberculosis, but thicker, its extremities are rounded and take the blue color more vividly than the central portion. It is immobile and exists in great numbers. After some days of culture the medium, formerly alkaline, becomes acid; this acidity persists for a long time, and is then replaced by an alkaline reaction. It preserves its vitality during a long time, and at the end of five months can be revived if kept at a temperature of 33° C. Dried and kept at this temperature it succumbs at the end of three or four months. The false membrane preserves its virulence after five months of desiccation; exposed to the sun and rain the membrane becomes sterile in one or two months. These facts are very important from a practical point of view, and explain certain cases of apparently spontaneous diphtheria.

The bacillus of Klebs, or the diphtheritic virus, when placed in contact with healthy mucous membrane does not provoke diphtheria; but a single lesion, a slight erosion, is sufficient for the infection to take place. The morbidity and the mortality also of diphtheria rise rapidly during the cold seasons. The mortality is particularly high in countries exposed to abrupt changes in temperature. As to the action of the diphtheritic bacillus in producing the disease, Klebs, Löffler, Roux, and Yersin, as well as others, have remarked that the bacillus does not invade the organs, is never found in the blood of patients or of inoculated animals, and remains confined to the primary false membrane. It is not, therefore, the bacillus itself which gives rise to the grave accidents which characterize diphtheria and its poisoning. It is evident that the morbid symptoms are produced by a poison secreted at the point of infection by the bacillus, which, taken up by the general circulation, may be carried into the tissues of the organism. This idea, started by Löffler, who considered the poison as a diastase or enzyme, was also expressed by Roux and Yersin. They pronounce in favor of the poison being a diastase, and have secured it nearly in a state of purity by means of the dialyzer. The researches of Babès in 1890 have confirmed all that Roux and Yersin have advanced. Carried by the cells and the liquids of the organism, the poison forms in the depth of the mucous and sub-mucous tissues similar nests to those upon the surface, and gives rise in this way to the various phenomena of the disease.

By daily microscopical examination of the false membrane it is possible to note the progress of any case of diphtheria toward a cure, as shown by a decrease in the number of the Klebs bacilli present. As regards treatment, cauterization of the membrane with a strong solution of phenol, washes for the mouth, and gargles, will avail most in arresting the infection of the organism.—ROMME, in *La Tribune Médicale*, January 29, 1891.

DISSOCIATION OF THERMIC SENSIBILITY IN SYRINGO-MYELIA.

IN *La Médecine Moderne*, February 5th, DEJERINE and THUILANT report a case of syringo-myelia occurring in a man thirty-four years of age, who presented a spasmodic paraplegia and atrophy of the muscles of the left hand and forearm, associated with fugitive pains in the lower limbs. There was a hyperostosis of the left olecranon, with diminution in the faradic and galvanic contractility of the muscles of the arm, without the reaction of degeneration. There was absolute integrity of the tactile sensibility of the entire cutaneous surface, as well as of the sensation of pain. There was complete sensibility for all temperatures below 20° C. upon the entire surface of the body, but by the skin of the upper extremities and of the trunk high temperatures could not be detected. Severe burns could be inflicted upon these portions of the body without the patient having any knowledge of the injury. In the other portions of the body the sensibility to heat was preserved. The insensibility to heat in the upper portion of the body acquired its maximum intensity in the hands, especially upon the palmar surfaces, in the forearms, and in the lower half of the arm.

The patient dying, soon after admission to the ward of the hospital, from an advanced tuberculosis of the lungs, an autopsy was performed thirty hours after death. An extreme flattening of the spinal cord was noted, extending from the first cervical portion to the level of the lumbar enlargement, the cord resembling a flattened ribbon. A cavity of large dimensions extended the entire length of the cord to the lumbar enlargement, where it diminished, and at this level small gliomata jutted out into the centre of the cord. There was a slight neuritis of the cutaneous nerves of the forearm, and intense neuritis of the muscular nerves corresponding to the atrophied muscles.

This case is of special interest clinically, from the proof which it gives of the possibility of encountering in the course of syringo-myelia a separation in the thermic sensibility, the sensibility to cold being preserved, while that to heat or high temperature is lost. It will be interesting to seek in the future, in analogous cases, for the opposite condition, the loss of the sense of cold, with the preservation of the power to distinguish high temperatures. From a physiological point of view the case reported sustains the opinion of those authors who admit the existence in the spinal cord of special conducting fibres for heat and for cold.

CORRESPONDENCE.

OLIVE OIL, OR COTTON-SEED OIL, IN GALL-STONE COLIC.

To the Editor of THE MEDICAL NEWS,

SIR: Having given the subject of the use of olive oil in the treatment of gall-stones some thought, I have

been especially interested in your editorial in the issue of March 14th. You express some surprise that Dr. Stewart's theory did not receive mention in the recent discussion by the North Carolina Medical Society. In my "Report on Practice of Medicine" submitted to the last annual meeting of the Virginia State Medical Society, published in the volume of *Transactions* for 1890, you will find the following reference and criticism:

"Dr. David D. Stewart, of Jefferson Medical College, thus explains the action of olive oil or cotton-seed oil in gall-stone colic: The pancreatic juice, by means of the fat-splitting ferment, steapsin, decomposes the oil in the duodenum into fatty acids and glycerin. The glycerin acts on the duodenum in the same way in which it affects the rectum when used by enema, withdrawing water, and causing hyperæmia and irritation of the afferent nerves of the part with which it comes in contact, thus leading to powerful reflex peristalsis. This irritation would also cause reflex contraction of the gall-bladder, cystic and common bile-ducts, thus promoting the expulsion of stones sufficiently small. The diffusibility of glycerin would also enable it to enter the gall-bladder and ducts leading therefrom, and produce similar depletion of the vessels there, locally, and reflexly promote contraction of muscular fibres. A copious outflow of diluted bile would also promote the dislodgment of stones. No satisfactory explanation has heretofore been offered as to the efficiency of the oil; and as it seems probable that glycerin can produce the effect now under consideration, it is likely that it is caused by it. If this can be proven, yet the oil would have to be given, as the hygroscopic properties of glycerin would cause its dilution if given by the mouth, so that it would be too weak by the time it reached the duodenum.

"To prevent the nausea and difficulty in retaining the oil, he uses, half an hour beforehand, the following:

℞.—Cocaine. . . . . ⅓ grain.
Comp. tr. cardamoms
Spts. chloroform } of each 10 minims.

"There are several objections to this theory. It seems to take too much for granted. The physiological explanation may be all right so far as it goes. The main difficulty is the promptness of relief and the size of the dose. Just how much of the oil would have to undergo the change spoken of, we do not know; but is the interval of half to three-quarters of an hour that elapses before relief is experienced, long enough for it to be accomplished? It is given, too, in such doses that quantities of it appear in the stools unchanged. If glycerin given by the mouth would be so diluted before reaching the duodenum as to be of no service, the bulk of the oil would interfere with its action when formed from it by pancreatic juice. Beside that, the pancreatic juice itself would be so diluted with the oil, that we believe its effect would be scarcely perceptible in the time stated. We certainly do not believe that it can in so short a time split up *enough* of the oil into glycerin and fatty acids as to cause the unusual irritant and local reflex action described above. The theory, however, is an ingenious one, and well worthy of consideration."

TRANSMISSION OF DIPHTHERIA FROM BIRDS TO MAN.

To the Editor of The Medical News:

Sir: In the May issue of the *Annual of the Universal Medical Sciences*, an article clipped from the *British Medical Journal*, from the pen of M. Jules Menard, appears, relating to the transmission of diphtheria from birds to man, wherein the author asserts that the disease is never transmitted from one to the other. To use his own words: "There is no analogy between that form of diphtheria (which affects birds) and the disease as it affects human beings."

I wish to report a case which occurred recently in my own practice which, I think, demonstrates quite conclusively that the disease is sometimes transmitted from man to birds, if not from birds to man:

On November 16th, during an epidemic of diphtheria in this city, C. D., aged three years, was attacked by the disease. Under the usual treatment the child made a good recovery. On November 23d, seven days after the child became sick, a red-bird, which was confined in its cage in the same room with the child, sickened with all the symptoms of diphtheria, and the following day a canary, whose cage hung beside that of the red-bird, was attacked in the same manner. On the following day both birds died. Now the question arises, Was this a case of "bird diphtheria" (so-called), developing spontaneously during the time the child was affected, or was it due to direct transmission of the disease from the child to the birds? I am inclined to the latter opinion.

F. Horton, M.D.

Newcastle, Wyo.

NEWS ITEMS.

Iowa State Medical Society.—The fortieth annual meeting of the Iowa State Medical Society will be held at Waterloo on Wednesday, Thursday, and Friday, April 15th, 16th, and 17th, under the Presidency of Dr. W. D. Middleton, of Davenport, Iowa. A cordial invitation is extended to members of the profession to attend the meeting.

Medical Ignorance.—The following clipping from the Elk Hart (Indiana) *Review* has been sent to this office:

One of our physicians recently received the following letter from a country physician (?): "Dear dock I hav a pashunt whos phisicol sines shoes that the windpipe has ulcarated of, and his lung have drop intoo his stumick. he is unabel to swoller and I feer his stumick tube is gon. I hav giv hym evry thing without efeckt. his father is welthy Onerable and influenshial. he is an activ membber off the M. E Chirsch and god nose I dont want too loose hym. what shal I due. ans buy returne male. yours in neede."

Mississippi Valley Medical Association.—The Mississippi Valley Medical Association will hold its seventeenth annual session at St. Louis Wednesday, Thursday, and Friday, October 14, 15, and 16, 1891. A large attendance, a valuable programme, and a good time are expected. Members of the medical profession are respectfully invited to attend.

The following officers have charge of the meeting: C. H. Hughes, M.D., President; E. S. McKee, M.D., Secretary; I. N. Love, M.D., Chairman of Committee of Arrangements.

Association of American Physicians of Berlin.—About forty American physicians held a meeting on February 19, 1891, at Berlin, in order to found a permanent organization, such as exists in Paris, London, Edinburgh, and Vienna.

Professor Miller, now Professor at the University of Berlin, called especial attention to the fact that such an organization would not only greatly benefit the physicians who remain here for purposes of study, but also that it would call the attention of Germany to the forward tendency of American medical science. He strongly urged the publication of the *Transactions* of the Association every year.

A permanent organization was effected—Dr. Judson Daland, of Philadelphia, being elected as President, and Dr. F. Weber, of Milwaukee, as Secretary.

Professor Miller, Dr. Amos, of Iowa; Dr. H. Douglas, of New York; and the President and Secretary were elected as a Committee on Constitution.

As a Committee on Information to New-comers and on Organization of Special Private Courses, Dr. H. T. Brooks, of New York City; Dr. Louis Frank, of Louisville; Dr. Crystal, of Baltimore; Dr. Neal Mitchell, of Florida; Dr. Marple, of New York; and Dr. Kennedy, of Montreal, were appointed.

The objects and scope of the Society, as set forth in the preamble, are:

First. The arrangement of medical work and the formation of special private courses so that any desired instruction may henceforth be obtainable at this University.

Second. The giving of advice to new-comers regarding instruction, lodging, books, instruments, etc.

Third. The reading and discussion of papers of general interest, exhibition of patients, and demonstrations of specimens in all lines of work taken up by members.

Fourth. The furthering of mutual ends by a more extended acquaintance of the physicians here.

The Society at its first session listened to an interesting demonstration of specimens of myocarditis segmentaire, and of a blood-cyst of the aortic valve by Dr. Henry Douglas, of New York City. Dr. Weber then demonstrated specimens of blood of leukæmia and pernicious anæmia, and talked of the value of Ehrlich's method of blood-staining. Dr. Daland talked about malaria and relapsing fever in Russia, and demonstrated the pathological microörganisms of these diseases.

An interesting discussion of these papers followed, thus at once making the benefit of the Association apparent to all.

Drs. Fitzgibbon and Mead, of Wisconsin, and Navy Surgeon Kenyoun were present as visitors. Professor Miller then kindly offered the use of the Dental Lecturing-room of the University, Dorotheen-strasse 40, as a permanent meeting-room for the Society.

New-comers and others desiring information will please apply to the Secretary, Dr. Frederick R. Weber, Charité, Berlin.

Congress of American Physicians and Surgeons.—The meetings of the Congress of American Physicians and Surgeons will be held in Washington from 3 to 6 P. M., September 22, 23, 24, and 25, 1891. William Pepper, M.D., Chairman of the Executive Committee.

Licensing Boards.—At the suggestion of Dr. William Perry Watson, Secretary of the State Board of Medical Examiners of New Jersey, Dr. Rauch has called a meeting of one or more representatives of the various medical licensing boards in the United States, to be held in Washington, D. C., on May 6th, during the meeting of the American Medical Association, in order to effect a permanent organization and to make rules and examinations as nearly uniform as possible. Licensing boards now control medical practice in twenty-one States. It is expected that much good will come of this meeting.

Tuberculosis in Public Schools.—The Health Officer at Milford, Michigan, reported to his State Board that several deaths by phthisis had occurred in the public schools, and that school attendance had been noticeably affected thereby. He inquired of the Board if any pupil or person known to have pulmonary consumption should be excluded from school, as is required in the case of scarlet fever and other contagious diseases. The Board adopted resolutions declaring that such cases should be excluded during the active stages of the disease and until the symptoms of cough and expectoration cease.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 4, 1891.

STEPHENSON, F. B., *Surgeon.*—Ordered to the U. S. S. "Marion."

BERRYHILL, T. B., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Marion."

WHITE, C. H., *Medical Inspector.*—Ordered to the U. S. S. "Baltimore."

CLARK, J. H., *Medical Inspector.*—Ordered to the U. S. S. "San Francisco."

HOEHLING, A. A., *Medical Inspector.*—Detached from President of Naval Examining Board.

CRANDALL, RAND P., *Assistant Surgeon.*—Promoted to Passed Assistant Surgeon, February 27, 1891.

BROWNELL, CARL DEWOLF, of Bristol, R. I.—Commissioned an Assistant Surgeon in the Navy, April 1st.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE TREATMENT OF SUPPURATION WITHIN THE FEMALE PELVIS.

BY NIEL MACPHATTER, M.D.,
OF DENVER, COLORADO.

I HAVE used the above caption in order to include all cases of suppuration, whether arising as the result of pelvic hæmatocele or that following inflammatory conditions of the tubes or cellular tissue. I do so in order to illustrate a principle in the treatment which I considered a great advance on that usually adopted, and one that has not yet received that attention to which it is entitled.

Turning first to abscess of the ovary and pyosalpinx, one cannot but be struck with the frequency of their occurrence. These are found in all ages from puberty on. How frequently they do occur has not yet been definitely determined, but sufficient evidence has been produced to show that they occur much more often than is generally believed, for large quantities of pus may lie in the ovary or tubes without producing any marked symptoms. As proof of my statement, I may only refer to the investigations of such men as Gregg, Fowler, and Lewars. The latter, after a careful investigation of one hundred consecutive deaths in women from all causes, found that no less than seventeen had had pyosalpinx. Of this number eight deaths were attributable directly to this condition.

It is not my desire to spend much time in consideration of the treatment of these two conditions, for the almost universal consensus of opinion in the profession is in favor of abdominal section, but will pass on to that of pelvic abscess proper. As there is a lack of opinion on the proper treatment in this disease, I will devote the balance of my paper to this important matter. As a preface, and speaking in general, there is no class of disease more unsatisfactory to treat nor more unfortunate to the patient than a pelvic abscess that has burrowed along a tortuous course and ruptured into the vagina, rectum, or bladder. This statement can be followed up with a parallel one equally true, that no class of disease which the gynecologist meets is more amenable to treatment than a pelvic abscess, providing it is taken before rupture and the formation of sinuses takes place; nor is there one to which he can insure more permanent relief.

Much discussion has taken place upon this important subject, because of its frequency and the evil consequences that often follow it. The views, I may say warnings, so persistently, but none too urgently, expressed, are becoming more generally recognized every day: and the claim that physicians delay too long in recommending surgical interference in many classes of female complaints, is in few of these more clearly justified than when a woman has a quantity of pus in her pelvis. Not only is there a great risk to life, but when deep and irregular sinuses take place, all lines of treatment become much more unsatisfactory and complicated. Occasionally, when the pus cavity ruptures it heals spontaneously, and the patient soon regains her health. This result is fortunate and much to be desired, for the number that rupture and periodically fill and discharge their contents, and continue as fistulous openings, is altogether too numerous.

Barring operations upon the vagina, cervix, or uterus—too often the starting-points of inflammatory conditions—I have long maintained, and recent events have added to the conviction, that in the history of a pelvic abscess, from an inflammatory cause, there are two periods in the treatment that call urgently for all the care and judgment of the physician, in order to prevent the catalysis that may occur. The first is, when sero-fibrinous exudations of lymph are thrown out, to cause a reabsorption, and thereby to avoid the formation of pus altogether. The second is, when the first object cannot be attained and the formation of pus goes beyond absorption, to have it evacuated by artificial means before it ruptures into some outlet, causing tortuous and irregular sinuses that will probably go on discharging for months or even years. When a severe attack of pelvic peritonitis, or so-called cellulitis, takes place about the third or fourth day after the onset of pain and fever, sero-albuminous and sero-fibrinous exudations are thrown out which can be detected by vaginal or abdominal examination. This exudation has at first a soft, almost boggy or doughy feeling, but afterward becomes much harder. In general, its size and extent will correspond to the severity of the attack. Not unfrequently all the cellular tissue, together with the tubes and ovaries, will be involved. It is at this stage of the process that much can be accomplished by careful and judicious treatment. The grand aim and object should be to aid in the

absorption of this exudation of serum, so that none may be left to cause the formation of pus. During this state perfect and absolute rest should be enjoined. This is peculiarly necessary. A sufficient amount of bland, unstimulating nourishment should be given. Local applications, such as poultices or flannels wrung out of hot water and turpentine, have often a beneficial effect. We are generally taught in our text-books that opium should be the main internal remedy given. Why this idea has become so thoroughly inculcated in the professional mind it is difficult to understand, unless it be on account of the advice long since given by the late Alonzo Clark, who recommended it in heroic doses in peritonitis and kindred diseases. His advice has been the cause of an incalculable amount of mischief. When you consider the physiological action both of the drug and the peritoneum, it will become apparent, and practical experience every day substantiates the conclusion, that, instead of being of benefit, opium is absolutely contra-indicated. What I have stated about the use, or rather abuse, of opium, finds its counterpart and applies with even greater force to the indiscriminate and empirical use of hot vaginal douches.

What will be found to be a beneficial remedial agent is small and frequently repeated doses of magnesium sulphate or Seidlitz powders, to secure a gentle daily motion of the bowels. When absorption has begun, small blisters of cantharides, about the size of a silver dollar, over the tumor, will be found excellent adjuncts. The patient should not be allowed to get up until long after all traces of enlargement and tenderness have disappeared.

Fortunate is the physician and thankful should be his patient when the trouble terminates in this happy manner. Occasionally, notwithstanding all care and skill in the treatment, absorption does not take place. It may take a variety of courses. It may remain for a long time stationary, ultimately breaking down and changing into an ichorous fluid and from that into offensive pus; or, it may form into numerous small abscess cavities in different compartments. These may remain an indefinite length of time encysted, but they ultimately burrow along through tortuous tracks and eventually rupture in some direction. The most frequent seat of this rupture is into the vagina, rectum, bladder above Poupart's ligament, or into the peritoneal cavity. All these are unfortunate terminations. The pus cavity will in all likelihood refill and keep discharging, rendering the patient a chronic invalid and making life a burden.

So soon as the medical attendant recognizes that the formation of matter has taken place, he should not delay in the hope that it will evacuate spontaneously, but should have it removed artificially and without delay. The principle I here advocate of opening these abscesses through the abdominal cavity, followed by subsequent drainage, is one that has given such excellent results as to justly entitle it to be considered the most satisfactory of all abdominal operations. When properly done it is almost entirely free from danger.

As suppuration is very frequently the result of the breaking down of a pelvic hæmatocele, and as the treatment is identically the same as when arising after inflammatory causes, it will be appropriate here to give a short paragraph to a consideration of the cause of this accident; and here we come upon a peculiarly interesting subject. It is now necessary to recognize the importance of the broad ligament in a physiological, but more particularly in a clinical, sense. Here lies the boundary line between a sudden, serious, and most alarming condition, and one of comparative safety. Both frequently result from the same course, yet the broad ligament draws a sharp line of distinction between their severity. It is not necessary for one to give a detailed anatomical description of these ligaments. It will suffice my purpose to say merely that they contain between their folds important vessels, and that any injury to these vessels will cause an effusion. From anatomical and physiological considerations, these effusions are either into the abdominal cavity or downward between these folds, giving us the two varieties of hæmatocele—intra-peritoneal and extra-peritoneal—the former fatal, if left to nature, ninety-nine times in a hundred, primarily from hæmorrhage or secondarily from suppuration and subsequent peritonitis. Everyone who has had much experience in abdominal surgery is familiar with the tendency there is for bleeding to continue when it occurs within the peritoneal cavity. Whether this is owing to the lymph which is always present there, rendering the blood too dilute for coagulation, or acting as an irritant and causing an increased secretion, it does not show much tendency to cease, save in a very imperfect manner. It rather keeps on until a dangerous, if not fatal, amount is poured out. This is quite otherwise with extra-peritoneal hæmatocele. There, as I have already stated, the effusion takes place between the folds of the broad ligament. There will be no lymph present there to render the blood too dilute for coagulation; on the contrary, it comes into contact with cellular and connective tissue, most powerful and natural hæmostatics. Again, the folds of the ligaments themselves form a limited cavity, so that it is almost impossible for a sufficient amount of hæmorrhage to take place to be dangerous to life. For these reasons this variety is not nearly so dangerous or fatal as when the effusion is into the peritoneal cavity.

It is due to the arrest of metrostaxis at the time

of normal menstruation, or to that pseudo-menstruation that occasionally follows operation on the ovaries or tubes. It is not dangerous, but delays convalescence for some time. It nearly always becomes absorbed, and seldom requires interference. A very frequent cause of this variety is the rupture of a tubal pregnancy downward. A hæmatocele of this kind comes on too suddenly to be inflammatory, and is indicated by a feeling of faintness, pain in the pelvis, small, rapid pulse, and sometimes the temperature rises. By examination there will be felt a soft, semi-fluctuating, doughy mass. The size will correspond to the amount of hæmorrhage. It is sometimes so extensive as to completely fill the cavity. When this is so, the rounded upper part can be felt above the brim of the pelvis. The upper limitations will correspond to the distended folds of the ligament. A remarkable and characteristic feature of this variety is an annular contraction of the rectum, caused by the blood pressing upon the lumen of the bowel, which renders defæcation difficult.

There can be but little doubt that many women have a metrostaxis following normal menstruation, and recover without ever consulting a physician. I am persuaded that a great number of these abscesses do not become absorbed, but go on to suppuration, and, eventually, if the surgeon does not come to the rescue, they burrow along in some direction, and finally rupture.

Heretofore, and, indeed, at the present time, the treatment usually adopted when the formation of pus takes place is by an opening made by a trocar or bistoury through the vagina, or waiting until the abscess finds an exit for itself. When they refill and discharge, efforts are made to facilitate drainage by dilating the sinus. I cannot regard but with apprehension the introduction of such instruments into these inflamed tissues. Such treatment is beset by innumerable difficulties and dangers. Experience daily illustrates the fact that there is considerable danger in passing a trocar, or other instrument, through the roof of the vagina. Beside the risk of doing irreparable injury to the bladder or a ureter, or to an artery, there is the uncertainty of finding the pus cavity. Should the surgeon be so fortunate as to come upon it, there is liable to be a *centre of débris* that cannot be removed in this manner. There is yet another probable chance that several pus cavities may be present, and then such treatment would not even be palliative, for obvious reasons. It is utterly absurd to endeavor to treat these cases, after their rupture, by dilating the sinus. I can understand that, when the abscess is well down and breaks directly into the vagina, such an opening may be all that is necessary; but these favorable cases are the exception. To follow the devious windings of sinuses high up is next to impossible. But the point I wish particularly to emphasize is, that we should not delay until this complication takes place, but as soon as pus is found accumulating we should have it removed without delay. Why the principles and laws that guide us in the accumulations of pus within the female pelvis should be different from those for the management of abscesses in other parts of the body, I cannot understand.

When properly done, the difficulties of the operation are comparatively few and the dangers are almost completely in the hands of the operator; so that to one accustomed to perform these operations the mortality is almost *nil*. When, however, the case has been neglected until the patient is reduced in health, and already has discharges of pus into the rectum, vagina, or bladder—and in those cases where all the pelvic viscera are bound down and matted together by dense adhesions—the difficulties become much more serious. Securing the walls of the abscess cavity to the abdominal walls, under these circumstances, becomes a troublesome task. This only illustrates the tenor of my argument, which is: Do not delay until this complication takes place. The general conclusion gathered from my own experience and from that of others is, that abdominal section for such abscesses is not a serious operation; that the recovery is much more rapid and certain; and that I cannot too strongly urge the advantages of this method of treatment.

1627 California St.

FIVE CASES OF SUPRAPUBIC CYSTOTOMY:

Three for Stone, One for Tumor in the Bladder, and One for Exploration with Catheterism of the Ureters; One Death.[1]

By W. W. KEEN, M.D.,
Professor of the Principles of Surgery, Jefferson Medical College, Philadelphia.

Case I. *Stone in the bladder; suprapubic cystotomy; prostatectomy; recovery.*—I was called to Vineland, N. J., September 12, 1888, by Dr. C. R. Wiley, to see Mr. B., aged sixty-five. He had had the usual symptoms of stone in the bladder for six years. A Petersen's bag was inserted in the rectum and distended with ten ounces of warm water. The bladder was injected with six ounces of water with four grains of boric acid to the ounce. Suprapubic dulness then existed to two inches above the pubes. The operation was done by the usual vertical incision, and two stones were removed, weighing together 763 grains. The prostate projected so much into the bladder at the mouth of the urethra that I removed a piece a slarge as the last joint of the finger, by the scissors. The bleeding was slight. The bladder was not sutured. A drainage-tube was inserted and removed on the tenth day: a catheter was retained in the bladder for four days more.

[1] Read before the Philadelphia Academy of Surgery, April 6, 1890.

The patient recovered without any trouble, his highest temperature being 100.6°, falling to normal, both morning and evening, within a week. The wound healed entirely in four weeks.

In July, 1889, he had a return of his old symptoms, and Dr. Joseph W. Hearn, being in Vineland, was asked by Dr. Wiley to see him again. Dr. Hearn having detected a stone by the sound, reopened the former wound by dilating a small fistula which had appeared, then crushed and removed two stones, weighing 412 grains in all. After that time he was well until his death recently from another disease, as Dr. Wiley informs me.

I have no question that the stones removed by Dr. Hearn had formed since the first operation, for the entire interior of the bladder was inspected at that time and no further stone was detected.

CASE II. *Ankylosis of the knee; stone in the bladder; suprapubic cystotomy; recovery.*—R. J. B., of Bridgeton, N. J., first consulted me June 19, 1888. A tall, spare man, aged forty-three, with ankylosis of the left knee from a white swelling twelve years ago. Has also suffered considerably from rheumatic gout, and has a deformed right hand following it. There is also considerable ankylosis of both elbows. He passed a stone from the bladder for the first time in 1876, and since then has passed dozens of them, mostly phosphatic, and he has had also renal trouble from gravel, attended with hæmaturia, seven or eight years ago. He has passed no stone by the urethra for eighteen months, but his present attack of vesical irritation has existed for three years. He is obliged to empty the bladder from one to four times an hour. Urine, specific gravity 1011, small amount of pus and albumin, with phosphates; reaction faintly alkaline.

Operation, June 4, 1888. The patient desired that the "high operation" should be done in order that the condition of the bladder could be explored by the eye and the finger at the same time that the stone was removed. The ankylosis of the knee, as well as his wish, made me decide to do the suprapubic operation. The rectal bag was distended with ten ounces of warm water, and the bladder with seven ounces of water with four grains of boric acid to the ounce. The dulness of the distended bladder extended two inches above the pubes. An incision two and one-half inches long was made and the bladder easily reached, except for the difficulty with the anæsthetic, as mentioned later. An incision two inches long was made in the bladder and the stone was extracted. Its shape was that of a flattened sphere; it weighed 421 grains when dry, and its surface was quite smooth except at the edges.

The bladder wound was then closed with eight stitches of interrupted fine chromic catgut. The bladder was now injected with warm water combined with the boric acid in order to test the accuracy of the closure of the wound. No water escaped. The wound was then filled with water and the bladder was injected with nine ounces of air, when instantly a leak was discovered by the air bubbling up through the water. A stitch closed this, and made the bladder both air- and water-tight. Six stitches closed the wound in the abdominal wall, which included with care the aponeurosis of the abdominal muscles. The peritoneum was not recognized during the operation. A flexible catheter was inserted into the bladder, and its end was at first corked up and the bladder emptied every hour; but, as this caused some pain, the catheter was uncorked and continuous drainage into a urinal substituted.

6th (2d day). He has had no pain; his highest temperature is 100°; he is hungry, and has slept well. The wound was re-dressed yesterday, when everything looked well.

Four days after the operation there was considerable local tenderness and irritation, and on the sixth day this was so marked that I removed the stitches and evacuated some urine and pus, which had formed as a result of the giving way of the stitches in the bladder. The wound was drained for a few days and then closed, and he went home on the 25th, three weeks after the operation. Since that time he has had no trouble.

REMARKS.—No other operation than the suprapubic could have been done in this case on account of the ankylosis of the knee. The operation was an extremely difficult one, because unless he was deeply anæsthetized he was struggling, with the abdominal walls as tense as boards, and in order to relax them anæsthesia had to be carried to a point which I felt involved serious danger. Between Scylla and Charybdis it was very difficult to steer a safe course. The difficulty was especially great in suturing the bladder. In fact, I think it would have been wiser had I not attempted to do so, but had simply drained.

CASE III. *Stone in the bladder; surgical kidneys; death from sudden œdema of the lungs.*—W. H. C. was referred to me by Dr. Julius A. Johnson, of Easton, Md., December 11, 1889. His age is fifty nine; his weight two years ago 185 pounds; at present about 135 pounds. Seven to eight years ago he first noticed that his water was passed very slowly. Four years ago had a brief attack of apparently acute inflammation of the bladder. Two years ago another attack of acute inflammation, with very thick urine, and required catheterization; has used a Nélaton catheter himself more or less ever since. Passes his water about ten times in the twenty-four hours; has never passed any blood, except as a result of the use of the catheter, he thinks. Has no pain in the small of the back, but suffers severely in the bladder and perineum, for which he has taken from one-half to one grain of morphia a day for about two years. In spite of his wasting, his appetite is good, and also his sleep, excepting that it is interrupted by the necessity of passing his water.

Eight years ago, while brushing his teeth, he touched a nerve, he thinks, and for a few minutes his face was "drawn." From one to two years later, while going home to dinner, his left arm and leg became weak, and he had no use of them for a

few minutes. He did not fall, but sat down, and after a short time walked home. A few times since then he has felt as if a similar weakness was coming on; seizing his wrist stopped it. In October, 1888, on a Saturday he had a fever and a chill from exposure to cold. On the following Tuesday his wife gave him a hot toddy. A little while afterward, while sitting in a chair, a "queer look" came over his face, so his wife states, and for a few minutes he "talked thick," but after that had no further trouble. He has never had any headache.

He has had at least three considerable hæmorrhages from the bladder. He is not quite sure, but thinks that the hæmorrhages came on only at the end of micturition, except the last time, when the urine was uniformly bloody from the beginning. The longest of these hæmorrhages continued for two to three days. By spells the urine has been alternately clear and bloody, and its passage attended with considerable soreness, which passed away as soon as the hæmorrhage occurred.

Once he passed a small calculus the size of a pea, and probably one hundred of about the size of a pin-head; these last at varying times.

Operation, December 26, 1889. I was assisted by Professor Brinton and Drs. Horwitz and Coplin. Owing to the bad condition of his kidneys, chloroform was given instead of ether. The field of operation was thoroughly prepared the day before. Petersen's bag was inserted into the rectum and distended with twelve ounces of warm water. I had not examined his bladder instrumentally before, as it gave him great pain even to introduce a soft instrument, and in view of his general poor health and the damaged condition of his kidneys, I determined not to give an anæsthetic twice. In order to fill the bladder as well as to explore it, I now introduced a silver catheter. The instant it entered I struck an evidently large stone. After washing out the bladder, nine ounces of warm, boiled water were introduced through the catheter; as soon as this limit was reached the water began to escape alongside of the catheter, and to prevent its further escape, rubber tubing was tied around the penis. Notwithstanding this double dilatation, the belly was still resonant down to the pubes, though the resonance slightly diminished as the pubes were approached. An incision was made in the middle line from the pubes three inches upward. As soon as the belly-wall was cut through, the peritoneum was encountered, reaching all the way to the pubes. It was readily lifted to the upper end of the incision, but as it was more than usually thin, and required an additional assistant, I determined at once to get rid of this necessity and danger, by placing the patient in Trendelenberg's position. A tall, stout nurse, with his back to the patient's perineum, took the patient's knees over his shoulders and thus lifted the pelvis about a foot from the table. The peritoneum at once disappeared at the upper extremity of the incision. The bladder was still so deep that a possibility, even, of its rupture from the injection suggested itself to me. It was found, chiefly by the aid of the catheter which had been placed in it, at a depth of three inches from the skin. Several large veins were first ligated, both on the bladder-wall and in the connective tissue in front of it. The bladder was then opened, and one large and three small stones removed. The small stones were about the size of Lima beans; the large one crumbled down, under the grasp of the forceps, into a number of fragments; the stones were phosphatic. The weight of all that was recovered was just 600 grains, and I estimated that fifty or sixty grains were lost in the débris in washing out the bladder. The wall of the bladder was much pocketed, and the three small stones were found in these pockets, and would almost inevitably have been overlooked had any other operation than the suprapubic been done. They were readily extracted by the finger in searching for fragments. The prostate, which had been found but little enlarged toward the rectum, was greatly enlarged on the vesical aspect, the enlargement being chiefly in the middle line and to the right, forming a uniform, rounded mass, bulging into the bladder just behind the orifice of the urethra, but not blocking it. Prostatectomy, therefore, was not done.

The walls of the bladder were rugose and about three times their natural thickness. The wound in the bladder was not closed. A drainage-tube of soft rubber with a bulbous end was introduced into the bladder. As there was so large a space between the bladder and the abdominal wall, I thought it prudent also to introduce a second drainage-tube for the first forty-eight hours into the pre-vesical space. The abdominal wall was then closed by interrupted sutures, the two drainage-tubes coming out together at one interspace.

31st. Reacted very well from the operation. For two days he had slight vomiting, and on the third and fourth days considerable hiccough, which yielded to one-quarter grain doses of cocaine. His temperature fluctuated between 97.9° and 99.6°, only once reaching 100°. The wound was irrigated through the drainage-tube with warm boric acid solution. The pre-vesical drainage-tube was removed at the end of forty-eight hours.

When I left him at 5 P. M. on the 30th (the fourth day) I felt very well satisfied with his condition and quite assured of his recovery. So far as could be judged, the amount of urine secreted was ample, and there was no danger apparently from the kidneys. At 9.30 P. M. on the night of the 30th acute œdema of the lungs set in, followed by death in seven hours. No post-mortem could be obtained.

Remarks.—This operation was only undertaken in view of the urgent symptoms. The bad condition of the kidneys and his serious antecedent history of cerebral disturbance of course contra-indicated operation, but his suffering from the stones in the bladder was so intense that relief was absolutely necessary. That life was terminated by the sudden œdema is not to be wondered at in view of the renal complications.

No case ever showed me better the value of Trendelenberg's position. The moment he was placed

in that position, not only did the peritoneum fall down and away, but the bladder was made accessible, although being so deeply placed. Neither the rectal bag nor filling the bladder with water raised it to the abdominal wall, and I was seriously afraid that the bladder had been ruptured, although no more water was injected than the capacity of the bladder easily permitted.

CASE IV. *Papilloma of the bladder; removal by suprapubic cystotomy; recovery.*—Mr. S., aged fifty-seven. (The following history was furnished by Dr. Lorini, his medical attendant.) Family history negative; no cancer. He had malaria in the sixties with biliary fever. He had marked trouble with his gall-bladder from 1878 to 1881, and visited Carlsbad, since which time he has had no return of the trouble. There is no history of urinary calculus or gravel. In 1885 he had an attack of cystitis with blood in the urine for a few days. He was circumcised in 1887. For thirty years he has had a sense of discomfort in the small of the back. About August 1, 1889, after a horseback ride at Ocean Beach, N. J., bleeding from the bladder began, but yielded to internal remedies after two days. August 15th, another attack came on and continued for a few days, but yielded again to the same remedies. In January, 1890, a third attack lasted for nine weeks, in spite of internal remedies and the actual cautery over the back. In April and May his bladder was washed out with boric acid and nitrate of silver solutions of various strengths. After five days the bleeding stopped, but returned again about the middle of June, and continued up to the middle of August, in spite of the use of the nitrate of silver and boric acid solution. He spent the summer in Maine and gained greatly in health. The capacity of the bladder was undiminished, and the urine contained neither casts nor albumin when there was no blood. There was slight prostatic tenderness. The blood was always thoroughly mixed with the urine from the very start, whether drawn by catheter or voided voluntarily. Clots were passed from time to time. These were of irregular shape and seemed to be fewer and smaller when he led an active life, more numerous and larger when he rested. No shreds of tissue have ever been found, in spite of the most careful watching, except one minute specimen, which was thought to be papillomatous, and the deeper cells possibly sarcomatous, by Dr. F. A. Packard.

November 13, 1890, the hæmorrhage returned more profusely than ever, and has continued to the present time, in spite of internal remedies, washing out the bladder, hypodermics of ergotine, etc.

Status præsens, Dec. 7, 1890. When I saw him for the first time, at this date, I found a short, stout man who appeared to be in good health, but with an anæmic, pale skin, and who was evidently suffering from the mental depression incident to the continued hæmorrhage. He had lost but little flesh, and his anæmic appearance, as was stated to me by Dr. Lorini, who had known him for many years, and under whose care he now was, was habitual and not a result of the bleeding, a rather surprising fact in view of the amount of blood lost. I saw him void his urine, which was porter-colored from the first drop. There were some small clots of irregular shape, and from the amount of urine passed and its color and clots I estimated that the amount of blood lost was not far from half a pint a day. Dr. Crozer Griffith examined a specimen of the urine for me. It showed no casts; a large amount of blood was present, with an excess of white blood-cells, which in some places were adherent to each other in masses, as in cystitis and other suppurative processes. No epithelial cells were found. Fragments of possible tissue were examined and found to be only clots which had rested somewhere in the urinary tract sufficiently long to become largely fibrinous. The urine contained 2 per cent. of urea. The blood count showed 3,890,000 blood cells, 53 per cent. of hæmoglobin, and no plasmodia. A careful examination of the region both of the bladder and the kidneys, not only by myself but by Drs. Lorini, W. J. Taylor, J. William White, and William Pepper, was entirely negative. There was no dulness, no tenderness, no pain, but simply hæmaturia and nothing more. On December 13, 1890, I attempted to examine the bladder by the cystoscope, but was unsuccessful in detecting anything. The bloody urine was first drawn and replaced with a warm boric acid solution, but in spite of the most careful use nothing further could be seen.

The day after the use of the cystoscope he observed in urinating that some air or gas bubbled out. I attributed this naturally to some air which had been injected into the bladder with the fluid, but he called my attention to this difference: that at the present time the gas produced no pain, but that when air was injected it produced distinct pain as it often had done a year ago when washing out his bladder. This discharge of air or gas has continued up to the present time. It does not occur with each act of urination, but occurs at least once a day, and takes place at the end of urination, not at any other time. It is especially noticed when he strains to press out the last few drops from the bladder. So far as he can observe the gas has no odor, and I have observed that the urine has none, nor have the clots that have been passed. He has had no pain in his bladder or rectum.

His wife tells me that she thinks there is a distinct loss of strength in the last few weeks, and also that for the last year or more he has been more drowsy than formerly.

Operation, December 29, 1890. Assisted by Drs. J. William White, William J. Taylor, Orville Horwitz, J. C. Da Costa and Dr. Lorini, his physician. The bladder was first washed out and then filled with 9 ounces of a boric solution, a drachm to the pint. The Petersen bag in the rectum was then dilated with warm water, but as soon as the capacity of eight ounces was reached the resistance became so great that I desisted from introducing any more. An incision in the median line disclosed the bladder, which was secured by two ligatures and then incised. As soon as the finger was introduced I perceived a

small tumor near the right ureter. With the electric light it was inspected, though with some little difficulty. In doing so I used both Watson's vesical speculum and my own, but each had to be supplemented by a long pair of forceps to push back the posterior wall of the bladder. The tumor was about the size of the end of the forefinger, say a little over half an inch in diameter, and about the same in elevation. It was strawberry-like in its appearance, though not quite so red. Near to it were two other small elevations of the size of a moderate pin-head, which were thought possibly to be the beginning of similar growths. There were several other very minute growths, but so small as to make it doubtful whether they were normal or pathological.

The tumor and the two small elevations near it were seized by the forceps and drawn forward somewhat forcibly, and the mucous membrane for some little distance around the base was removed with the tumor by curved scissors. The bleeding was very moderate and required no special means for its control.

One stitch was put in the wound in the bladder and four stitches in the abdominal wall. Two drainage-tubes were introduced, one into the pre-vesical space and the other into the bladder, both secured in place by stitches in the skin. A large wood-wool dressing was then applied over the wound, and aristol ointment spread over the abdomen under the dressing. The dressing was to be changed whenever it was wet, and the bladder to be washed out with a warm boric acid solution.

He was put to bed in a very fair condition. During the operation Trendelenberg's position was also tried, but its advantages were not very manifest. Still there was, I think, slightly greater ease of access to the bladder. The ureters were seen and an attempt was made to catheterize one of them, but without obtaining any urine. In justice to the procedure, however, it should be said that we did not persist long enough, probably, to make the attempt valuable. We had found sufficient to account for his condition, and we did not deem it just to him needlessly to prolong the operation.

No communication was discovered between the bladder and the bowel, though the interior was carefully examined at every point.

January 1, 1891 (the third day). Since the operation, now three days, he has gone on steadily improving. His highest temperature was on the night following the operation, since which time it has been 99° and a fraction. The wound looks perfectly well. On the second day he developed spasmodic pain, which he referred to the prostate, the attacks of which were quite severe. Thinking that it might be due to the pressure of the end of the drainage-tube in the bladder, I removed this rubber tube and replaced it with a shorter tube of glass, but during yesterday, his pains being so severe, Dr. White, as I was absent from the city, removed the tube from the pre-vesical space. This was not followed by immediate relief, but with some amelioration of the attacks, and finally their disappearance at the end of about twenty-four hours. The tube in the bladder I removed to-day. His appetite is very good, so that he enjoyed a small chop yesterday and a small beefsteak to-day. His sleep has been very fair.

3d (fifth day). He has had a good deal of vesical tenesmus, for which I cannot see any reason. The wound looks well. Two of the four stitches were removed to-day; some small shreds of sloughing connective tissue came away. In examining the rectum a few days ago Dr. White thought he detected a nipple-like prominence, just as would exist if there were a fistulous opening in the rectum, and at the operation a pouch in the posterior wall of the bladder was discovered, which possibly corresponds to this, although no opening or other lesion could be detected either at the operation or since. A large enema yesterday emptied the bowels thoroughly, and there has not been, either from the bladder or from the bowels, any evidence of communication between the two.

From this time on he improved very rapidly. His pain quickly lessened and the wound closed at the end of five weeks. Since that time he has been perfectly well. There has been no escape of fæces or of gas from the urethra, nor has there been the least return of the bleeding.

The tumor was examined by Dr. J. P. Crozer Griffith and Dr. Burr, and was found, on section, to be a compact sessile form of papilloma without any filiform fringes.

Case V. *Possible tumor of bladder; boutonnière operation; later exploratory suprapubic cystotomy, with catheterism of the ureters by the aid of the electric light; recovery.*—M. H., of Mauricetown, N. J., aged twenty-eight; weight 121 pounds. Was referred to me by Dr. Samuel Butcher, November 22, 1889. Family history negative. No venereal history. On June 5, 1887, when he rose from bed he passed clear blood from the bladder without pain and without apparent reason, he being then apparently in perfect health. The blood was intimately mixed with the urine from the very first drop. With slight intervals the urine has been bloody ever since. A week after the hæmaturia he became a little better, when a sudden retention for twenty-four hours was followed by the evacuation of a quantity of clots. There are usually no clots, but the blood and urine were intimately mixed. For the first year he suffered a little pain; since then he has only had slight pain in the loins, possibly more marked on the left side. In June, 1888, he had bilious fever, and in December, 1888, and January, 1889, clots accumulated again and required a catheter. He thinks that occasionally the clots were long and slender, especially when few in number, being one to two inches long and about the thickness of a pin.

When clots accumulate in the bladder he has considerable pain near the anterior superior spine; his water then clears up and is apt to be more colored when the pain disappears. No calculus is discovered by sounding, and there is no pus in the urine. He passes about the usual quantity and urinates five or six times a day. Nothing is found in the urine by microscopic examination but blood. A small amount of albumin is present when there is blood

in the urine, but when there is no blood the urine is absolutely free from albumin.

Dr. Hearn examined the patient some months ago, and believed that there was a papilloma in the bladder. I admitted him to the Jefferson Hospital in December, 1889, and watched the urine with great care. No long, slender clots were at that time found, but only irregular-shaped clots. Small fragments of a possible papilloma were watched for carefully, but only one or two were found at intervals, which were believed by Drs. Longstreth and Coplin to be fragments of a doubtful papilloma. The renal symptoms were practically *nil*, for the pain in the loin was but slight, and scarcely more marked on one side than on the other. No increase in the dulness over either kidney was noted, nor was there any tenderness on palpation by one hand nor on bimanual examination. The tenderness near the anterior superior spine only existed when there were clots in the bladder, and there is no tenderness at present.

First operation, January 3, 1890. I explored the bladder by the boutonnière opening. As soon as the finger entered the bladder, I found at the upper right wall posteriorly a soft, velvety mass. Whether it was a tumor or the bladder-wall I was not able definitely to decide. I introduced a pair of smooth-bladed stone-forceps until the bladder-wall was touched, then withdrawing them half an inch and closing the jaws I found that I had grasped something, which by traction gradually yielded with a sensation as if thread after thread was being torn. In the jaws of the forceps was a florid mass, looking not unlike a blood-clot, but traversed by threads which looked like fibrous tissue. Nothing like mucous membrane was seen. A number of small masses were removed in this way, amounting in all to a mass about twice as large as an English walnut. Twice I tried Sir Henry Thompson's serrated tumor forceps, but both times, in spite of using every precaution, I found that I had caught the bladder-wall, as was manifested by its not yielding after the same gentle traction as before, and by the mucous membrane being drawn into the wound. The bleeding was inconsiderable. Watson's perineal drainage tube was inserted.

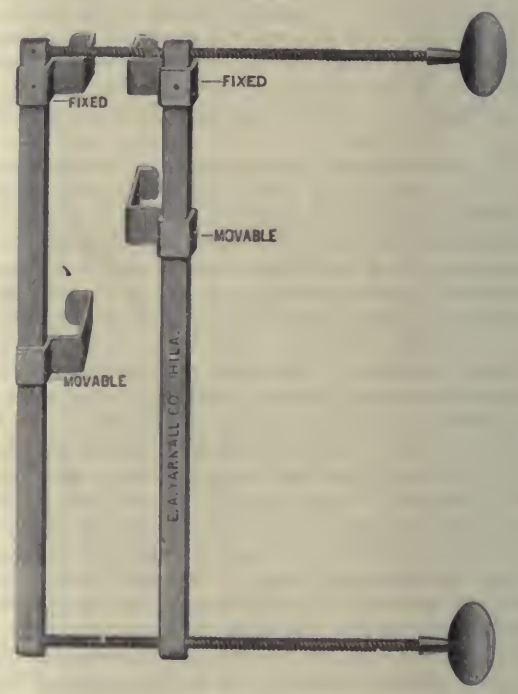
He recovered from the operation without difficulty, the wound closing in twenty days, at which time he went home. The urine at first cleared up considerably, though afterward it again became bloody, but two months later it was almost clear. The mass removed was again submitted to Drs. Longstreth and Coplin, but in spite of careful examination they were still doubtful whether the masses were blood-clots or fragments of a papillomatous growth, although rather inclined to the latter opinion.

May 23d. He has gained fifteen pounds in weight, feels much better, and has had no pain since the operation. The urine has generally been clear until the last two or three weeks, when the blood has reappeared, with small clots. I have repeatedly seen him pass his water, both before the operation and since, and it is uniformly bloody from the start.

November 15th. I examined the bladder by the cystoscope, but could only see a uniformly red and apparently healthy bladder-wall.

Second operation November 18th, at the Jefferson Medical College Hospital. Nine ounces of warm boric-acid solution (four grains to the ounce) were injected into the bladder, and eleven ounces of warm water into the rectal bag. The injection into the bladder alone produced dulness of but one finger's-breadth above the pubes. This was increased, by filling the rectal bag, to 2.5 inches. A three-inch incision in the middle line disclosed the bladder very readily. The peritoneum was not seen. The bladder was opened, and the edges of the opening caught with two hæmostatic forceps. A special retractor, which I had devised (Fig. 1), was

FIG. 1.



then inserted, in order both to separate the recti muscles and the edges of the opening in the bladder, and a small, hooded, two-candle power electric light was used to examine the bladder. A prior examination by the finger the moment that the bladder was opened gave an entirely negative result. The examination by the electric light was extremely satisfactory; on the right upper and posterior wall of the bladder was seen a scar about one and one-half inches in diameter, evidently the result of the first operation. It was smooth and healthy. I found a good deal of difficulty in examining the posterior wall, inasmuch as the bladder contracted as soon as the water escaped, and was thrown into deep folds. By inserting the angular large hæmostatic forceps, or pedicle forceps, and opening the blades, I was able to push the bladder upward and unfold the creases in its wall. To obviate this difficulty I have lately devised another instrument (Fig. 2) which as yet I have not had an opportunity to test. I then

discovered between and above the orifices of the ureters a small ulcer, a scant quarter of an inch in diameter, possibly tubercular. A piece of the bottom of it was pinched off for examination microscopically, but showed no bacilli.

Fig. 2.

Bladder-dilating instrument.

I found that I could examine the posterior wall of the bladder a great deal better when the rectal bag was removed. The orifices of the two ureters were seen, and both successfully catheterized. From the left ureter bloody urine was obtained, and from the right one clear urine.

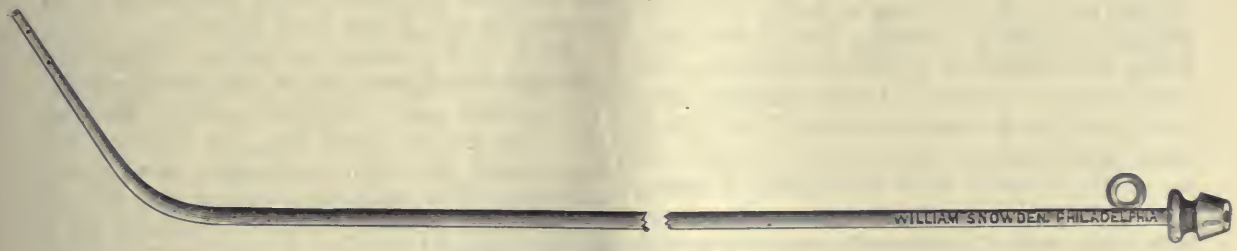
When the urine escaped into the bladder no difference in the urine from the two ureters was perceptible, as the red wall of the bladder made both look alike. But when they were collected in a small glass cup the difference in their appearance was instantly perceptible.

recovery. He still has bloody urine. Whenever he is ready I intend to explore the left kidney.

Remarks.—In the case of M. H. (Case V.) I have been a good deal puzzled as to what it was that I removed at the first operation. Certain it was that the mass was adherent to the bladder wall, and certain it was, also, that it was not the mucous membrane. The differentiation by means of the two kinds of forceps was perfectly clear. In some way the blood-clot apparently became attached to the wall of the bladder and sufficiently attached for its removal to leave a visible scar.

The catheterization of the ureters in this case by the aid of the electric light was perfect. I beg to call especial attention to the fact that the difference in the color of the urine from the two kidneys could not be noticed so long as the urine escaped into the bladder, for the uniform redness of the mucous membrane prevented the true color from being detected. Only when the water was drawn in a glass was the difference between the two distinctly perceptible. Whether the hæmaturia which is now determined to be from the left kidney is a case of hæmophilia, pure and simple, for which Brown[1] has recently done a successful nephrectomy, or whether there is any true disease of the left kidney I do not know. It was only after the catheterization of the ureters that the significance of the slender, cylindrical clots was really known. It is true that the question of ureteral clots had been considered, but yet when I saw him nothing had been seen that resembled them, nor was it at all

Fig. 3.



Instrument for catheterizing the ureters.

To facilitate this ureteral catheterism I have devised an angular catheter which I believe will be of service (Fig. 3).

The opening in the bladder was then stitched, except at its lower end, where a drainage-tube was inserted. The external wound was partly closed.

December 8 (three weeks). The patient went home to-day. The drainage-tube was removed on the second day after the operation. The rest of the wound healed very well, but the opening in the bladder did not close until two weeks after the operation. Until that time the urine had been much freer from blood, but it now became much more bloody. No especial incident attended his

certain that they were anything more than accidental. They were certainly not common.

As a result of my present experience with the boutonnière and the suprapubic operations, I would certainly prefer the latter as by far the better. In view of the persistent hæmaturia, with its baneful effects both on mind and body, I propose to explore the left kidney whenever the patient is ready, and if the indications point that way, to do a nephrectomy.

[1] American Journal of the Medical Sciences, November, 1890, p. 522.

Case IV. resembles this one in many ways. In both the hæmaturia was the only symptom present, and the diagnosis was correspondingly obscure. Although Mr. S. had the advantage of the most skilful diagnostic opinions, yet it was with great doubt as to whether the papilloma really existed in the bladder or not, that the operation was begun. It was clear, however, that something ought to be done, for the disease was making inroads on the patient's nervous system quite as much as on his physical condition. The kidney was so absolutely exempt from any indication of disease, that it did not seem right to explore there; and even if I had decided to do so, the question *which* one, was still a difficult one to solve. I would call especial attention to the fact that in both these cases the urine *was uniformly bloody from the beginning of micturition.* In the case of M. H. (Case V.) it ought to have been so, for it came from the kidney, but in the case of Mr. S. (Case IV.) it ought not to have been so, for as a rule a tumor in the bladder bleeds only toward the end of micturition when it is squeezed by the contracting bladder. The element of uncertainty thus introduced was very puzzling.

SURGERY OR ELECTRICITY IN GYNECOLOGY.

BY HORATIO R. BIGELOW, M.D.,
OF PHILADELPHIA.

"THE difficulty of separating a man from his opinions tends often to give scientific controversies the appearance of a personal attack, when nothing should be further than that from the minds of those engaged upon the questions at issue. Jealousy for truth should so absorb the attention of all honest workers that friction of thought, as afforded by free discussion, should be courted as a means for stimulating the intellectual processes essential to the development of science. If the maintenance of individual opinion is the chief object in such discussions, they degenerate into trials of strength, and are utterly useless so far as the interests of science are concerned. Indeed, one might as well contend with a stone wall as to attempt to argue with a mind that is not open to conviction."[1] This is very happily phrased, and altogether truthful. Who shall define the "stone wall?" If my "doxy" be not to the liking of my professional brother over the way, he immediately infers that I am not open to conviction, because I cannot accept his demonstrations as proven facts. And, as opposed to this, I may be quite as prone to think him stubborn, or a victim of one "idea," because he fails to keep in elbow-touch with me. Here lies the necessity of that power granting the "giftie" to see ourselves as others see us. Here the necessity, also, of close introspection to see if the fault be really not a personal one, in which our scientific blindness is the result of prejudice. To arrive at the point of conviction, the more especially if such conviction shall carry with it the necessity of a total surrender of previous views, practices and opinions, the argument must be based upon a solid foundation of fact—as opposed to inference—upon the best possible investigation of the claim, in the clearest light of the most recent developments. I should not, for instance, care to surrender my present opinion of the value of gynecological electro-therapeutics upon the simple record of the doctor's experience; neither would she, if I read her tenacity of purpose aright, forego the surgical euthanasia of the scalpel, because I consider laparotomy a greatly condemned and sadly handicapped alternative, with much of humbug in its claims. I may be the "stone wall," or the doctor may be. With the opinions of intellectual men pretty evenly divided upon the question, and with goodly hosts behind each of us, clearly the much-berated middle-man must be called in to decide between us. This middle-man is the consentient verdict of the profession which will be delivered after all the evidence is in. I have said that the doctor's argument would not carry much weight with me, since I should be inclined to question the method used, no matter by whom employed. I am more than ever impressed with the danger that may befall a useful discovery by enthusiasm and faulty tools, since I have examined the electrodes used by some practitioners in the United States, and since witnessing their limited knowledge of electrical currents. For the good of the cause, for the honor of the good name of my master, Apostoli, I must speak plainly.

There are few among us, whether calling themselves pupils of Apostoli or not, who use his method. When people assert, as I have heard it asserted, that they get no result from the galvanic current, though they try it thoroughly, using a *one-cell battery*, I am inclined to believe that they do not know the difference between a galvanic and a faradic current. But this is really not a particle more lamentable than the efforts of a physician to arrest the hæmorrhage of a uterine myoma by using within the cavity a *small platinum electrode*—and yet these small electrodes are used almost exclusively by those employing electricity in this country. *The only kind of an electrode that will surely arrest bleeding in the vast majority of cases is one that will completely fill the whole cavity of the uterus, so that not one bleeding-point shall escape.* After the most thorough application with the platinum electrode the bleeding often continues. Why? Simply, because only one part of the endometrium has been reached, and the other bleeding-points are un-

[1] Dr. Anna M. Fullerton: Annals of Gynecology, January, 1891.

touched. Hence Apostoli's device of olive-pointed carbon electrodes of different sizes. The doctor has had some inflammatory reaction after some applications. In a very large experience with the method of Apostoli I have never seen one such, save in a few cases of puncture of big pus tubes, when there should be rightly and necessarily more or less reaction. Did the doctor ever see a laparotomy without some kind of reaction? Why have I seen no such reaction? Because the applications were all made by a man who knew what he was about—by Apostoli himself. The doctor feels "in floundering about after such blind guides, as if the earth beneath our feet was 'without form and void;' and as if the dictum of the Creator, 'Let there be light!' would alone dispel the mists which still shroud in darkness the properties and activities of this wondrously 'subtle' and 'potent' agent." I am sorry that the good doctor should flounder about so hopelessly, but flounder she must, unless she, of herself, will study up the subject, and then, with proper knowledge and proper tools, apply the subtle agent as the necessities of the case may demand. If she wants to be well served she must serve herself, and if she wants to be really honest and just, she must be sufficiently *au courant* with the subject to know that the method is being used as it was intended to be used. To one who will read his writings without surgical spectacles, and who will not offer to public criticism little bits of excerpts here and there, there is nothing obscure in what Apostoli has written. The obscurity is within the brains of those who do not want to understand—another "stone wall," as it were. I would say: *Go as high as the patient can stand it*, and as *the clinical indications need*. This seems to me, and will seem to anyone else who has had sufficient experience in electro-therapeutics, even when conjoined to the other citations made by the doctor from the writings of Apostoli, to be plain enough. Why flounder in this? Is not individual idiosyncrasy a fact recognized by physicians? And this is the summing-up in a word of what Apostoli says. Find out the idiosyncrasy, and regulate the dose accordingly. This is what he says. Good, plain sense, and easy of comprehension.

I use intra-uterine applications and punctures continuously in the dispensary work in which I have the honor to be associated with Dr. Massey. There is no objection to it, *if the method be carried out in all of its details*. I would ask the doctor if she has not found it rare among her pupils, and indeed among practitioners as well, to find one who could introduce the sound easily up to the fundus, or to find *any one* who could introduce it in a canal made extremely tortuous by a fibroid growth. I have seen the effort made over and over again at Apostoli's clinic, by men well educated in the gynecological world, without success. I know of one, as highly placed as any name on record, who totally failed to introduce the sound in a case where the cervix was pressed against the symphysis pubis and the canal extremely tortuous. Yet, with marvellous deftness, Apostoli introduced it in a twinkling. Now, until this dexterity has been acquired, it would be folly to practice electro-therapeutics, because with each application half of the endometrium would escape. I would also like a more definite statement from the doctor as to the current strength used, and the particular current employed, whether + or —. I believe the doctor to be thoroughly honest in the expression of her views. I believe her to be sincere in her search for truth, and I believe, without questioning, that she did her very best to demonstrate the value of electricity; but since her experience is so entirely opposed to my own, I must believe that there was something wrong, either in the application or in the diagnosis. Electricity will not answer in all cases. It will do harm under certain conditions. It is the duty of the thoroughgoing electrician to differentiate between these. A harum-scarum service, with unbounded faith in electricity as a panacea, is the devil's work, and will go to the wall when attacked by professional morality. It is not a panacea. No good man and true has ever said it is. The services of the surgeon will always be needed. We all admit it. We hope, however, to reduce the number of cases that seek surgical interference, and this, too, with a painful appreciation of the consequent tumble of incomes that may result. Let me commend to all readers of The Medical News the article presented by Dr. Apostoli, at the Tenth International Medical Congress at Berlin last year, which has been translated for the *Annals of Gynecology* by Dr. Lapthorn Smith.

Bingham House.

ON CERTAIN FORMS OF TREMOR.

By HENRY S. UPSON, M.D.,

Attending Physician to the Lakeside Hospital; Neurologist to the City Hospital and to the Huntington Dispensary, Cleveland, Ohio.

It is a striking fact that, although much light has in late years been thrown upon the pathology of paralysis and anæsthesia, the organic changes which cause tremor are almost as little known as ever, being confined to the two suppositions, that tremor is often caused by lesions in and about the optic thalamus, and that it may sometimes be of cortical origin. Of the possibilities of tremor from spinal cord and peripheral lesions we know little or nothing. The first working hypothesis of any value in this field comes to us from Mercier, a disciple of Hughlings Jackson, in a work entitled *The Nervous System*

and the Mind. Mercier's statement is based on a consideration of the processes of generating, storing, and liberating of force in nature, and although not supported by inductive evidence in sufficient quantity to amount to a demonstration, as a theory deduced from general laws it is of great value, especially as it brings what little is known of the conservation and liberation of energy in nerve tissues, into harmony with similar facts in the rest of the organic and inorganic world.

Stated briefly, his argument is as follows:

The storage of force in nerve-cells is effected by nutritive processes; that is, by the appropriation and segregation of materials which, by a rearrangement of their molecules into more stable compounds, liberate energy. The building-up of these complex molecules is going on all the time, while their falling into simpler shapes, with the consequent liberation of energy, is only occasional; so that we have to study here the mode of action of a force constantly accumulating and occasionally discharged. The first question which presents itself is, What causes the discharge; or, rather, when once begun, what causes it to cease? We know that force, like matter, is persistent; that is, it continues in the same way and with the same intensity until altered by some other force; so that the discharge of a nerve-cell, once begun, unless influenced from without, can never stop until the energy of the cell has entirely exhausted itself. As a matter of fact, healthy cells do always stop short of complete exhaustion, and, as a rule, stop at once after the ceasing of the determining cause of their action; and as the doctrine of persistence of force, completely proven to hold throughout both the organic and inorganic worlds, absolutely requires an active force as the cause of this cessation, one has been postulated and called inhibition; and it is Mercier's idea that this is a force constantly exerted by each nerve-centre on the centre just before it in importance, so that the centres are arranged in a hierarchy, each subject to the one just above it.

A moment's consideration will show that the resultant of two opposing forces is not, as might at first glance appear, a single force acting regularly, but is almost invariably a rhythmical motion. Examples of this fact are the motions of the planets in their orbits, as a result of the opposing forces of gravitation and tangential momentum; the swaying of a reed in the wind, as a result of the opposing of the elasticity of the reed to the impact of the air; the rattling up and down of the lid of a tea-kettle, as the result of the opposing actions of the steam within and the weight of the lid. Such examples might be multiplied indefinitely, so as to prove, as Herbert Spencer has shown, that all motion and all progress, moral, mental, and physical, is not uniform but rhythmical, consisting of oscillations on either side of a mean point, which may itself be stationary, but is usually slowly advancing or receding.

In nerve tissues we have to do with two opposing forces, one of which, inhibition, may, for any given time, be regarded as constant; the other, the force within the cell, is ever on the increase, so that the condition of equilibrium within the cell must become more and more unstable until the inhibiting force is overcome, and a discharge is the result. As above pointed out, the discharge is rhythmical, and consists of a succession of puffs or outbursts, which, in the case of a motor ganglion cell, gives rise to successive contractions of the corresponding muscle. Under normal conditions one contraction follows so closely on the other that they are merged, and the muscle does not relax until the discharge ceases. This is the case in health. What will happen if, for any reason, storage occurs much more slowly, or inhibition is much stronger? We see at once, from analogies in nature, that the separate discharges will be more powerful and will take place at longer intervals. If, for instance, the fire under the kettle be gradually diminished, the lid, instead of rattling up and down, will give an occasional vigorous jump; a stiffer reed in a stream of water will vibrate more slowly, but with a wider excursion, than will a slender one.

The epileptic convulsion is the result of a discharge so widespread and intense, that it furnishes possibly the best instance in which to study the opposing forces which are readjusted in every muscular act. The liberation at the beginning of the convulsion is enormous, and as the inhibitory force is at this time little or nothing, the result is a series of discharges which follow each other so rapidly as to be practically merged, and the result is a tetanic contraction of all the muscles. As inhibition increases, the discharges follow each other more and more slowly, until they are no longer completely merged, and a slight tremor begins to be manifest. This tremor becomes coarser as inhibition begins to preponderate, until, finally, after a few tremendous contractions of all of the muscles together, inhibition predominates and the attack ceases. This explanation of the epileptic convulsion is, of course, largely hypothetical, but it illustrates beautifully Mercier's theory, and brings the phenomena of convulsion into harmony with that which has, by physiological methods, been proven in regard to the contraction of a muscle in health. This view of inhibition also explains very well the tremor of fatigue, alcoholism, poisoning by tea and tobacco, in fact, of all conditions in which storage of force is diminished. It is especially applicable to Charcot's view of the characteristic tremor of multiple

sclerosis. It may well be supposed that nerve-fibres deprived of their myeline sheaths and running through sclerosed tissue would have less conductivity than would normal ones; that is, their resistance would be increased, and this would constitute a practically increased inhibition to the wave of nerve force; so that the latter, instead of coming out at rapid intervals, would come in strong and widely separated shocks. There is another view of the causation of tremor in this disease, which ascribes it to the location of sclerosed areas in the brain, and mainly in or about the optic thalami. German observers have pointed out the fact that in cases of multiple sclerosis with the typical tremor, patches of sclerosis are invariably found in this locality, and in no case of purely spinal sclerosis has the typical tremor been present. The case which follows is an example of this, and is one of several which have recently come under the writer's observation:

O. L., forty-seven years of age, married, worker in sewer pipe. The patient was entirely well until he went into the army in 1861. He served about a year, and left on account of lung trouble. He had great pain in the left side of his chest, cough and expectoration. He spat blood twice about nine years ago. This trouble lasted for years. He still coughs a little, but has been much better for the last four years. He has been subject to headaches ever since he left the army; these are in the frontal and occipital regions, and last two or three days. There are usually no eye symptoms, but sometimes in the last few years he thinks he sees spiders and other objects. The headaches are accompanied with much dizziness and vomiting.

The patient had typho-malarial fever eleven years ago, and after that his left arm became very weak, and he thinks he lost feeling in it. The left leg then became weaker. There were some gnawing pains and prickling sensations; no shooting pains. He has had three attacks, the last one six years ago, in which he lost consciousness for a few minutes; became purple in the face; there were no clonic movements, but the hands were tightly clenched. There was no headache afterward, but great weakness for two or three days, and the patient was quite forgetful, so that he entirely lost the three or four days following the attack. The patient was in bed two or three weeks five years ago, with severe pain through the temporal region and in the left chest. The left leg and arm have grown weaker, so that the patient has been unable to be out of bed for the last three years. He has severe pain in the head a large part of the time, worse at times, unrelieved except by morphine. At times the pain has started in the right temporal region and shot into the right eye. The pain feels as if it were deep in the head. The memory is clear, and intellectual faculties as good as ever.

The right eye has lately been removed by Dr. B. L. Millikin, on account of an injury sustained by the patient when a young man.

On examination, the left pupil reacts to light and with accommodation; no paralysis of the external eye-muscles; no deviation of tongue or face. There is marked loss of power in the left arm and leg; fair power in the right arm and leg. Anæsthesia to tactile, painful, and temperature impressions is very marked on the left side, but nowhere absolute. There is no anæsthesia of the face. The knee, triceps, and wrist reflexes are well marked on the right side, and much exaggerated on the left; ankle clonus is marked on the left side, slight on the right. The muscles on the left side are moderately wasted, and this side feels cooler than the other. There is no reaction of degeneration; the muscles all react well and promptly to the induced current. The hearing is fairly acute on the left side, slightly diminished on the right. There is no tremor of the face, nor speech defect. There is a simple tremor of the hands, of voluntary type, not marked. There is no specific history. The patient has three children, all healthy, but one is feeble-minded. There have been, so far as the patient knows, no nervous diseases in his family.

The diagnosis in this case presented some difficulties. The tremor which was noted was a simple tremor, of not sufficient intensity to warrant a diagnosis of multiple sclerosis. At the same time, the very long course of the disease—at least eleven years—was strongly suggestive of a sclerotic process of some kind. A hemi-lesion of the cord was ruled out, from the fact that paralysis and anæsthesia occurred on the same side of the body. Tabes dorsalis was excluded by the absence of ataxia and the presence of knee-jerks; amyotrophic lateral sclerosis by the absence of the reaction of degeneration, and of marked atrophy and fibrillary contractions; so that the indications pointed strongly, by exclusion, to multiple sclerosis, which was the provisional diagnosis made just before the autopsy. A condensed statement of the post-mortem appearance of the central nerve tissues must suffice:

The brain substance appeared normal throughout, except that there was a grayish-looking patch in the left middle peduncle of the pons about the size of a pea, and another in the lower part of the medulla. All through the spinal cord, but especially in the cervical and dorsal portions, there were grayish translucent patches, scattered irregularly, and involving white and gray matter alike. On microscopical examination, these were found to be patches of sclerosis, in which were many naked axis cylinders, as seen in both gold chloride and nigrosine sections. The Weigert stain showed few, if any, normal myeline sheaths in these areas, but occasional drops of disintegrated myeline.

As an obverse of the fact that many cases of multiple sclerosis occur which do not show the characteristic tremor at any part of their course, we have the occurrence of typical tremor, exaggerated reflexes, and other signs of multiple sclerosis, when the autopsy fails to show any lesion whatever. These

cases were first described by Westphal, and are obviously analogous to cases of paralysis agitans; they show with the latter the seeming anomaly presented by a disease, so far as we know, purely functional, yet running a progressive course, and regularly ending in death. The fact that typical symptoms of multiple sclerosis may occur in a case which after death presents no lesion, makes particularly difficult a diagnosis in those cases which have some of the symptoms of multiple sclerosis, and others of paralysis agitans. Such a mixture is presented in the two following cases, the first of which is of probable organic origin, the second probably functional.

M. E., a man, fifty-one years of age. The patient was thrown out of a buggy nine years ago, was unconscious two or three minutes, but made a good recovery without further symptoms. About eight years ago a tremor began in the right hand, which gradually extended to the right leg, and since he had the "grippe," a few months ago, the left hand and leg began to be involved. He has had feelings of soreness and weakness in the extremities, and subjective feelings of heat and cold are very marked. He often wakes in the night and finds himself sweating. When he combs his hair he has a pain over the right eye. The right side of the face was the part injured when he was thrown out of the buggy. He has a good deal of headache over the right eye.

On examination, the right hand is held in the writing position; there is no tremor in it, except during voluntary motion. When he attempts to put his finger on his nose there is marked tremor, coarse in character, and increasing as the action proceeds, until toward the end of the movement the excursion of the hand is very wide and violent. There is a comparatively slight tremor of the same kind in the left hand on voluntary motion. The gait is rather hesitating, stiff, and slow, with the body not much bent forward. The pupils are equal, and react to light. There is no nystagmus, but as the patient follows the finger with his eye there is tremor of the head and in the orbicularis palpebrarum. The deep reflexes are fairly marked in both the upper and the lower extremities. The knee-jerk is stronger on the right than on the left side. There is no ankle clonus. Sensibility is acute in the face and in all four extremities. All of the muscles of the upper extremities react well and promptly to the faradic current, and with the galvanic current CCC > AnCC.

The grasp of the right hand is considerably weaker than is that of the left. The patient, formerly a good whistler, is now unable to whistle, and has a good deal of trouble in managing his food when he eats, the muscles of the mouth being weaker on the right side. The tongue is not deviated on protrusion.

In this case the subjective feelings of heat and cold, the writing position in which the hand is held, and the slow and stiff gait, are, at first sight, strongly suggestive of paralysis agitans. On the other hand, the fact that tremor only occurs during voluntary movement, and, still more, the fact that it is coarse and slow, compared with the finer tremor of shaking palsy, is strongly indicative of a sclerotic lesion. On closer examination, the muscles are not found to be so rigid as is the case in shaking palsy, and the position, although stiff, is not the typical bent posture, as appears in an accurate photograph of the patient in his habitual attitude. We have, therefore, in all probability, to do with a patch, or patches, of sclerosed tissue in the brain, and very likely in the neighborhood of the optic thalamus.

Hydrobromate of hyoscine, given in doses of $\frac{1}{200}$ to $\frac{1}{100}$ of a grain, has had, in this patient, little, if any, effect on the tremor.

The following case is, in most respects, a fairly typical one:

S. G., a woman, seventy-three years of age. The patient, who had always been a strong, hard-working woman, began three years and a half ago to notice a weakness in the third finger of the right hand, and this spread so as to involve the whole hand. Finally, a tremor began in the right hand, and spread gradually to the left hand and to both legs. The patient is

now unable to walk; when she attempts it she starts very slowly, and has a tendency to fall forward. When standing she must support herself by holding to something. The patient always feels hot now; can bear few, if any, bed-clothes on her bed; is very lightly clad, even in winter, and complains constantly of the heat. She has had no headache, no double vision.

On examination, the patient has a marked and rather coarse tremor, affecting all four extremities and the orbicularis oris. The tremor is continuous, easily controlled, so that it ceases during voluntary movement, and has a rhythm, as nearly as can be counted, of two hundred to two hundred and fifty per minute. Muscular power is much lessened; the grasp almost nothing on the right side, weak on the left side. Sensation to tactile and painful impressions is acute all over the body. The triceps and knee reflexes are fairly marked, not exaggerated. Pupils equal and react to light. None of the muscles appear wasted, except the extensor muscles of the right forearm and the small muscles of the right hand; these appear smaller than the corresponding muscles on the left side. The reaction to the faradic current is normal in the muscles of the upper extremities, except in the extensors in the right forearm; here the reaction is either absent, or so slight as to be entirely obscured by the constant tremor. The small hand muscles react well. The position of the body as shown in the photograph, a reproduction of which is given, almost suffices for a diagnosis in this case.

Although the symptoms began with weakness rather than with tremor, and there is marked wasting of one muscle group, the remaining symptoms are so typical that probably no lesion would be discoverable on autopsy, and the case must, therefore, rank as one of paralysis agitans.

A LARGE VAGINAL ENTEROCELE COMPLICATING PREGNANCY AND OBSTRUCTING LABOR.

By BARTON COOKE HIRST, M.D.,
of Philadelphia.

Vaginal hernia, with a vaginal enterocele large enough to cause mechanical difficulties in labor, must be one of the rarest complications in the child-bearing process. Many text-books do not refer to it, and those which do have a perfunctory account as though the writer had no personal experience in the method. For example, in *Müller's Handbuch*, in many respects the most complete work on obstetrics of recent times, the whole subject of hernia as a complication of pregnancy and labor is granted but sixteen lines, and this in a work of 2381 pages. Vaginal hernia is dismissed in a very curt fashion as follows:

"The intestines may be pressed downward between the bladder and uterus through a fissure in the pelvic floor, so that they may be felt between the lateral vaginal and pelvic walls, or until they reach the corresponding labium. So also may the intestines, in the same manner, make their way downward behind the uterus, and between the anus and the genitalia may give rise to the so-called perineal hernia. These ruptures, especially during the exit of the head, may become exceedingly serious by compression of the sac-contents; the early reduction of the hernia is therefore indicated. If this is impossible, and there is danger from pressure by the head, the termination of labor by the forceps is required."

In the Maternity of the University of Pennsylvania I have had recently under my charge the case of vaginal hernia in a pregnant and parturient woman about to be described. Stimulated by this experience, I am engaged in a search through medical literature for similar cases, with the idea, in the near future, of writing a more extensive paper on the subject. I would, therefore, be very much indebted to any fellow-practitioner who would tell me of unpublished cases in his own or others' experience:

Mrs. B., aged forty-three, has been pregnant fifteen times, and has had only three premature deliveries. Her last pregnancy was ten years ago. In this she went to term, and fell into labor without medical attendance. She had been in labor six to eight hours with hard pains, when suddenly a large tumor, "as big as a child's head," was seen protruding from the vulva. Two old women, who were with the patient, superintended the delivery two hours later, pulling the tumor forcibly to one side while the child's head was emerging from the birth-canal. After delivery the tumor disappeared, and the woman was only conscious of its presence, in the following years, a day or two before each menstrual period, when it "came down a little." She menstruated for the last time April 4, 1890. Two months later the protrusion became marked, and began to trouble her. The tumor then increased steadily, she suffered more from it daily, and finally took to her bed on October 20th. She was brought to the University Hospital on November 3d. She was then in a wretched condition.

Her bowels had only operated once in the past three weeks; her pulse was 140; her temperature slightly elevated. She was too weak to stand without assistance, and had an extremely anxious expression, although not at all of a nervous temperament. The urine was very high colored and contained pus. A tumor projected from the vulva covered with vaginal mucous membrane, measuring on its exposed surface 2 inches antero-posteriorly, 1⅛ inches transversely. The projection, she said, had been very much larger two weeks ago, before she went to bed. At first sight it seemed as though the tumor inverted the posterior wall of the vagina, but a closer inspection showed that it sprang from the right side, but pressed the right vaginal wall so far to the left that the vaginal canal was reduced to a small passage running directly behind the symphysis pubis. The cervix was reached with great difficulty—an inch above the symphysis pubis and close to the anterior abdominal wall. The tumor occupied all the space within the pelvic cavity, pressing upon the bladder in front and the rectum behind. The forefinger in the rectum and the thumb in the vagina could grasp the mass distinctly, and were as widely separated as the antero-posterior diameter of the pelvis would allow; they could, however, be approximated until they met, except for the rectal and vaginal walls, partly by slight displacement of the tumor upward, but mainly by compression of its contents. The tumor

had the characteristic feel of a hernia and evidently contained no fluid. The portion of the tumor projecting from the vulva was not resonant, but the impulse on coughing was very distinct. The signs of pregnancy were plain.

A diagnosis of vaginal hernia was made. The bowels were opened for the first time in two weeks by three compound cathartic pills and an ounce of castor oil. By rest in bed, regulation of the diet and bowels, and an irrigation of the bladder, the patient's general condition became quite satisfactory. She was still troubled, however, by constant bearing-down pains, which had commenced early in the pregnancy, and continued incessantly, causing her much suffering. On November 21st (231st day since beginning of last menstruation) the membranes ruptured while the patient was lying quietly in bed. Eight hours later the os was sufficiently dilated to admit two fingers. The woman was then anæsthetized. Passing the whole hand into the vagina and displacing the tumor laterally, I found a presentation of one knee. The corresponding foot was seized and brought to the vulva. The gradual extraction which followed occupied two and one-half hours. As the body descended and the head entered the pelvis, the tumor protruded from the vagina to an enormous extent and distended the right side of the pelvic floor and the perineum. Two assistants pulled the tumor off to the right while I extracted the head quickly, but with great force. The child was alive when born, but deeply asphyxiated. It was revived, but died the next day.

The subsequent course of the case as regards the woman was entirely satisfactory. The puerperium was afebrile and uncomplicated. Two weeks after delivery I examined the patient and made the following entry in my case-book:

Tumor still felt on right side, extending down to the pelvic floor, covered by little more than skin, to the right of the posterior commissure of the vulva. The tumor increases in size as one follows it up in the pelvis until, at the level of the cervix, to the right and behind, it is as large as an orange. It can be displaced upward to a slight extent, but it is impossible to reduce it. The impulse on coughing is plainly to be seen on the right side of the pelvic floor.

The woman was advised to return to the hospital for an operation in case she suffered from the hernia.

ORIGINAL LECTURES.

ON THE IDENTITY OF SO-CALLED SPECIFIC AND NON-SPECIFIC URETHRITIS.

BY HENRY J. REYNOLDS, M.D.,
OF CHICAGO, ILL.,
PROFESSOR OF DERMATOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; DERMATOLOGIST AND GENITO-URINARY SURGEON TO THE WEST SIDE FREE DISPENSARY.

GENTLEMEN: We find in this case, as you see, a discharge from the meatus which is purulent or mucopurulent in character. As a pathological product of this character is always indicative of inflammation, it is very evident we have here an inflammation of some portion of the genito-urinary tract; and as the same condition which prevents a continuous flow or discharge of urine from the bladder would naturally prevent a discharge from the meatus, as we find the case here, should it come from any point posterior to the urethra, the natural inference is that in this case the inflammation is located in the urethral canal; and while this may seem a roundabout way of saying that the gentleman has the clap, it is always advisable, in pursuing a scientific study, to take up the subject thoroughly and systematically. We have in this case, in other words, a urethritis; a condition which may perhaps with propriety in every case be termed a gonorrhœa. In this connection, however, I must not neglect to state that the word *gonorrhœa* or *clap* should be used with considerable discretion, inasmuch as to the laity it usually indicates a disease which has been derived by contagion or impure contact.

Two forms of urethritis have been described by many authors, the one being termed *specific* urethritis, which was supposed in every case to be the result of contagion, and to which has also been given the name *true* gonorrhœa; and the other, *simple* or *non-specific* urethritis, to which they regarded the word gonorrhœa or clap inapplicable, and which has sometimes been termed "bastard gonorrhœa."

Before proceeding further, it is perhaps advisable to consider more fully the question of the identity or non-identity of these two so-called forms of urethritis. The chief points or characteristics upon which observers have endeavored to establish the non-identity of so-called specific and non-specific urethritis, I will endeavor to illustrate by the following diagnostic table:

Specific.	*Non-specific.*
1. The result of contagion.	1. Not specific.
2. Disease well pronounced.	2. Mild.
3. Long duration.	3. Short duration.
4. Stubborn to cure.	4. Yields readily to remedies.
5. May be communicated by contact.	5. Not communicated by contact.
6. Discharge contains specific microbe.	6. Discharge does not contain specific microbe.

It is, I believe, principally upon these differential points that certain observers endeavor to establish the dual character of so-called specific and non-specific urethritis. Now, let us see if they are really sufficient to constitute distinct diseases, or whether there is any essential element in one that may not exist or be developed in the other.

In regard to the first differential point, *contagion*, it is undoubtedly true that the discharge from one urethritis may convey the disease to another, while the discharge from another urethritis will not be capable of reproducing itself in another individual by contact. It is, however, in all probability true that the disease containing the contagious element (specific), may and does lose its contagious quality or character in certain stages of its course. In other words, it is probable that even the contagious or so-called specific form of the disease is only so at a certain time, and that during a certain period in its progress it loses its contagious character, when it, of course (as regards the differential point of contagion), becomes identical with the so-called simple

or non-specific urethritis. That this change takes place will be admitted by nearly everybody, but a few will argue that the disease, when this change takes place, is, to all intents and purposes, cured, the gonococcus having been, for instance, destroyed. But such is not the case, for this same condition may even yet be aggravated so that it may return to its original profusely purulent contagious character (wherein the gonococcus may be found). That this is true the clinical experience of every practitioner will indicate, and that it is not so, has never been and cannot be shown. It would, therefore, seem that the contagious character of the so-called specific disease depends rather upon the stage or activity of the inflammation than upon the particular *kind* of inflammation. So much, then, for the behavior of the so-called specific form.

Now, on the other hand, as to the action of the so-called *simple* form of the disease; there is great evidence to show that an inflammation arising from natural causes, or more correctly speaking, without the etiological factor of contagion, and one wherein the pathological product is not at first contagious or capable of reproducing itself by infection (*simple* or *non-specific*), may and does become *contagious* in character. This condition of affairs, I think, we frequently see in inflammations of the conjunctiva. The disease having arisen idiopathically, when developed, remains for a certain time simple or non-contagious, but eventually, if subjected to bad hygienic and therapeutic conditions, becomes aggravated into a purulent disease which is eventually contagious; and to reason by analogy, there is probably no valid reason why a simple inflammation of the urethra may not go through the same course, and by aggravation eventually become contagious in character. This being the case—and it has never been and cannot be proven to the contrary—we have a so-called simple or non-specific or non-contagious urethritis, arising independent of contagion, eventually developed into a so-called specific or contagious urethritis; and we likewise have a specific or contagious urethritis eventually, before the complete disappearance of the discharge, mitigated into a non-contagious or simple urethritis. Hence, this being the case, either form of the disease is susceptible of development into the other so-called form—a fact which must prove conclusively that the deviations in character of the so recognized two forms of the disease are but different stages of, or indicate different degrees of activity of, one and the same disease.

In regard to the second recognized point of distinction between *specific* and *non-specific*, it is no doubt true that the disease developed from contagion is, as a rule, more pronounced or violent in its symptoms than one arising from natural causes independent of the element of infection. But there is nothing about this differential point that can in itself show any essential difference in character between one form of the disease and another, other than that of degree.

In regard to the third and fourth points that are claimed to differentiate the so-called specific and non-specific cases, there is nothing about the *activity* of the disease, its *long duration*, or its *unyielding* character that can in any way indicate an essential difference in character from a mild form of the disease, which is of short duration and yields to treatment, other than that of *degree* (but not of *quality*). These points do not establish a difference in quality any more than a confluent eruption indicates that smallpox is a different disease from varioloid with its scanty, discrete eruption.

In regard to the fifth differential point, there is no doubt, as shown in speaking of the first differential symptom, that one urethritis differs from another as regards its *communicability*, but this, as shown in discussing the first differential symptom, does not necessarily establish the essential difference in quality, inasmuch as the simple may be aggravated into the so-called specific or contagious, and that the contagious, as most everybody must admit, may be so mitigated as to eventually become non-contagious—a condition which only refers to *degree* or *activity*, and not to *quality*.

With reference to the last or sixth differential point, we now come to consider the hobby or pet of the micropathologist, and this brings up a question which has never been settled, as to whether this little atom is the axis upon which the disease revolves or *vice versa*. It is undoubtedly true, as has been known during all ages, that a contagious disease necessarily contains elements of some character, microscopical or otherwise, which do not exist in the non-contagious disease. Certain microscopic bodies, however, have been noted as existing in certain diseases which it has been claimed (not, however, proved) constituted the only essential element of contagion; or which are, in other words, the germs of disease. Not to enter at the present time into a discussion of the subject of bacteriology, it is sufficient to state that something has been discovered in the pathological product or discharge of one urethritis, which it is claimed does not exist in another, and which has been termed the micrococcus gonorrhœæ, gonococcus, etc. The discovery of this element has of late years, especially by the advocates of the germ theory, been the strongest point of argument in favor of the non-identity of the so-called specific and non-specific urethritis, it being claimed by Neisser, Bumm, and certain other investigators that this element was to be found in a contagious gonorrhœa or urethritis, and was not to be found in a non-contagious urethritis. Now, even if this be the case, it would not be sufficient to convince every careful reasoner that the disease in which the element is found was from first to last essentially and entirely distinct from the other. In the first place, I think it cannot be proven that these elements or so-called germs contain exclusively the contagious elements of the disease. In other words, it has never been proven that a simple condition wherein these elements do not exist cannot be aggravated and developed into a condition where they will eventually be found. Further than this, it has never been conclusively shown that these elements are peculiar to, and are to be found only in, a contagious gonorrhœa. Other investigators have found bodies which they claim to be identical, not only in non-contagious inflammations of the mucous membrane, but also in other secretions and fluids of the body.

To sum up: The germ theory fails to establish a distinction between the so-called specific and non-specific urethritis, and as careful reasoning and analogy seem to show conclusively that a mild, non-contagious inflammation may be aggravated and developed into a contagious one, and that a contagious one may become so

mitigated as to eventually become non-contagious in character, I fail to see, like many other observers, any substantial reason why the subject should be complicated by endeavoring to establish the existence of two distinct forms of urethritis, where, in reality, only one disease exists. Every case of the disease I would simply term urethritis or gonorrhœa (for reasons as previously suggested), making, however, very cautious use of the term gonorrhœa.

163 STATE STREET.

MEDICAL PROGRESS.

Prescription for Whooping-cough.—VON GENSER is said to use the following prescription in the treatment of whooping-cough:

℞.—Carbolic acid . . . . 1½ grains.
Rectified spirit . . . . 2 drops.
Tincture of iodine . . . 5 "
Tincture of belladonna . . 10 "
Peppermint water . . . 2 ounces.
Simple sprup . . . . 1 drachm.

To a child of two years a teaspoonful of this mixture may be given every two hours.

Hyperæsthesia of the Larynx.—The *Revue General de Clinique et de Thérapeutique* gives the following treatment of MOURE for those hysterical cases of hyperæsthesia or anæsthesia of the larynx. Internally he prescribes large doses of bromide of potassium for hyperæsthesia, or the sulphate of strychnia to those who have anæsthesia.

Externally he makes application of the following on each side of the larynx:

℞.—Hydrochlorate of cocaine, dissolved in alcohol . . . 2 grains.
Metallic iodine . . . . ½ grain.
Iodide of potassium . . . 1½ grains.
Laudanum . . . . . 15 drops.
Pure glycerin . . . . 1½ ounces.

Or,

℞.—Hydrochlorate of cocaine, dissolved in alcohol . . . 4 grains.
Laudanum . . . . . 15 drops.
Bromide of potassium . . 45 grains.
Pure glycerin . . . . 1 ounce.

Or in other cases morphine may be used in place of the cocaine as follows:

℞.—Hydrochlorate of morphine . 2 grains.
Metallic iodine . . . . ½ grain.
Iodide of potassium . . . 1½ grains.
Pure glycerin . . . . 1 ounce.

Injections for Hypertrophy of the Prostate.—*La Tribune Médicale*, gives the following prescriptions from the practice of KOBNER for the relief of hypertrophy of the prostate:

℞.—Iodide of potassium . . . 45 grains.
Bromide of potassium . . ½ drachm.
Extract of belladonna . . 4 grains.
Water . . . . . 6 ounces.

This is enough for 20 rectal injections. Six drachms of this solution in from two to four ounces of hot water may be employed once or twice a day or the following may be used:

℞.—Iodide of potassium . . . 2½ drachms.
Bromide of potassium . . 2 "
Extract of belladonna . . 8 grains.
Water . . . . . 10 ounces.

Six drachms of this may be injected twice a day into the bowel.

Five to ten drops of pure tincture of iodine may be placed in the liquid if the large intestine will bear it.

Treatment of Whooping-cough.—Löffler recommends the following solution to be used in the treatment of whooping-cough:

℞.—Freshly prepared chloride of silver . . . . . 1½ grains.
Water . . . . . 2 pints.
Hyposulphite of sodium, a saturated solution.

Use by an atomizer, the liquid being directed into the pharynx. Repeat the application every two or three hours. This treatment is both prophylactic and curative.

Treatment of Jaundice.—According to *La Semaine Médicale*, Carreau employs with great success the oil of turpentine in large doses in the treatment of severe jaundice. He believes that its value depends upon its diuretic and hæmostatic properties, and he uses it in all conditions of severe disease, such as in infectious jaundice, bilious fever with hæmoglobinuria, and yellow fever, particularly if anuria and hæmorrhages are present. In grave cases as many as sixty capsules, containing two or three drops, are given in thirty-six hours, the dose being given as frequently as every half hour. Where vomiting prevents their action he administers oil of turpentine hypodermically in the following formula:

℞.—Ozonized oil of turpentine . . 2½ drachms.
Liquid vaseline . . . . 3 ounces.

The following cases are detailed by Carreau as instances in which this treatment was of service. The first of them was that of a woman suffering from severe icterus with profound coma and uræmic convulsions. Three drops of the turpentine were given every half hour for the first few hours, and after that two drops. Simultaneously with the appearance of the peculiar violet odor of the urine, produced by the turpentine, the albuminuria decreased, the coma became less, and soon passed into simple somnolence, so that convalescence was soon established.

The second case was suffering from yellow fever, accompanied by persistent vomiting, and in this instance twenty-three hypodermic injections of oil of turpentine were made in thirty-six hours. The symptoms rapidly ameliorated, and the patient recovered, although he afterward suffered from two abscesses as a result of the injections. In still another case which was suffering from bilious fever with hæmoglobinuria, the administration of the turpentine every hour or hour and a half was without effect, and it was only when three drops were used that the symptoms rapidly ameliorated.

The Treatment of Diphtheria.—Löffler recommends the following gargle in the treatment of diphtheria:

℞.—Carbolic acid . . . . 15 drops.
Alcohol . . . . . 2 ounces.
Distilled water . . . . 5 "

This should be used as a gargle.

In other cases a solution of 1 to 2000 of corrosive sublimate can be used in the same manner, or the following antiseptic mixture, which is not poisonous, may be employed:

℞.—Thymol . . . . . 15 grains.
Alcohol . . . . . 3 ounces.
Water . . . . . 12 "

It is stated that the gargle of corrosive sublimate acts generally more favorably than does that containing carbolic acid.

Treatment of Cancer of the Stomach.—*Journal de Médecine de Paris* states that Dujardin-Beaumetz secures gastric antisepsis in cases of cancer of the stomach by the use of salicylate of bismuth, naphthol, or salol, prescribed in the form of capsules, made as follows:

℞.—Salicylate of bismuth
Calcined magnesium
Bicarbonate of sodium } of each 2½ drachms.

To be made into 30 capsules, or,

℞.—Salicylate of bismuth
Betanaphthol
Charcoal } of each 2½ drachms.

To be made into 30 capsules, or, again,

℞.—Salicylate of bismuth
Salol
Bicarbonate of sodium } of each 2½ drachms.

To be made into 30 capsules.

For the relief of the pain he uses laudanum, or opium pills, or hypodermic injections of morphine associated with atropine, as, for example, in the following prescription:

℞.—Hydrochlorate of morphine . 1½ grains.
Neutral sulphate of atropine . $\frac{1}{10}$ grain.
Sterilized water . . . . 6 drachms.

Twenty or thirty minims of this may be given at a dose.

The objection to this treatment is that the constant use of morphine may produce the morphia habit, but in the majority of instances the disease progresses so rapidly that this danger is not of any importance. The diet should be absolutely vegetable in its character. The stomach should be allowed to rest as much as possible, and the physician endeavor to use such foods as will be digested by the intestine. This is particularly important in view of the fact that in the majority of the cases of cancer there is a diminution in the digestive activity of the gastric juice. When the cancer is at the pylorus, lavage may be practiced, but if it be at the cardiac end of the stomach this measure is not to be resorted to. The solution employed in washing out the stomach should consist of naphthol in the proportion of 1 to 1000.

Prescriptions for Flatulence.—*Journal de Médecine de Paris* gives the following prescriptions for the relief of flatulence:

℞.—Naphthol . . . . . 1 drachm.
Carbonate of magnesium . . 1 "
Powdered charcoal . . . 1 "
Essence of peppermint . . 2 drops.

This is to be divided into 15 powders, and 1 taken at the beginning of each meal.

When the flatulency is accompanied by constipation the following may be used:

℞.—Magnesium . . . . . 1 drachm.
Flowers of sulphur . . . 1 "

To be made into 15 powders, 1 of which is to be taken at each meal.

When diarrhœa accompanies the flatulency:

℞.—Bicarbonate of sodium . . 30 grains.
Prepared chalk . . . . 15 "
Powdered nux vomica . . 3 "

May be made into 10 powders, 1 of which is given with each meal.

In still other cases, where neuralgia of the stomach or true gastralgia accompanies the tympanites.

℞.—Hydrochlorate of cocaine . . 4 grains.
Quinine sulphate . . . 6 drachms.
Cinnamon water . . . 8 ounces.

Distil, and order a tablespoonful every two or three hours.

The Prevention of Ophthalmia Neonatorum.—The *Revue Générale de Clinique et de Thérapeutique* gives the following treatment used by Valenta for the prevention of this dangerous affection of the new-born. After pointing out that Credé's method, that is, the instillation of solutions of nitrate of silver, possesses many dangers, he proposes that we replace this liquid by solutions of permanganate of potash. The solution which he employs is sufficiently concentrated to be of a dark-red color. This is to be applied to the eyelids by means of a cotton tampon, and immediately afterward by the aid of another tampon the conjunctival sac is to be cleansed. These operations should be performed immediately after birth if they are to be successful.

Treatment of Granular Blepharitis by Ethylate of Sodium.—Symons (*Revue Générale Clin. et Thér.*, March, 1891) prefers this treatment to that by nitrate of silver. It is less painful and causes no reaction. The following is the method: He everts the eyelid and anæsthetizes the conjunctiva with cocaine; then he touches the granular surface with a point dipped in the sodium, cleaning off with a cotton tampon any excess of the agent. Finally, to diminish the caustic action of this substance, he advises the addition of several drops of chloroform.

Toxic Action of Exalgine in Large Doses.—Conning Hartley observes, in *Revue Générale Clin. et Thér.*, March, 1891, that, contrary to those who affirm the harmlessness of this substance, he has seen repeated accidents following its use.

Five minutes after the administration of methyl-acetanilide the patient lost consciousness, suffered intense pain, and was unable to speak, from dyspnœa; pallor of the face was intense. He observed an irregular heart-beat and weak pulse, with profuse perspiration. These accidents are those usually thought to accompany syncope.

Abdominal Hernia.—WOLF, in the *Revue Générale de Clinique et de Thérap.* (March, 1891), gives the following conclusions arrived at by Schrede in regard to the radical operation for abdominal hernia. In 165 operations performed by Schrede for the relief of strangulated inguinal, and 69 for strangulated femoral hernia, there were 2 per cent. of deaths, and 29.5 per cent. of certain successes. By the term "certain" is meant that the hernia did not return within one year. These conditions are the most favorable for the success of the operation: ligature of the sac, and as much tissue as possible; extirpation of the latter; suture of the orifice by which the hernia produced itself; finally, division of the inguinal canal. Schrede prefers to use a metallic suture. Extirpation of the sac simplifies the rest of the operation.

Antiseptic Papers.—For application over wounds or bandages antiseptic paper prepared in the following manner is stated by *L'Union Médicale* to be of value:

℞.—Bichloride of mercury . . 2½ drachms.
Pure glycerin . . . . 6 "
Distilled water, which has been boiled and cooled } 1 pint.

Filter-paper is to be impregnated with this solution and applied where needed.

Treatment of Broncho-pneumonia in Children.—According to *L'Union Médicale*, SIMON recommends the following prescription in the early stages of this condition:

℞.—Acetate of ammonium . . 7 grains.
Tincture of aconite . . 15 drops.
Codein . . . . . 2 grains.
Simple syrup . . . . ½ ounce.
Water enough to make . . 3 ounces.

A teaspoonful of this may be given every hour until five or six doses are taken. At the beginning of an attack a mustard plaster or other form of counter-irritation should be applied over the thorax, and after it has acted for one or two hours should be followed by an emollient poultice. It is also well to allow steam from boiling water to pass into the air of the sick-room.

Parasiticide Ointment.—*L'Union Médicale* gives the following ointment for the removal of parasites:

℞.—Salicylic acid . . . . 45 grains.
Borax . . . . . 15 "
Balsam of Peru . . . 30 "
Etherial essence of anise . . 5 drops.
Essence of bergamot . . 20 "
Vaseline . . . . . 6 drachms.

Make into an ointment and apply to the part affected.

Treatment for Coryza.—*Gazette Médicale de Liège* recommends that in acute coryza a small tampon impregnated with the following solution shall be passed into the nares:

℞.—Hydrochlorate of cocaine . 15 grains.
Distilled water . . . 1½ ounces.

This application may be made twice a day, and should be continued for twenty minutes until the pain and congestion of the mucous membrane is relieved. By this means the frontal headache will be removed, and a complete cure may be obtained.

Powders for Indigestion.—*L'Union Médicale* states that DUJARDIN-BEAUMETZ uses the following powder in the treatment of dyspepsia:

℞.—Subnitrate of bismuth
Carbonate of magnesium
Prepared chalk
Phosphate of sodium } of each, 2½ drachms.

This is to be divided into forty powders, and 1 powder taken after each meal.

Treatment of Erythema of the Eyelid.—BROCQ, in the *Revue d'Ophthalmologie*, states that he employs the following ointment in the treatment of erythema and swelling of the eyelids:

℞.—Salicylic acid . . . . 7 grains.
Lactic acid . . . . 7 "
Resorcin . . . . . 10 "
Oxide of zinc . . . . 30 "
Pure vaseline . . . . 5 drachms.

Care should be taken that none of this ointment enters the eye.

In other cases the following ointment may be applied:

℞.—Salicylic acid . . . . 15 grains.
Pyrogallic acid . . . . 30 "
Vaseline . . . . . 15 drachms.

This treatment is to be applied at night, and it may be alternated with that containing resorcin just given.—*L'Union Médicale.*

Ointment for Phthisis.—*L'Union Médicale* states that the following ointment is useful in the treatment of pulmonary phthisis:

℞.—Creasote . . . . . 2½ drachms.
Lanolin
Olive oil } of each, . . . 1½ ounces.
Lard

This ointment is to be applied with friction each night to the thorax, and the absorption of the creasote from the skin will be of value to the patient.

Treatment of Bed-sores.—BILLROTH is stated to apply the following treatment for bed-sores: Upon the appearance of reddening of the skin he applies a lotion of vinegar or lemon-juice. If excoriation is present, he applies nitrate of silver, and protects the part by zinc ointment or soap plasters. Where gangrene comes on, antiseptic compresses are to be applied, the wound being cleaned by the use of chlorine water, or carbolated oil may be used with care as the phenomena of intoxication may appear. Internally, he employs supportive treatment with wine, acids, quinine, and musk.

Current Literature.

SATURDAY, APRIL 18, 1891.

ALBUMINURIA IN RENAL LITHIASIS.

Marboux (*Lyon Médical*, January 25, and February 8, 1891) has noted the existence of albuminuria in subjects afflicted with established gravel, but whose general health is maintained, and who appear to be benefited by a course of mineral waters. Whenever the urine of a patient is found to contain albumin, an explanation of this vice of secretion should be searched for in the following directions:

1. Has the albuminuria any relation to gravel, is it due to a physiological disposition, to a traumatism, to a dyscrasic state engendered by a recent eruptive fever, or to an attack of renal catarrh?

2. Is it the result of a renal inflammation, engendered it may be by lithiasis, but developing alongside and independently of it?

3. Is it intimately connected with a lithiasis, an agglomeration of sediment, a migration of stones, and does it constitute a passing accident consequent upon the renal congestion arising from the injury to the mucous membrane of the canaliculi? In other words, is it, properly speaking, the albuminuria of gravel?

It is a simple thing to distinguish between *traumatic* and *scarlatinal* albuminuria. *Physiological* albuminuria should be suspected when the urine appears to be normal in every respect, and the quantity of albumin very small, especially if the subject is known to be a heavy eater, or if he has been exposed to great muscular fatigue or depressing emotions. This physiological or functional albuminuria is usually transitory and intermittent, and disappears under the influence of the night's rest; the urine is not otherwise modified in its composition, there are no casts, but there is very often an excess of the crystals of the oxalate of lime. *Nervous* albuminuria is extremely rare, and when present is associated with lesions which are not compatible with a state of health. *Catarrhal* or *congestive* albuminuria is of frequent occurrence, especially in gouty individuals. Chronic Bright's disease is likewise a frequent cause of albumin in the urine. It is associated with certain fugitive, and but slightly prominent symptoms, such as troubles of the eyes, the sensation of dead finger, the sensation of cold flashes, the appearance of erratic œdemas, and the commencement of cardiac hypertrophy. Finally, the presence of albumin may be explained by the existence of gravel or renal lithiasis. Lécorché has formed four stages of this affection. The first consists simply in an excess of uric acid, which is noticed only by chemical analysis. A degree more pronounced corresponds to the presence of sand and gravel in the urine; this is the microscopic gravel. A degree more gives rise to small calculi capable of causing the pains of nephritic colic; this is gravel properly speaking. After this comes renal calculi as the last stage of the affection.

The pathogeny of the albuminuria of gravel embraces: 1. Alterations in the blood crasis; 2. Modifications of the pressure and flow of the blood in the renal vessels; 3. Alterations in the renal epithelium. The primary effect of the clogging of the uriniferous tubules is to hinder the excretion of urine, and to determine a renal congestion by pressing upon the vessels in the vicinity. To this interference of the circulation from mechanical obstruction is added an irritation of the epithelium, which is the second cause of the passage of the albumin into the urine. In review, the causes of the condition are mechanical interference with the circulation of the blood, obstruction to the emission of urine, the congesting influence of pain, injury to the mucous membrane, and, finally, alteration of the epithelium.

This albuminuria may be the first symptom of lithiasis, and the red deposit in the urinals will establish the diagnosis. The albuminuria is simply a protestation of the kidney against the foreign bodies which encumber it, injuring the mucous membrane, and irritating the glandular elements. The urine is limpid, contains a little albumin, is generally excessively acid, and in consequence permits a rapid deposit of urid acid. The deposit contains cells and epithelial casts, very rarely hyaline casts. Nephralgia, usually unilateral, is present in these cases, with lumbar weight and muscular twitchings. Nephritic colic may accompany albuminuria in its early stages during its course or in its convalescence.

The mineral waters are of service in these cases, if properly administered. They may be classed thus:

1. Those with a sodium base: sodium bicarbonate; strong (Vichy, Vals); weak (Royat).

2. Those with a calcium base: calcium bicarbonate (Pougues); calcium sulphate (Contrexéville, Vittel).

3. Those with a feeble undetermined mineralization (Evian).

If the albuminuria is physiological, there exists neither indication nor contra-indication to the use of these waters. In the scarlatinal form the sodium bicarbonate waters are contra-indicated. The calcium sulphate water of Contrexéville will be found of service. In advanced Bright's disease all hydromineral treatment should be avoided. In the albuminuria of gravel, where the mucous membrane is irritated and congested by the presence of the foreign bodies, the mineral waters relieve the condition by washing them out of the tissues.

A COMPARATIVE STUDY OF THE EFFECTS PRODUCED BY BULLETS OF LARGE AND SMALL SIZE.

Delorme and Chavasse (*Archiv. de Méd. et de Pharm. Militair.*, Feb., 1891) have recently made an extensive investigation of the effects produced by shots of various sizes fired from equal distances and travelling with the same rapidity. They have found that the difference observed between the actual projectile of the gun of 8 millimetres

(Lebel) and the lead projectile of the gun of 11 millimetres (Gras) lies, for the most part, in the greater force of penetration of the former, in the difficulty of its deformation, and in its smaller diameter. In both balls, especially when they encounter a resisting bone, the damage inflicted increases with the velocity. The shock produced is also increased with the velocity, and according to whether one bone or more be affected, but it is much more marked with the ball of the Gras gun. The explosive effects, in firing at short distance, are identical for the two projectiles. The orifice of cutaneous entrance, which is always associated with loss of substance for the two projectiles, increases with the velocity, but seldom exceeds the diameter of the vulnerating body. The hole of exit of the ball of 8 millimetres is usually as rounded as that of the ball of 11 millimetres. The smaller dimensions of the holes of entrance and exit end of the passage of the smaller ball approach more to the nature of subcutaneous lesions, which is a favorable circumstance for their more easy and rapid cure. Holes of exit of the diametrical dimensions of the index-finger or thumb, produced by either ball, indicates a comminuted fracture with free splinters; but, for the ball of 8 millimetres, a torn hole of exit, admitting the little finger, gives rise to a suspicion of this lesion. The same indications can be furnished by the holes of exit in the clothing. In firing from equal distances, without the zone of the explosive effects, it is found that the types of fractures remain the same for both projectiles; but at distances of from 300 to 800 metres the ball of 8 millimetres produces effects slightly different from those of the larger ball. These differences consist:

1. In a rending of the cortical layer at the point of contact with retrograde projection of the osseous particles in the line of entrance.

2. In the greater propulsion of the small fragments into the medullary canals.

3. In the breaking up and more complete separation of some splinters belonging to the second osseous wall traversed.

4. In the smaller quantity of splinters driven into the canal of exit; the passage through the muscles is clearer.

5. In the extension of the cracks to a smaller distance in the two fragments.

In short, aside from these common secondary differences, the gravity of the fractures produced by the two balls at these distances is almost the same. From 800 to 1200 metres for the ball of 8 millimetres, the comminution is less, the breaking up of the free splinters is not so frequent, the dislocation is less pronounced, and the projection of splinters into the passage of exit is not as considerable. Therefore, these fractures seem to be of less gravity than the others. For distances of over 1200 metres the ball of 8 millimetres appears to produce fractures comparatively more comminuted than the leaden ball of 11 millimetres. Fractures from direct perpedicular contact, which are frequent with the ball of 11 millimetres, become quite exceptional with the ball of 8 millimetres. Tangential contact is most often accompanied by isolated cracks upon the face opposed to contact with a ball of 8 millimetres slightly deformed. In the epiphyses and short bones both balls produce fractures, perforations, etc., of the same type. But here, taking out of consideration the explosive force, the ball of 8 millimetres seems to cause less extended general fissuring, less rending of tissues, a smaller number of splinters, and more numerous simple perforations. In short, the articular lesions made by the Lebel ball are, in general, less comminuted and less grave.

Upon flat bones the lesions are almost comparable, with the sole difference of the relative dimensions in the diameters of the two projectiles. Here still, the ball of 8 millimetres with less velocity produces a retrograde projection of splinters in the muscular passage of exit. In perforations of the skull the direction of the fissures is identical for the two projectiles according to the point struck. The holes of entrance and of exit of the distorted balls of 11 millimetres are relatively larger than those of the ball of 8 millimetres. With similar velocity the ball of 8 millimetres produces upon the bone disorders less grave than those of 11 millimetres. The smaller balls stop more rarely in the tissues than do those of 11 millimetres.

HYDATIO CYST OF THE LIVER. ABLATION OF THE CYSTIC PORTION BY THE ELASTIC LIGATURE.

IN the *Bulletin de l' Académie de Médecine*, January 20, 1891, DUPLAY reports an operation performed by Terrillon for the relief of hydatid cyst of the liver. The patient was a woman, fifty-three years of age, who had always enjoyed good health until forty-seven years of age, when she suffered severely from violent pains in the right hypochondriac region. This painful attack lasted about six months, and was accompanied from time to time by bilious vomiting, but no jaundice. When the pains commenced to decrease, the patient noticed, for the first time, the existence of a tumor below the border of the right false ribs. This was diagnosed as a cyst due to impaction of gall-stones, and she was treated successfully by electricity and by other methods. She consulted Terrillon in 1889. At that time she was subject to painful crises, which occurred every five or six weeks, of more or less violence, lasting some days. There was considerable emaciation and general weakness. An examination revealed a tumor descending about four inches below the margin of the ribs, which was displaced by the respiratory movements. It was undoubtedly connected with the liver. Anteriorly the tumor did not quite reach the median line, while it was impossible to determine the posterior limit. A slight sensation of fluctuation could be elicited. An exploratory puncture revealed a colorless, transparent fluid. Upon the withdrawal of the fluid the size of the tumor was not sensibly diminished, which gave rise to the conclusion that the cyst was multilocular.

An incision for the removal of the tumor was made, about four and a half inches in length, parallel to the border of the right lower ribs. As soon

as the peritoneum was incised the tumor was revealed, more mammelated, and of a less violaceous color than the healthy hepatic surface. The gall-bladder was healthy. The incision was lengthened and the whole cyst of the size of two fists was revealed. A line of demarcation, very distinct, existed between the diseased and healthy tissues of the liver. There was no depression at this point, but the difference lay in the coloration and consistency of the parts. There being no pedicle, ablation of this portion of the liver would be attended with danger of hæmorrhage. After some consideration, it was decided to pass a rubber tube tightly around the cyst, as is done in the case of uterine fibroids, so as to produce an artificial pediculation of the diseased portion of the liver, which was strangled in this manner. It became turbid and violaceous in color, and swelling occurred, which held the ligature firmy *in situ*. The mass was then held in place between the lips of the abdominal wound by means of a suture upon either side. It gradually sloughed off, and was removed on the seventh day. The wound was entirely healed by the thirtieth day.

DIAGNOSIS OF RENAL CALCULUS, AND ITS OPERATIVE TREATMENT.

Nephro-lithotomy, according to James Israel, is intended to remove stone from the kidney before the kidney has suffered irreparable damage from the presence of the foreign body; while nephrotomy is applicable when pyo-nephrosis, atrophy of the kidney from pressure, and inflammatory changes in it, have so altered the kidney that its restoration in complete integrity is impossible. Nephrotomy is among the most frequent of surgical operations upon the kidney, but nephro-lithotomy is, in Germany, still rare. Israel reports a case occurring in a man forty-one years old. The patient had had pain in his left side since his apprenticeship, but from the spring of 1884 the pains became violent and were accompanied occasionally with vomiting, but without colic, so that for two years he was treated for disease of the stomach. Since 1886 the attacks of renal colic became steadily more violent and more frequent. The pain shot into the inguinal canal, to the left knee, and upward to the shoulder. The character of the pain was boring and unbearable, so that the patient had to twist and writhe. In addition to the paroxysms of pain, the patient had a permanent pain in the region of the left kidney. Hæmaturia occurred occasionally; the urine was strongly albuminous. The violent pains occurred nearly every night about one o'clock, so that the patient was unable to remain in bed. There was considerable emaciation and loss of strength. Finally the pain became unbearable, and on January 18th Israel operated with the consent of the patient. The urine before operation contained scattered red blood-cells, though it was clear in color. The constant occurrence of this, or its occurrence after movement, Israel regards as of great diagnostic importance. Palpation detected no enlargement of the kidney, but pressure both in front and behind was painful.

The operation was performed January 18, 1890. An incision was made below the twelfth rib and parallel to it, extending fourteen centimetres forward from the external border of the sacro-lumbalis muscle. The kidney, which was not enlarged, lay surrounded by the several fibrous layers of the fatty capsule. The latter was loosened from the posterior surface as far as the pelvis of the kidney, and, when no stone could be felt there, from the anterior surface also, so that the kidney and its pelvis could be subjected to the most careful digital examination between the thumb and index-finger. As no sign of a stone could be detected by touch, a fine needle was employed to puncture the kidney in a systematic manner. Nothing was detected by the needle. As Israel was certain that stone was present, he determined not to give up the search. Two ways were possible—either to open the pelvis and examine each calyx with a suitable sound, or to divide the parenchyma of the kidney itself, in order to give access to the finger into the pelvis and the calyces. He chose the latter, as injury to the thin wall of the pelvis of the kidney may easily leave behind a urinary fistula. He therefore incised the kidney on its convex border for a distance of two centimetres and deepened the incision to correspond with the entire thickness of the organ until the finger penetrated through the opening into the pelvis and discovered the stone, which was then easily extracted with fine forceps. The profuse bleeding was checked by pressure for five minutes with a wad of cotton, and the wound in the kidney closed by three deep catgut sutures, which stopped the hæmorrhage. When the bleeding from the kidney had ceased, the separated fatty capsule was sewed, and also the belly wall, leaving room for a drainage-tube, which reached to the capsule. The wound healed throughout by primary union. The tube was removed on the eighth day. For the first few days there was pretty severe renal colic. The urine was mixed with blood for eight days, and then became entirely normal and free from albumin. The patient has pain no longer and feels as though born anew.

Israel passes in review the usual symptoms of renal calculus, and shows how inadequate for diagnosis each is, except palpation of the stone, which is only possible in the extremely rare cases of free-lying kidney. The pain, usually regarded as characteristic of renal colic, may be present when there is no stone. Apart from those cases in which too great acidity of the urine, with the excretion of uric acid and oxalate of lime, is sufficient without calculus formation to produce renal colic, Israel says he has seen renal colic in pyelitis, with alkaline fermentation of the urine, when there was profuse throwing off of epithelium from the pelvis of the kidney, intermixed with triple phosphates. He has also seen renal colic in the remittent hydro-nephrosis of movable kidney, when it evidently depended upon a sudden increase of fluid pressure in the pelvis of the kidney, due to temporary complete occlusion of the ureter. There are cases of long-continued and very severe renal colic in which nothing can be found *post-mortem* to explain their cause. In one case in which a patient apparently had severe renal colic

and passed urate of sodium, the cause of the pain was discovered to be a spondylitis of the middle thoracic vertebra.

Another symptom is lessening of the quantity of urine during the attacks, frequent impulse to urinate during them, and evacuation of concentrated urine. This is true of many cases, but it occurs also in painful colic from other causes, such as that from gall-stone and intestinal colic, and it may also be absent in renal colic.

Spontaneous pain in the kidney region in the intervals between attacks is a symptom of renal colic; but it occurs also in cases of beginning tuberculosis and in simple pyelitis.

Changes in the quality of the urine may be wholly absent in renal colic.

The most valuable symptom is the occurrence of blood in the urine; but it is to be considered diagnostic only when it occurs constantly or very frequently where there is no other catarrhal change, and in small quantity—often only detectable by microscopic examination. Admixture of blood in a purulent urine occurs not rarely without stone in pyelo-nephritic or pyo-nephrotic conditions of a simple or tuberculous character. Profuse bleeding at rare intervals is in favor of a tumor of the kidney; but it may occur in renal calculus.

Microliths in the urine prove nothing if present, and are frequently entirely absent.

When the clinical symptoms do not enable the surgeon to decide as to the presence of stone, Israel recommends an extra-peritoneal exploratory incision. Both anterior and posterior surfaces should be felt, the fatty capsule being separated for the purpose. He regards the operation, if done under antiseptic precautions, as free from danger. If nothing can be felt with the thumb and finger, puncture, and, in the event of that failing, incision into the kidney, as described in the case reported, should be tried. Incision into the pelvis of the kidney should be reserved for the cases in which either the stone is felt in the pelvis or is suspected, from the occurrence of sudden anuria, to be in the beginning or upper third of the ureter.

The details of the operation and the subsequent treatment may be gathered from the case reported. At the conclusion of his paper, Israel reports a case in which death followed an exploratory incision into the kidney for supposed stone. Death appears to have resulted from occlusion of the bowel.—*Berliner klin. Wochenschrift*, March 2, 1891.

REVIEWS.

PRINCIPLES OF SURGERY. By NICHOLAS SENN, M.D., Ph.D., Professor of the Principles of Surgery and Surgical Pathology in the Rush Medical College, Chicago, Ill., etc. Philadelphia: F. A. Davis, 1891.

A TREATISE upon the fundamental principles which underlie modern surgery, from the pen of so noted an author as Dr. Senn, will certainly have an unusual interest for the profession. Yet, after a careful perusal of this work, we must confess to a certain amount of disappointment, occasioned not by what the author has written, but rather by that which he has omitted. We had anticipated finding all that was latest and best in antiseptic surgery, together with Dr. Senn's views upon abdominal work, within this volume. But we find that the title should rather read "Principles of Surgical Pathology," for in the preface we observe: "In writing this book it has been my intention to keep in constant view the difference between the cellular processes as we observe them in regeneration and inflammation, and to connect the modern science of bacteriology more intimately with the etiology and pathology of surgical affections than has heretofore been done."

Dr. Senn discusses at length the processes of inflammation, necrosis and suppuration, and the various bacteria which are their causation. Septicæmia, pyæmia, erysipelas, tetanus, hydrophobia, and tuberculosis in all its forms are next considered.

Great care has been taken to make the discussion of each *disease* as full as possible, and the author certainly deserves great credit for the experimental work he has done. The surgeon who is interested in pathology, this volume cannot fail to enlighten, but we fear that the profession in general will desire a treatise devoted rather to the principles underlying the more practical subdivisions of general surgery, than one entirely pathological in its scope.

ÉTUDES SUR LA RAGE ET LA MÉTHODE PASTEUR. Par le DR. LUTAUD, Editor-in-Chief of the *Journal de Médecine de Paris*. Second edition. Paris, 1891.

DR. LUTAUD has in this volume considered very fully the pathology, causation, and treatment of rabies, both previous to and since the introduction of the method of inoculation devised by Pasteur. The opening chapters treat of the different varieties of rabies produced by the bite of the cat, dog, and wolf, together with the mortality statistics. Then follows an account of Pasteur's experiments upon the lower animals, and an exposition of the methods employed in attenuating the virus, with directions as to the mode of administration. In France, during the period from 1850 to 1872 inclusive, Dr. Lutaud finds 685 cases of undoubted hydrophobia reported. Since that time, though no exact statistics are given, he claims that the disease has increased, and especially since the introduction of Pasteur's treatment in 1886. He, however, admits that many of the cases lately reported are exceedingly doubtful. While arguing that the methods of Pasteur are based upon sound principles and have been of inestimable service to the human race, he nevertheless admits that rabies has increased to five times the number of cases reported prior to 1886, with a death-rate of over 13 per cent. The book concludes with detailed statements of the results of the inoculations in Paris and elsewhere, together with the opinions of the profession and secular press as to its utility.

CORRESPONDENCE.

PARIS.

New Method of Treatment of Pulmonary Tuberculosis.

THE appearance or announcement of the discovery of a remedy against tuberculosis, such as in the case of Koch's lymph, and the rather discouraging results

of the same, have encouraged several experimenters to make known to the scientific world various methods applied by them to that terrible disease. In this letter I shall try to review, in as short and concise a manner as possible, the principal methods advanced during the past few weeks.

Some years ago, Prof. Charles Richet, of the Faculty of Medicine of Paris, and Dr. Héricourt, demonstrated that the introduction of a certain quantity of blood obtained from an animal refractory to tuberculosis, such as a dog, to an easily tuberculized animal, would prevent, or, at least, would have a decided slowing action upon the development of tuberculosis in that animal. Two months after the peritoneal injection of the dog's blood into rabbits, with subsequent inoculations, it was found that, of the twenty-four rabbits who had received no blood, eight had died; while of the nineteen transfused animals, two only were dead. It was also found that the transfused animals gained in weight, while the others, the witness animals, lost. In proportion, the normal standard being 100, this would be represented by a gain in the transfused animals amounting to 125, and a loss in the witness, or non-transfused, to 80.

Five months later, however, the above experimenters admitted that the difference between the two lots of transfused and witness animals was equal. It is true that only one transfusion of blood was made, and had this operation been several times repeated it is probable that the results in favor of the transfused animals would have been more noticeable.

Later on, Drs. Héricourt and Richet, in another series of experiments, tried to increase the resisting power of rabbits to tuberculosis, and for this purpose they injected into the transfusion dog a great quantity of very active tubercular virus, about 20 cubic centimetres. For a few days the dog appeared normal, but a month later he looked sick and had lost weight, although his temperature remained normal. At that period 70 cubic centimetres of the dog's blood was transfused into the peritoneal cavity of three rabbits; seven days later these three transfused rabbits and three witnesses were inoculated with an active tubercular virus. Twenty-five days later, two of the witnesses had died and the weight of each rabbit, 100 being taken as the standard, was: for the three transfused animals 99, 108, 101, and for the remaining witness 78.

These favorable results have led Dr. Richet to experiment upon man; he has injected blood-serum obtained from a dog, and aseptically kept in a sealed glass tube, into several patients. Each injection was made in the dose of from 1 to 2 cubic centimetres, which was well borne by the patient. In only one case have there been any unpleasant symptoms, and no untoward results have been observed; moreover, in a therapeutical point of view, these injections appear to be very beneficial to the patients.

The first patient experimented upon presented on physical examination dulness and gurgling râles at the left apex; on the right side a sub-dulness with loud crackling râles and a quite marked congestion of the right apex with fine râles extending to the point of the scapula. Abundant muco-purulent expectoration, night-sweats, and evening temperature. Loss of appetite and marked feebleness.

The injections were begun in the middle of December and continued every two days, the quantity varying from 1 to 1½ cubic centimetres. The patient has greatly gained in strength, has no more night-sweats, has a good appetite, and has gained over five pounds in weight. As to the physical condition: On the right side there are a few sub-crepitant and crackling râles left at the apex; on the left side the gurgling has almost disappeared, and has been replaced by a cavernous respiration, the dulness has diminished in extent, while expectoration has become mucous.

The second history is that of a man fifty years of age, having had tuberculosis for three years. The physical signs indicated sub-dulness at the left apex, mucous râles in the sub-clavicular region, generalized bronchitis of the whole lung. On the right side, dulness under the clavicle, bronchial respiration, prolonged expiration with moist crackling râles. Yellowish thick sputa containing a large number of tubercle bacilli. General condition very bad, extremely feeble, with night-sweats, etc.

The patient received, first, 1 cubic centimetre of dog's serum; six days later, 2 cubic centimetres; and about every six days an equal quantity; the amount having been once, however, 4 cubic centimetres. Six weeks after the beginning of the treatment, after having received 19 cubic centimetres, the condition of the patient was as follows:

The general condition is much better; no more night-sweats; the appetite is good and the patient has increased ten pounds in weight. Cough has greatly diminished, and expectoration has become mucous and much reduced in quantity. On the right side, no more râles; on the left, a few sub-crepitant and sibilant râles at the apex. An important fact was, that a fistula-in-ano, which, before the treatment, suppurated a great deal, now gives a few drops of blood only.

A third case—a man, aged fifty-two years, suffering from laryngeal and pulmonary tuberculosis of two years' duration. The physical examination of the lungs showed on the right side a sub-dulness at the apex with bronchial respiration and fine sub-crepitant râles, the left apex being in the same condition. The larynx, on the other hand, presented a very large epiglottis, much swollen, thickened, immovable, presenting on its surface small ulcerations. In the larynx a gelatinous swelling, especially on the left side, was noticeable. Tubercle bacilli were found in the sputum.

One cubic centimetre of dog's serum was first injected, followed by an injection of 2 cubic centimetres every three days. After twenty days' treatment no great change was found in the lung. On the other hand, the epiglottis had greatly diminished in size, and it was no longer immovable, while the pain, which had been very marked during deglutition, had almost disappeared.

The last case was a man twenty-nine years of age, who presented the same lesions as the preceding patient, the treatment having the same results.

These experiments really deserve to be continued, as they possess the great advantage of not being detrimental to the patient.

Another method of administration of the blood-serum has been employed, and that is *the direct injection* of the serum into the trachea of the patient. On men these injections have proven to be absolutely without

danger. Drs. Saint-Hilaire and Coupard have injected 4 cubic centimetres of the serum from a dog, at six different sittings, into a young man of twenty-two years of age, who suffered from laryngeal and pulmonary tuberculosis, and in no instance have they observed any cough or dyspnœa following. The advantage of this method over the preceding ones is that it enables one to inject much more serum than can be done by the hypodermic method.

Prof. Lépine, from Lyons, uses, instead of dog's serum, goat's serum, as it is claimed that this animal is much less liable than the dog to tuberculosis. Dr. Lépine, however, no longer injects his serum hypodermically, as he formerly did; he now employs the intravenous transfusion, which is done very slowly, and can be easily regulated, provided the reservoir containing the liquid is not elevated too much. In this manner, by the intravenous method the physician can inject *very slowly* from 80 to even 100 cubic centimetres of the serum, and it can be repeated every two or three days.

Goat's serum is preferable to dog's serum for another reason than the one above mentioned, and that is, because it is much less injurious to the human blood-corpuscles than to that from the dog. The same animal can be bled four times in ten days, giving each time 400 grammes of blood. Twice the blood is obtained by opening the external jugular veins and twice by opening the crural veins. After each of the first three bleedings, Dr. Lépine replaces the blood withdrawn by an equal quantity of salt solution of seven per cent. strength. The blood is obtained by means of a glass canula introduced into the vein and is received in a vase placed in cold water and is defibrinated. Dr. Lépine has not yet indicated the results of his experiments by this new method.

Another method was presented at the last meeting of the Society of Biology, by Prof. Picot, of Bordeaux. This practitioner gives hypodermic injections of a liquid composed of sterilized olive oil and vaseline, holding in solution the active principle of creasote, guaicol, and iodoform. This liquid contains 0.01 gramme of iodoform and 0.05 of guaicol in each cubic centimetre. The injections are given in the cellular tissue of the scapular region. These injections produce no general symptoms except occasionally a sweat, which lasts about two hours; no hæmaturia nor albuminuria is produced; nor are there any local symptoms at the point of injection.

A post-mortem examination of three well-advanced cases of tuberculosis who had undergone these injections, indicated a drying-up of the pulmonary cavities, in which no more caseous material or liquid could be found. From a therapeutic point of view, these injections increased the appetite, diminished and even arrested the expectoration, prevented night-sweats, and increased the weight of the body.

In two cases, in which there was a decided pulmonary tuberculosis with cavities, the physical signs of cavity disappeared in one patient, while in the other desiccation of the cavity was manifested by a complete cessation of the râles; while in two other cases of tuberculosis of the second degree, the crackling râles totally disappeared. Fifteen patients have been treated in all, with equally good results. This practitioner declares that this method is an excellent one in the treatment of pleurisy, removing in ten to twelve days very large effusions into the pleural cavity. In a case of double pleurisy the same result was obtained without any external counter-irritation having been used.

The quantity used is from 1 to 3 cubic centimetres daily. When the patient has not reached the very last stage of the disease, marked improvement of the general and local conditions is quickly observed; cough and expectoration are rapidly diminished; the crackling râles disappear; the bacilli in the sputa diminish greatly in number, and the weight of the body greatly increases.

The results which will be obtained by these different methods cannot, of course, be indicated now. Several months of experiments and observation are necessary; for, in a disease like tuberculosis, we have no right to arrive at a hasty conclusion, such as has, unfortunately, been done in the series of experiments with Koch's famous remedy.

NEWS ITEMS.

International American Medical Congress.—Dr. Charles A. L. Reed, of Cincinnati, has indicated his intention to introduce at the meeting of the American Medical Association at Washington resolutions to the following effect, viz.:

1. That the American Medical Association extend an invitation to the profession of the Republics and Colonies of the Western Continent to assemble in this country in an International American Medical Congress.

2. That the Committee on Nominations be instructed to nominate one member for each State and Territory, and one each for the Army, Navy, and Marine-Hospital Service, to constitute a committee, with power to act, to which shall be referred time, place, and permanent organization of the proposed Congress.

There are sound reasons why such a Congress should be held. Learning always follows in the wake of commerce. The development of politico-commercial relations between this country and those of Latin America must be followed by interchange of literature and science. Medicine will be pushed forward by necessities arising out of commerce. Naval hygiene, quarantine, epidemiology, and the relation, through bacteriology, of these to all other departments of medicine, raises a communal interest between the countries of the two Americas on all subjects which could come before a medical Congress. Interests in medical education might be reciprocally conserved by bringing the Anglo-Spanish profession closer together. Dr. Reed's personal correspondence with Central and South America indicates a favorable disposition there toward the proposed Congress.

Obituary.—Dr. Thomas Baird Reed, Attending Surgeon to the Presbyterian Hospital, and Attending Physician to Girard College Hospital, Philadelphia, died, after an illness of three days, on the evening of April 1st. The immediate cause of death was uræmia, an old nephritis having been aggravated by the passage of a renal calculus. Dr. Reed was born in Washington, Pennsylvania, in 1834, and after a good common-school education graduated from Washington College in 1852.

Soon after taking his degree of A. B., Dr. Reed matriculated at Jefferson Medical College, from which institution he received his degree of M.D. in March, 1859. He was immediately thereafter appointed a Resident Physician in the Pennsylvania Hospital, and served in that capacity the full term of one year and six months. Upon leaving the hospital in May, 1861, he was commissioned Major and Surgeon of the Second Pennsylvania Reserves, with which regiment he went to the front, where, for brilliant professional services, as well as for gallant conduct in several important engagements, he was rapidly promoted to the positions of Brigade and Division Surgeon, and finally became Medical Director of the Army of the Potomac. While engaged in military practice Dr. Reed planned and built many large military hospitals in cities where his corps had their base lines. After being mustered out of the army at the close of the war with the brevet of Colonel, he began private practice in Philadelphia. Upon the organization of the Presbyterian Hospital, in 1871, Dr. Reed was elected an Attending Surgeon, and faithfully served this institution in that capacity until the day of his death.

In addition to his private duties, he was, for more than twenty-five years, medical examiner for the Philadelphia office of the Mutual Life Insurance Company of New York. Dr. Reed was a Fellow of the College of Physicians of Philadelphia, a member of the Association of Ex-Resident Physicians of the Pennsylvania Hospital, and of the Military Order of the Loyal Legion.

In his social, as well as professional life, he had hosts of friends, and to the younger members of the medical profession he always willingly gave advice and assistance. His loss is one that will be keenly felt by all those who knew him.

Resolutions on the Death of Dr. T. B. Reed.—At a meeting of the medical staff of the Presbyterian Hospital, held April 6, 1891, the following resolutions were offered and unanimously accepted:

"Inasmuch as it has pleased our Heavenly Father to remove from our midst our personal friend and late colleague, Dr. Thomas B. Reed, it becomes us, his fellow associates in the Presbyterian Hospital, to take some action in recognition of his former position and his valuable personal relations with each one of us, as well as his interested and efficient services to the institution he so loved and served.

"*Therefore be it Resolved*, That in his death this Board has lost one of its most efficient advisers. Endowed with a strong personality, conscientious in the performance of the simplest duty, painstaking, devotedly interested in behalf of any patient submitted to his care, thoroughly equipped by a long experience in the management of hospitals in the army, he brought to bear upon all his professional and hospital duties such qualities as are rarely associated in a single individual.

"*Resolved*, That we tender to his family an expression of our heartfelt sympathy in this their hour of bereavement and trial."

Upon motion it was decided to enter these resolutions upon the minutes of the meeting, to transmit a copy to the family of Dr. Reed and to the Trustees of the Presbyterian Hospital, and to publish them in the Philadelphia medical papers.

Dr. L. S. McMurtry, of Louisville, Kentucky, President of the Southern Surgical and Gynecological Association, delivered two lectures before the Alumni Association of the College of Physicians and Surgeons, Baltimore, at the College Building, cor. Calvert and Saratoga Streets, on Saturday evening, April 11th, at 8 o'clock, and on Monday afternoon, April 13th.

His subject was "The Pathology, Diagnosis, and Treatment of Ectopic Gestation."

Congress of American Physicians and Surgeons.—Preliminary programme of the American Association of Andrology and Syphilology. The following papers have been promised:

"A Review of the Evidence of the Transmission of Syphilis to the Third Generation." By Abner Post, M.D., of Boston.

"Relation of Syphilis to Stricture of the Rectum." By R. W. Taylor, M.D., of New York.

"Surgery of the Ureter." By A. T. Cabot, M.D., of Boston.

"Some Experience with Suprapubic and Perineal Drainage, Temporary and Permanent, in Vesical Disease." By Edward L. Keyes, M.D., of New York.

"Some Cases Illustrating Urinary Retention from Unusual Causes." By Francis S. Watson, M.D., of Boston.

"On the Radical Cure of Urethral Stricture by Restoration of the Mucous Membrane to the Normal Condition." By John P. B. Bryson, M.D., of St. Louis.

"Observations upon the Syphilitic Cachexia." By J. Blake White, M.D., of New York.

"An Obscure Case of Chronic Non-specific Urethritis of Sixteen Years' Standing." By George E. Brewer, M.D., of New York.

"New Methods for the Treatment of Urethral Disease Effected by the Use of the Speculum." By F. Tilden, M.D., of New York.

"Rupture of the Bladder." By A. T. Cabot, M.D., of Boston.

"Encysted Stone, Complicated with Growths of the Bladder." By C. H. Mastin, M.D., of Mobile.

"Short Note on a Case of Urinary Tuberculosis Treated by the (Koch) Subcutaneous Method." By Edward L. Keyes, M.D., of New York.

"On the Use of Salicylic Acid in the Treatment of Certain Forms of Cystitis." By John P. Bryson, M.D., of St. Louis.

"The Dry Poultice in the Treatment of Epididymitis." By George E. Brewer, M.D., of New York.

"Exhibition of an Antiseptic Syringe for Hypodermic Medication." By J. Blake White, M.D., of New York.

"On the Occurrence of Nephritis in Early Syphilis." By J. A. Fordyce, M.D., of New York.

The Prevention of Narcotic Inebriety.—At a meeting of the American Association for the Cure of Inebriety, held February 18th at the Academy of Medicine, New York, Dr. J. B. Mattison, of Brooklyn, offered the following preamble and resolutions:

Whereas, a leading cause of morphinism, chloralism, and cocainism is the facility with which morphine, chloral, and cocaine can be procured from pharmacists; and

Whereas, the refilling of prescriptions containing

these drugs is a potent factor in the rise and growth of these diseases:

Therefore be it Resolved, as the sense of this Association, that no retail druggist should sell morphine, chloral, or cocaine, except on a physician's prescription, and that no prescription containing morphine, chloral, or cocaine should be refilled except on the written order of a physician.

These were unanimously adopted, and a committee consisting of Drs. Mattison, Crothers, and Wright, was appointed to secure legislation in accordance with the resolutions.

Number of Students in the German Universities.—The *Wiener klinische Wochenschrift* states that during the present semester there are the following number of students in each of the Universities of Germany:

Berlin	5527	Freiberg	931
Leipsic	3458	Gottingen	890
Munich	3382	Marburg	855
Wurzburg	1544	Griefswald	773
Tubingen	1250	Konigsberg	680
Breslau	1246	Jena	640
Bonn	1219	Geissen	549
Ehrlingen	1054	Kiel	489
Heidelberg	970	Munster	385
Strasburg	947	Rostock	371

The whole number of students in Germany amounts to 28,762.

A Legal Absurdity.—The following is taken from the *London Medical Recorder*: "A curious case came before the New York City Court last week, with a still more than curious termination. A gentleman discharged a wet-nurse because she went out at night, and on this and other grounds was not satisfactory to him. The nurse brought suit for breach of contract, and asserted that as long as she supplied the infant with good milk, the father had no right to dismiss her. A pair of healthy-looking twins was produced in court as evidence of the superior lactogenetic capacity of the wet-nurse, whatever might be the irregularity of her habits or the delinquencies of her morals. The jury rendered a verdict for the plaintiff, and awarded her the full amount of her salary according to her alleged contract. This may be good law, but it is not good sense, and the decision will certainly discourage the employment of wet-nurses, already a notoriously uncomfortable addition to the family circle. A bottle is much more amenable to reason, and is far less expensive."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 31 TO APRIL 13, 1891.

By direction of the President, the following-named officers are detailed for duty under the Inter-Continental Railway Commission, appointed under a provision in the Act of Congress approved July 14, 1890, for the purpose of making "a preliminary survey for information in respect of a continental railway recommended by the International American Conference," and they will report in person to the Commission in this city accordingly: EDGAR L. STEEVER, *Captain*, Third Cavalry; STEPHEN M. FOOTE, *First Lieutenant*, Fourth Artillery; LYMAN W. V. KENNON, *First Lieutenant*, Sixth Cavalry; ANDREW S. ROWAN, *First Lieutenant*, Ninth Infantry; SAMUEL REBER, *Second Lieutenant*, Fourth Cavalry; and CHARLES A. HEDEKIN, *Second Lieutenant*, Third Cavalry. WILLIAM C. SHANNON, *Captain and Assistant Surgeon*, for duty as Medical Officer of the party to which he may be attached.—Par. 9, *S. O. 73, Headquarters of the Army, A. G. O., Washington*, April 1, 1891.

HUNTINGTON, DAVID L., *Major and Surgeon.*—On being relieved by Henry G. Burton, Captain and Assistant Surgeon, from duty at San Diego Barracks, Cal., will report in person to the commanding officer St. Francis Barracks, St. Augustine, Florida, for duty at that post, reporting by letter to the commanding general Division of the Atlantic.—Par. 5, *S. O. 71, Headquarters of the Army, A. G. O.*, March 30, 1891.

BURTON, HENRY G., *Captain and Assistant Surgeon.*—Now at San Diego, Cal., on sick-leave of absence, is relieved from further duty at Vancouver Barracks, Wash., and will report in person to the commanding officer San Diego Barracks, Cal., for duty at that post, relieving David L. Huntington, Major and Surgeon, and reporting by letter to the commanding general Department of Arizona.—Par. 5, *S. O. 71, Headquarters of the Army, A. G. O.*, March 30, 1891.

By direction of the Acting Secretary of War, JOSEPH B. GIRARD, *Major and Surgeon*, is relieved from duty at Fort Lowell, Arizona Territory, to take effect upon the withdrawal of the troops from that post, and will report in person to the commanding officer, Alcatraz Island, Cal., for duty at that station, reporting by letter to the commanding general Department of California.—Par. 5, *S. O. 70, Headquarters of the Army, A. G. O., Washington*, March 28, 1891.

By direction of the Acting Secretary of War, JOHN VAN R. HOFF, *Captain and Assistant Surgeon*, now in New York City on leave of absence, is assigned to duty as an additional member of the Board of Medical Officers constituted by Par. 18, S. O. 52, March 7, 1891, from this office, to meet in New York City, for the examination of candidates for admission to the Medical Corps of the Army, etc.—Par. 6, *S. O. 78, A. G. O., Washington*, April 7, 1891.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING APRIL 4, 1891.

WYMAN, WALTER, *Surgeon.*—To inspect Delaware Breakwater Quarantine Station, March 27, 1891.

PURVIANCE, GEORGE, *Surgeon.*—Detailed as Chairman of Board of Examiners, April 3, 1891.

SAWTELLE, H. W., *Surgeon.*—To proceed to Rockland, Me., on special duty, March 25, 1891.

GASSAWAY, J. M., *Surgeon.*—Granted leave of absence for five days, April 2, 1891.

GODFREY, JOHN, *Surgeon.*—Detailed as member of Board of Examiners, April 3, 1891.

IRWIN, FAIRFAX, *Surgeon.*—Detailed as Recorder of Board of Examiners, April 3, 1891.

PECKHAM, C. T., *Passed Assistant Surgeon.*—Granted leave of absence for ten days, March 26, 1891.

WASDIN, EUGENE, *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, March 27, 1891.

STIMPSON, W. G., *Assistant Surgeon.*—To proceed to Charleston, S. C., for temporary duty, March 26, 1891.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

THE TREATMENT OF POSTERIOR DISPLACEMENTS OF THE UTERUS WITH THE UTERO-VAGINAL LIGATURE.[1]

BY H. J. BOLDT, M.D.,
OF NEW YORK CITY.

IN the *Centralblatt für Gynäkologie*, 1888, No. xii. p. 181, Dr. Adrian Schücking, of Pyrmont, calls attention to a new method of treatment by operation for this sometimes so exceedingly unmanageable pathological position.

I will not enter into the various methods of operating employed by different gynecologists. In my opinion, according to the condition present, an operation, if such is to be adopted at all, should be performed which will suit the respective case; we cannot therefore say, with any view to science, "I consider the operation originated by Dr. X. Y. Z. the best for retroflexion." Under certain conditions a simpler operation for this pathological condition seems quite feasible, and such a one, I have no hesitation in confirming positively, has been introduced by Dr. Schücking. We should be conservative in the acceptance of a new operation; but when we have a considerable number of cases which render absolute proof of the utility of a certain operation, then we should have the right to speak a word in its favor and to request those experienced with gynecological work to give it a trial in suitable cases. That this new operation is one deserving such investigation, I hope to be able to demonstrate satisfactorily by citation of the cases thus treated by various operators.

The cases in which this operation is clearly indicated are those posterior displacements in which the uterus is freely movable and yet a pessary will not keep it anteposed, or a pessary will keep the organ anteposed only when it is worn, and the patient desires something done for her so that the support can subsequently be dispensed with.

[1] Read before the Medical Society of the State of New York, February 4, 1891.

Posterior displacements held in malposition by moderate perimetritic adhesions can be treated, after first breaking up the adhesions, by Schultze's or Brandt's method. According to Shücking and Thieme, even cases of prolapsus can be cured by the utero-vaginal ligature. I should, however, want better proof than I have experienced before speaking favorably of it.

The operation is done as follows:

After disinfecting the vagina and the external genitals, with the same care as for an abdominal operation, the bladder and bowels having been previously emptied, the uterus is drawn down as far as possible with a double tenaculum forceps. The cervical canal should be sufficiently dilated and the uterus curetted and washed out with hot water, if necessary. The anterior lip of the portio vaginalis is now grasped and the organ thoroughly anteflexed, making sure that no intestines are in front of it, which can be most readily done by placing the patient in Trendelenberg's position. An assistant draws the uterus gradually downward and to the left. The needle invented by Schücking is now introduced, with the needle *within* the canula. An assistant now pushes the bladder to the left side, and the operator, having anteflexed the uterus and having the corpus pushed to the right by the instrument, with the index-finger of his left hand marks the place where the needle will protrude—which is readily done by feeling the end of the canula. Now the thumb pushes forward the lever, which is screwed on to the needle wire within the canula; this causes the needle to pass through the uterus and

vaginal wall. The carrying thread, with which the needle has been previously armed, is now grasped and pulled out, whilst the needle is drawn back again within the canula by means of the lever. The ligating silk is now drawn through by means of the carrying thread, and the two ends are tied together, when it will be found that the uterus is in a position of anteflexion. A serous agglutination subsequently forms in the lower part of the vesico-uterine space.

A suitable pessary should be introduced after

operation, which ought to be worn about three months. The silk ligature should be removed in from six to ten weeks. A modification of this operation by Thieme seems to me worthy of notice, viz.: instead of bringing the proximal end of the uterine suture out at the os externum, the anterior wall of the portio vaginalis at its vaginal junction is pierced again, and the suture is brought out at that point, the object being, *first*, the prevention of cutting of the suture in the cervix; *second*, placing the uterus more into anteversion instead of flexion.

One of the main dangers in doing this operation is injury to the bladder, which has occurred several times in the hands of various operators, but I am confident that with proper care it can always be avoided. To me it occurred in the first case operated upon; it was due to an instrument whose canula was too weak and to improper technique. In no case of injury to the viscus has any ill consequence followed. I use a block-tin sound to push the bladder to one side. Sometimes bloody tingeing of the urine occurs after the operation, which I think due to slight injury by the sound used to push the bladder to one side, rather than to injury with the needle; in the only case in which it occurred in my hands it disappeared at the second urination. Schücking and Thieme both advise irrigation of the bladder before and after operation with a solution of thymol. Zweifel makes a transverse incision in the anterior vaginal wall, at the point where the needle should pass through, which facilitates that part of the operation. This is corroborated by Schücking, who followed Zweifel's advice.

Altogether 141 patients have been operated upon by this method *without* one serious accident; for the purpose of statistics, however, all are not available. In Schücking's list there are 20 who were operated upon by his original method, viz., leaving in the suture only ten to fourteen days, and no pessary after operation; here there were 8 failures.

Klotz, of Dresden, has operated 22 times without stating the results. It is to be presumed, however, if these had not been satisfactory he would not have done the operation so frequently.

Nine cases operated upon by myself show 2 failures; that is, the uterus is again posterior in 2 cases. This I think also due to the neglect of a pessary after operation.

Of 53 operations done by Schücking according to his present method only 2 failures occurred; Thieme, 14 cases, no failures; Zweifel, 7 cases, no failures; Ruhl, 4 cases, no failures; Debrunner, 12 cases, 4 failures.

Two of the latter's cases cannot be counted as evidence for final result.

I have read the letter of one patient to Dr. Schücking, in which she states that she is now relieved of her former suffering. She had been ill for a number of years, during which time she was in the hands of one of the ablest men in Germany without much improvement.

To Dr. Schücking I hereby express my sincerest thanks for his kindness in showing me the proper technique of his operation and for the statistics of cases.

245 WEST FORTY-SECOND ST.

SO-CALLED LACERATION OF THE PERINEUM.[1]

BY HENRY J. GARRIGUES, A.M., M.D.,
PROFESSOR OF OBSTETRICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CONSULTING OBSTETRICIAN TO THE NEW YORK INFANT ASYLUM; VISITING OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL; GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

ON account of its hidden position between the buttocks, the perineum is little exposed to injury from without. Still, under particular circumstances, wounds of this kind are incurred. Thus, punctured, incised, torn, or contused wounds, which may be extensive enough to cause a complete laceration of the partition between the genitals and the rectum, are occasionally produced by falling down on the upright of a chair, the slat of a fence, or a pitchfork concealed in a haystack, or by sliding down the balusters of a staircase against the boss of the newel-post. Similar lesions are sometimes caused by the goring horn of an infuriated bull, or by rape, especially when there is a marked disproportion between the organs that come in contact.

Of much more frequent occurrence are injuries due to a force coming from within. An acute prolapse of the uterus or the expulsion of a large fibrous polypus may cause such lacerations; but by far the most common cause is childbirth, and that is the kind of laceration to which I shall confine myself in this paper.

In most text-books upon obstetrics and gynecology we find descriptions of laceration of the perineum, which give an entirely erroneous idea of the lesion sustained, and are unfit to form the base of an intelligent conception of the pathological conditions caused by it, and the proper therapeutic measures to be adopted in different cases.

The common way of dividing perineal lacerations takes only the extension of the tear into consideration. Thus, authors distinguish three, four, or five degrees of laceration, according to the extension of the tear—through the fourchette alone, to a point between the vulva and the sphincter ani muscle, to the external circumference of the sphincter, to some point in the expansion of the sphincter, through

[1] Paper read before the New York Academy of Medicine, March 5, 1891.

the whole thickness of the muscle, and more or less up the recto-vaginal septum.[1] In my opinion this doctrine overlooks the most important point.

While it is unnecessary thus to divide a tear between the vulva and the rectum into half a dozen varieties, this elaborate division does not comprise some of the most important lesions of the genital outlet resulting from childbirth. It is due to the deplorable confusion between the entrance of the vulva, *rima pudendi*, and that of the vagina, *introitus vaginæ*, to which I have already called attention in my paper on "The Obstetric Treatment of the Perineum," published in the *American Journal of Obstetrics*, in 1880.

The old authors used the expressions *vulva*, *matrix*, and *uterus* to designate the whole genital canal from the rima pudendi to the fundus uteri, just as the public yet nowadays frequently uses the word womb in this sense. Modern medical authors would never confound the uterus and the vagina, but it is by no means rare, or, rather, it is quite common yet to confound the vulva and the vagina and to speak of the vaginal canal in such a loose way that it gives rise to considerable confusion. Still, the two latter organs are divided by just as distinct a line of demarcation as the two former, the limit between the vulva and the vagina being the hymen or its remnants, just as the vaginal portion with the os forms the limit between the vagina and the uterus. The rima pudendi is a slit in the skin, running in a straight line in an antero-posterior direction from the mons veneris to the fourchette; the entrance to the vagina lies an inch or two deeper, is circular, surrounded by mucous membrane and muscles, and is the seat of the hymen or its remnants. These two openings form two comparatively narrow rings at and near the outlet of the parturient canal, and the upper one is, again, the narrower of the two. These rings are, therefore, the two places where laceration commonly begins during childbirth, and from which it may extend more or less into the neighboring tissues. The upper ring being the narrower of the two, is also more frequently torn.

These two rings differ much from one another in their component parts. The outer or vulvar ring consists of skin, a thin expansion of unstriped muscular fibres called *woman's dartos*, adipose and connective tissue.

The inner or vaginal ring is covered with mucous membrane, and under that lies a collection of muscles and fasciæ which give it greater solidity, allow a considerable dilatation, especially after the softening and new growth of loose connective tissue that takes place during gestation, but which, if the tension becomes too great, may give way. These muscles deserve particular attention, since it is injury to them that constitutes the true cause of the sufferings usually attributed to laceration of the perineum. They form three layers. The superficial layer consists of the bulbo-cavernosus or sphincter vaginæ muscle, the superficial transversus perinæi muscle, and unstriped muscle fibres uniting the two posterior ends of the bulbo-cavernosus muscle. The middle layer is represented by the transversus perinæi profundus muscle and the constrictor vaginæ. The deepest layer is formed by the levator ani muscle.

The *bulbo-cavernosus* muscle receives some fibres from the external sphincter ani, the levator ani, and the superficial transversus perinæi muscles, and others originate from the ischio-perineal ligament and the neighboring tendinous tissue. It is inserted on and near the clitoris. It lies outside of the vulvo-vaginal gland and the vestibulo-vaginal bulb, which it compresses, and is not a very powerful muscle. It surrounds the vaginal ring on the sides, but does not close it in front nor behind, and the name sphincter vaginæ is therefore less appropriate.

The *transversus perinæi superficialis* muscle closes the vaginal ring behind. It is a pair of still weaker muscles, but, going from the inside of the tuberosity of the ischium to the transverse septum of the perineum, bisecting the angle between the bulbo-cavernosus and the sphincter ani externus, intermingling with both, it steadies the perineal body, and helps during parturition in pushing the presenting part of the child forward toward the pubic arch. In many women this muscle takes a more forward course, so that it does not reach the perineal body at all, but is fastened to the outer edge of the bulbo-cavernosus muscle. With such an insertion its function can only be to open the vaginal entrance. The superficial layer of muscles is situated between the superficial perineal fascia and the anterior layer of the deep perineal fascia.

The muscles of the deeper layer are little developed, not clearly separated from one another, and differently described by different anatomists. They are situated between the two layers of the deep perineal fascia.

The *deep transversus perinæi muscle* arises from the ramus of the ischium and goes horizontally to the sides of the vagina, which it helps to steady.

The *constrictor vaginæ muscle* consists of a few fibres which arise from the transverse septum of the perineum and encircle the vaginal entrance as a sphincter.

Thus the deep transversus and the constrictor vaginæ correspond to the superficial transversus and the bulbo-cavernosus of the superficial layer.

Of all the muscles contributing to the formation of the vaginal ring, the *levator ani* is by far the strongest and most important. It forms a horseshoe-

[1] A. Charpentier: Traité pratique des Accouchements. Paris, 1883, vol. ii., p. 223.

shaped muscular expansion, which is open in front, is attached in a wide circumference to the walls of the pelvis and forms a double loop behind the vagina and the rectum. It is generally described as two muscles—the levator ani proper and the coccygeus—but they touch one another with their edges, so that one is a continuation of the other, and they often even coalesce. Under all circumstances they form together a pelvic diaphragm corresponding to that which limits the abdominal cavity above. The levator ani takes its origin from an oblique line on the posterior surface of the body of the pubic bone, from a small circle just in front of the spine of the ischium, and from the tendinous arch, part of the pelvic fascia, extending between these two bony attachments, the pubic portion goes backward and inward, crosses the vagina, to the sides of which it is bound by strong connective-tissue attachments. Its fibres are interwoven with the longitudinal fibres on the lateral aspects of the vagina. Some loops go from side to side between the vagina and the rectum, but the greater part of the muscle goes behind the latter, forming loops without any intermediate tendon. They hug the concavity of the end-curve of the rectum and support it from below. The levator goes in between the external and internal sphincter and intermingles with both of them, as well as with the longitudinal fibres of the rectum.

This muscular expansion is covered above and below with a fascia; above it is the vesico-rectal part of the pelvic fascia; and below it is the anal fascia, part of the deep perineal fascia.

Beside other functions that do not concern us here, it draws the anus forward in the direction of the symphysis, pulls the vagina forward during childbirth, and pushes the child forward, so as to make it turn the pubic arch.

Between the vulvar and vaginal ring behind is the *fossa navicularis*, and between both rings and the rectum is the *perineal body*. After having been entirely neglected until it was described by Henle and Savage, this structure acquired all of a sudden an enormous importance, and was made the "keystone" that supported all the pelvic organs. A great deal has been written about it, and different authors have assigned a very different shape to it, but the study of sagittal sections of the pelvis show that it has a great variety of shapes. Sometimes the whole space between the rectum and the vagina, up to the cervix uteri, forms one triangular surface. In other cases this space is easily distinguishable as an upper narrow and a lower broad part, the latter alone deserving the name of perineal body; but this body appears again with very different forms and differs in extension upward. It may just form a slight swelling, so that the whole sagittal cut becomes nearly club-shaped. Sometimes the whole body lies below the hymen, while in other cases it extends more or less up behind the vagina. The shape is sometimes nearly quadrangular, with one side turned to the skin, one to the rectum, one to the vulva, and one to the vagina. In others it has the shape of the quadrant of a circle; in others again that of the receiver of a retort, the neck of which is formed by the narrow part between the vagina and the rectum. This great diversity of forms is easily understood when we take into consideration the fact that all the parts concerned are made of more or less soft tissue.

The perineal body is composed of the posterior ends of the bulbo-cavernosi muscles, unstriped muscle fibres uniting them behind, fibres belonging to the superficial transversus perinæi muscle, the external and internal sphincteres ani and the levator ani muscles, the ischio-perineal ligament, the posterior part of the superficial and deep perineal fasciæ, the anal fascia and adipose tissue. It is covered below by the skin lying between the anus and the rima pudendi, behind by the rectal mucous membrane, above and in front by the mucous membrane of the vulva and sometimes of the vagina. It has no definite lateral limits, unless we artificially suppose it to be continued to the tuberosity of the ischium. The cutaneous surface is shorter than in man, measuring only one-half to one inch in length, while the distance from the anus to the entrance of the vagina, the true length of the perineal body, is about one and three-fourths inches. According to what has just been said about its upper limit no definite height can be ascribed to it.

Small as this body is, it is of great importance in forming the centre of the whole perineal region, where muscles, fasciæ, and ligaments come together. As they are fastened to the surrounding bones the perineal body becomes the chief support of the pelvic floor. It keeps the vagina and the rectum in their proper relative position. During childbirth it forms a strong barrier against which the child is being pushed from above and pressed forward around the pubic arch by passive and active counterpressure. During this act its power of resistance is often overcome, and a laceration takes place.

Beside the two rings we have called attention to at the outlet of the genital canal, a third ring, formed by the internal and external sphincteres ani muscles, must be considered. Its function is to close the intestinal canal. Examined from the vagina, the anus forms a weak point in the pelvic floor. During childbirth it is pushed and drawn forward, and becomes enormously distended, as does all the surrounding tissue between the coccyx and the vulva.

When the child is pushed against the vaginal ring it may break through to the rectal ring and be born

through the rectum. The rectal ring may either burst or withstand the great tension, and the vulvar ring remain intact. The child may also be born between the rectal and vulvar ring, so that both remain intact, while the vaginal ring above is broken—so-called central perineal rupture.

A modification of this is the condition where first a central rupture forms and then extends into the vulvar ring. Another modification is that in which the central laceration stays incomplete, that is to say, no perforation takes place in the perineum, part of the tissue between the skin and the vagina remaining entire.

While the lesions so far mentioned are rarities, we come now to the most common of all, namely, those cases in which the vaginal ring alone is affected. These tears may be superficial or deep, open or concealed, longitudinal or transverse.

According to Duncan[1] every primipara sustains a laceration of the posterior part of this opening, but my own observations have taught me that this is a mistake. I have notes of cases in which there were tears of the labia, the fossa navicularis, the fourchette, and even the vagina, without any injury to the vaginal entrance. Tears here are, however, common, and may extend more or less upward into the vagina and more or less downward into the fossa navicularis. If they are superficial and only go through the mucous membrane they are of little importance, the severed parts being kept in contact by the deeper, and healing easily.

The deep tear of the vaginal entrance, implicating the levator ani muscle, is usually found backward and outward in the direction of the tuberosity of the ischium, the reason for which is probably that the muscle is caught between this point and the head, while in the median line the intervening rectum and the double fascia that descends in front of it as a continuation of the pelvic fascia, furnish a soft pad which protects the muscle.

Sometimes the muscle snaps in the depth of the tissues, while the mucous membrane, containing more elastic fibres, resists the strain, so that the result is a submucous tear, just as the biceps during a sudden flexion of the arm may burst under the skin. As in rupture of the biceps we can put our fingers in between the two retracted ends of the muscle, so in the rupture of the levator ani we can put one finger into the gap, only with this difference, that the rupture does not extend through the whole width of the muscle. At, and to some variable extent above, the vaginal entrance, we feel a V-shaped break in the ring.

The power working eccentrically, the rupture in the vast majority of cases takes place in a radius; in other words, the ring is broken, and the lesion is a longitudinal rent in the genital canal. Exceptionally, the direction of the rent may be more or less transverse. The most common rent of this last kind is a tear along the base of the insertion of the hymen, whereby this membrane is torn more or less completely loose from its connections. Drs. T. A. Emmet[1] and Matthews Duncan[2] describe also other transverse tears, and the former thinks that this form of lesion is the common one. Admitting the possibility of such a tear by which the whole vaginal ring is sundered from the upper part of the vagina, or a partial tear produced by a transverse fold being caught by the advancing child and torn loose from side to side, in my opinion this is and must be a comparatively rare lesion. When the distinguished American author thinks that it is the common form of injury in childbirth, I am inclined to account for it by the fact that at the time he turned his observation to the tears of the vaginal outlet he had long ago given up obstetric practice. Because we find transverse cicatrices in gynecological patients, we cannot conclude that the fresh tear had the same direction. When a longitudinal rent does not heal by juxtaposition of the torn surfaces, it changes direction, and leaves a transverse line of cicatrization. This, I believe, is the explanation of the two facts with which everybody who is engaged both in obstetrical and gynecological practice will be familiar, namely, that fresh rents examined immediately after delivery nearly always follow the direction of the axis of the parturient canal; and, on the other hand, that transverse cicatrices are exceedingly common in women who seek relief for diseases of the genitals.

A tear involving the levator ani at the vaginal entrance deprives the pelvic structures above of their necessary support. As soon as the patient gets up she has a disagreeable feeling of looseness and bearing-down. In the course of time the vaginal mucous membrane bulges out in front and behind, the bladder sinks down, the uterus is first retroverted, then retroflexed, then it descends, and may finally hang between the legs. The strain on the utero-sacral ligaments, the broad ligaments, and the connective tissue of the pelvis causes pain in the sides of the pelvis, and backache. It interferes with free circulation in the pelvis, causes a sensation of heaviness, and produces hyperplasia of the uterus. The vagina is inverted, and becomes unfit for one of its purposes. The cervix is drawn out to a great length, its lips everted, and, in consequence of friction against the clothes, a large ulceration forms around what seems to be the os, but in reality is a point situated much higher up in the canal.

[1] Matthews Duncan: Papers on the Female Perineum, London, 1879, p. 8.

[1] T. A. Emmet: Trans. Amer. Gyn. Soc., 1885, vol. x. p. 161.
[2] M. Duncan: Loc. cit., p. 24.

The prolapse of the anterior wall of the vagina is commonly called cystocele—a correct name, since the bladder always forms part of the swelling. The prolapse of the posterior wall is commonly called rectocele, which is not correct. The rectum nearly always stays in its normal place, and the vagina slides away from it. It is easy to satisfy oneself on this point by seizing the prolapse between the index-finger and the thumb. If it contained the rectum, two slips would be felt when the seized tissues slip out between the fingers: one representing the rectal wall, and the other the vaginal wall; but we feel only the latter. The reason of this difference is, that the bladder is bound to the upper part of the vagina and the cervix with short, tight connective-tissue, while that connecting the posterior wall with the rectum is much looser.

It is possible that the anal ring alone may be broken. Dr. T. A. Emmet[1] has reported a case of this kind in which the rupture had taken place behind, leaving the vulvar ring uninjured, and since nothing is said about the vaginal entrance, it is probable that that also had escaped.

The vulvar ring may be broken, and that is the lesion that has been earliest recognized, and which yet forms the base of most desciptions of lacerations of the perineum. The many classes into which this tear has been subdivided are superfluous. The only question of importance is whether the vulvar ring alone is implicated, or the tear extends through the anal ring—so-called incomplete and complete laceration of the perineum.

The injury commonly takes place in the median line, beginning at the posterior commissure and extending more or less backward. But if the perineum escapes, or only suffers little, especially if the accoucheur helps to press the head forward against the symphysis, the injury to the distended vulva often takes the shape of superficial tears on the labia majora, or deeper tears in the labia minora and the vestibule, near the clitoris.

Nearly all these tears have a longitudinal direction, more or less parallel to the axis of the parturient canal, or at right angles to the rima pudendi, but if the severed halves of the perineum do not unite by first intention, they heal separately, each forming one-half of the cicatrix, in which way cicatrices with a transverse direction are formed. By involution taking place in the vulva after the enormous distention during childbirth the direction of cicatrices is also changed. I have seen real transverse tears by which a strip of mucous membrane extending from one side to the other of the rima pudendi, is torn loose from the fossa navicularis, and tears of the labia majora parallel to the rima pudendi, but such lesions are exceedingly rare compared with longitudinal tears.

The consequences of tears limited to the vulvar ring are slight or none. Most women are little concerned about an affection which does not cause them any discomfort, but the male may find less satisfaction in sexual intercourse on account of the enlargement of the vulva, and sometimes there is a tenderness of the scar which causes the woman pain.

In a complete superficial tear both the vulvar and the anal ring are broken and form a single instead of a double ring; the sphincter retracts, its ends being plainly marked by a little glazed pit on either side; where the perineal body should be is seen a V-shaped cleft; the mucous membrane of the rectum rolls out, forming a little red, soft, puckered cushion at the posterior circumference of the anal opening; and the patient has no control over flatus and fæces, which escape involuntarily, and make the poor woman an object of disgust to herself and others. But if the vaginal ring is intact she has none of the symptoms appertaining to prolapse, which we have referred to in speaking of the rupture of that aperture.

I recently operated on an elderly lady who had had for twenty years a tear through the perineal body, extending one inch and a quarter up the rectum, but where the vaginal ring had not suffered at all. The sphincter ani could be felt as a thick resistant ring without a break, and there was neither cystocele, rectocele, nor the slightest descent of the uterus, nor any symptom of pelvic trouble whatever.

Just as the tear in the vulvar ring may be combined with that of the anal ring, we may have a combination of the vulvar and vaginal rupture, or of all three, the result as to symptoms being a combination of those characteristic of the single tears.

In regard to treatment I shall limit myself to some general remarks.

The preventive treatment lies without the scope of this paper, and has been considered at length in my earlier paper, referred to above.

Under lucky circumstances Nature can, perhaps, effect a cure of any tear. I have myself seen this in incomplete laceration, where the whole perineal body was severed to the rectum; and by a cure I mean agglutination of the entire torn triangular surfaces.

During my services at the Maternity Hospital in the years 1885–86, I examined numerous primiparæ shortly after delivery, and again before they left the hospital, and took detailed notes of the tears of the parturient canal at the two periods. Thus, I satisfied myself that, with few exceptions, the tears in the fossa navicularis, on the labia, through the

[1] Trans. Amer. Gyn. Soc., 1883, vol. viii. p. 202.

vaginal ring, and in the vagina, healed so as to form linear cicatrices. In all the observed cases there was no, or only a very slight, tear of the cutaneous perineum, since all longer tears are immediately stitched, and therefore cannot be examined, and all the patients were treated with my occlusion bandage,[1] which exercises a certain pressure on the external genitals.

Similar results are claimed to have been observed in cases in which the tear extended so far up the rectum that all three rings must have been broken. But as natural cures in such cases are little short of miraculous, no man in his senses would wait for them. As a rule, Nature effects only a partial healing; the parts heal, of course, in the end, but the ultimate condition is far from being identical with the pristine one. With few exceptions we do not get a healing *together*, that is an adaptation and coalescence of the torn surfaces, but a healing *over*, that is to say, a torn surface forms an independent scar, and does not grow together with the corresponding surface on the other side.

The first paper I ever heard read in this Academy was one by Noeggerath on the primary operation for lacerated perineum. Then he stood alone, every speaker either declaring that perineal laceration was so rare that he never saw it, or deprecating immediate interference. All this has entirely changed since then. We all know that, to those who look for them, perineal lacerations are very common, and the many members of the American Gynecological Society who have written on the subject unanimously recommend the so-called primary operation, which means the insertion of sutures, so as to bring the torn surfaces together, immediately after or at least within twenty-four hours after delivery. Immediately after the tear has taken place the torn surfaces fit exactly to one another, and grow much more easily together than pared surfaces. A much smaller number of sutures are, therefore, required. Secondly, if only a partial success should be obtained, the great point is gained that the parts retain their normal shape and relations, so that a secondary operation becomes easier and has greater chances of being successful.

If the vulvar ring is torn behind, alone or conjointly with the vaginal ring, perineal sutures alone, and only from one to three in number, are required. If the anal ring is broken, too, it is best to insert a triangular row of sutures, following the outlines of the triangles which immediately after childbirth represent the perineal body. If the tear extends higher up into the vagina, vaginal sutures alone are placed in the septum above the perineal body. Tears through the anal ring are united with at least two rectal sutures, so as to bring the whole breadth of the torn ends of the sphincter well together. The central perineal rupture is brought together with deep perineal sutures. If the rima pudendi and the skin perineum are intact, there is, as stated above, great prospect of the parts uniting under the comparatively aseptic condition and the pressure ensured by a well-adapted perineal dressing.

Where no lesion is visible on the outer surface the friends of the patient may object to an operative interference the importance of which they do not understand. When circumstances are favorable some deep sutures may, however, be inserted from the vagina in such a way as to bring the edges of the rent in the vaginal ring together. The subcutaneous tear of the levator ani muscle might be treated in a similar way after cutting down upon it, but such an undertaking would probably meet with still greater opposition, not only from the public, but also from the profession. This accident is, therefore, left until bad consequences develop, and is then remedied by the secondary operation.

As I invariably stitch up tears involving the cutaneous part of the perineum immediately, and they always grow together under my antiseptic dressing, I have little personal experience with the so-called *intermediate operation*, which consists in attempting union at any time while the torn surfaces are granulating. I have, however, notes of a case occurring in September, 1882, before the new treatment was introduced into the Maternity Hospital, in which there was a tear through the whole perineum into the rectum, with incontinence of fæces. Three silk sutures were put in at the time of delivery, but no union took place. On the thirteenth day after confinement the granulating surfaces were scraped, dusted with iodoform, and brought together with three stitches, which led to a complete restoration of the perineal body. If, therefore, the primary operation has not been performed or has failed, and the case comes under observation in time, it is well worth while trying the intermediate operation.

If the torn parts have not been united by this or the primary operation, secondary operations are often required. There is a great variety of them, but the time allotted to me being spent, it is impossible to enter on a criticism of their respective values. I will only state which methods I prefer, because they have given me the best results. For incomplete perineal laceration, where the vaginal ring has not sustained much injury, Tait's flap operation is sufficient, and is an easy and expeditious operation, which with proper antiseptic precautions can hardly fail. For cystocele I use Sims's or Stolz's operations; for prolapse of the posterior vaginal wall, with or without rectocele, Hegar's colpo-perineorrhaphy, with slight modifications of my own, has

[1] Garrigues' Practical Guide in Antiseptic Midwifery; Detroit, Mich., 1886, p. 27.

given me most satisfactory results; and for the complete perineal laceration the same author's modification of the operation built up by many predecessors, using a trianglar row of sutures, has yielded excellent results at my hands.

TREATMENT OF THE UTERINE CAVITY IN ABORTIONS.[1]

BY H. C. CROWELL, M.D,
OF KANSAS CITY, MO.

THOUGH the treatment of abortion is quite familiar to most practitioners, viewing it from their individual standpoint, it has appeared to me that there is yet room for discussion of some of the indications in such cases. In view of such a conclusion, as a result of some personal observation, I have undertaken to consider, briefly, certain indications which seem to me to be of practical importance, looking toward the most perfect result.

We will note primarily the physiological state of an impregnated uterus, and then the pathological, as I am disposed to consider it, in case of abortion. Then let us follow with some observation on the treatment as usually practised, noting some of the common results. Thus, considering the subject together I think that we may hope for new ideas and suggestions which may be of assistance to us in like cases.

It is not my intention to consider in detail the management of cases of abortion, but only that stage which comprehends the management of the uterine cavity following abortions. I realize full well that many very excellent authorities will not agree with me on every point, but in principle or theory I think there can be no variance, with our present understanding of processes and sequences. Since there *is* a possibility of difference of opinion, the object of this paper will be attained if it serves to awaken local observation and investigation, which will be of use to us now or in the near future.

The significance of abortions consist in their immediate and, more or less, remote effect upon the subject aborting. The immediate dangers are traumatism and hæmorrhage, either of the cervix or endometrium. The remote danger lies in resulting *endometritis*, *salpingitis*, *oöphoritis*, *sepsis*, pelvic inflammation, and sometimes pelvic abscess.

Martin says, and this is also in accordance with my own observation: "Chronic metritis occurs extraordinarily often after abortions, not only because the women do not take suitable care of themselves, since they (and some doctors) think that a pregnancy which is interrupted too early does not require the same attention as one that ends normally, but especially because this premature interruption of pregnancy is very frequently associated with insufficient evacuation of the cavity of the uterus, and permanent disturbance of the functions of the mucous membrane." Now, realizing the possibilities in a given case of abortion, it becomes evident that we should fully understand the process Nature requires to be fulfilled, and how the result is accomplished, and how we may best render assistance when it is required. We should also understand when Nature is able to effect the various steps necessary to a safe and perfect result.

By an abortion, then, we mean an expulsion of the contents of an impregnated uterus any time within the period of the first three or four months of impregnation. After this period, or during the fourth, fifth, sixth and seventh months, should such expulsion take place, we term it a miscarriage, and after the seventh month to full term it is called premature labor.

Now, in order that we may grasp the significance of abortion, as I have said, it will be necessary for us to familiarize ourselves with the physiological condition of the uterus after the ovum shall have entered its cavity, and, having done that, we can readily see the processes to be performed when, from any cause, the ovum shall be separated and expelled. It has been shown that the uterine mucosa, in way of preparation for the reception of the ovum, is thickened about ten-fold, becomes more vascular, and is thrown into numerous folds or convolutions, due to the increase of the cellular elements, this producing a soft, pulpy bed for the reception of the ovum. This soft, thick mucous membrane is known as the decidua vera. In this decidua vera lodges the ovum, and the surface under the ovum, made up of the decidua vera, is now known as the decidua serotina, and is the beginning of the *placenta*. Folds of the decidua vera grow up around the ovum, and finally meet and enclose it in a cavity of its own, shut off from the general cavity of the uterus. These folds of the decidua vera now become known as the decidua reflexa. During the first two months the fœtus is surrounded by a shaggy enveloping membrane, through which it draws its nourishment. At the end of this time this villous membrane becomes bald in its outer aspect down to the third of its surface, which lies most intimately attached to the uterine mucosa, and is now to be the placenta. Thus we see that a formed placenta does not exist until about the third month, or the termination of the period in which we may have an abortion.

The fœtal membrane or chorion is intimately applied to the maternal or decidual membrane. The decidua vera is not shed and expelled naturally in every case, until the term of gestation shall have expired, at which time it is thrown off by a very

[1] Read before the Kansas City Academy of Medicine.

moderate degree of contraction of the uterus, without much hæmorrhage (except when the placenta is attached) this constituting complete gestation and parturition. Now that the office of the decidua has been fulfilled, at full-term delivery, a new membrane is developed underneath, ready to supply the place of the old to be exfoliated, and this protects the intra-uterine muscles.

With this brief physiological examination of the processes taking place in the uterine mucous membrane during gestation, and especially in the early stages, we must be impressed with the fact that Nature has placed in the uterus a thickened membrane with certain offices to perform, requiring for their perfection the period of nine months, or a normal gestation; hence, whenever we have an abortion, from any cause whatever, we have a pathological condition to treat, and in this no more than in any other pathological condition can we leave it to Nature in every case; nor, on the other hand, can we profitably do that which shall defeat a natural or philosophical process. We must be impressed, it seems to me, that the treatment should be almost unanimous, or having the same end in view, viz.: the removal of the decidua, maintenance of perfect asepsis, and drainage. Now, when we shall have so treated a case as to fulfil these indications, we shall have done all that can be done in averting conditions of sepsis which are attended with serious results to the patients, in the shape of septic endometritis, metritis, salpingitis, abscess, etc.

Let us examine now some of the more common methods of treatment employed, and note the result in not a few cases. Perhaps the most orthodox plan of treatment in the majority of instances is, if the fœtus is expelled, to give ergot and retire. If the cervix is partially dilated, with the membranes protruding, ergot is given to expel them. If the cervix is not dilated, and an abortion is imminent, a tampon is used, if anything is done. When the fœtus is expelled a finger is introduced, and the clots and some of the membranes which are loose are cleaned away. A possible vaginal douche completes the antisepsis of the case. The patient gets ergot, and possibly quinine, for a few days until she recovers or develops a septicæmia, which sometimes receives the proper care and saves the patient; or she may go on and die, as do not a few every year.

Now let us see if there are not certain indications to be met in every case of evacuation of the uterus before the fourth month. We have seen the uterine mucosa developed into a thickened protective or receptacle, so to speak, destined to do a certain work for a certain period, viz., for nine months time, then to be exfoliated, being supplanted by a submucous membrane destined to replace the decidua. Such, however, is not the case in these earlier months, and yet a process of disintegration and shedding must take place, and a new membrane follow. This disintegration consists of a fatty degeneration, a dissolution and discharge, called the lochia. If, then, the uterine cavity is to be freed of its membrane, which has by the separation of the ovum been in a greater or less degree injured, we see as a first consideration the necessity of free drainage; hence we conclude that ergot, which causes uterine contractions and closure of the cervical canal, is contra-indicated. To me the rational plan would seem to consist in cleaning out the uterine cavity of all its contents at once—membranes of the embryo and decidual membrane of the uterus—thus removing the possible cause of sepsis, checking hæmorrhage, and facilitating early involution and a safe convalescence.

By the use of the dull curette, the os being freely dilated, the uterus should be cleaned perfectly, then swabbed out with pure carbolic acid or tincture of iodine, and ample drainage maintained by some means—my own preference being for iodoform gauze—leaving it in place for twenty-four or thirty-six hours, to be replaced after an intra-uterine douche of bichloride. Small doses of ergot and quinine, and possibly iron, may then be given to assist in the process of involution. I am convinced that when left to themselves these cases not infrequently, even when credited with making an unusually good recovery, go on to a state of ill health, though without symptoms which alarm or disturb the patient sufficiently to cause her to consult a physician. Perhaps the larger part of all cases of chronic tubal troubles date their bad feelings to the time of a previous abortion.

Miscarriage, or even parturition, may figure, as do these cases of abortion, in originating an endometritis, which travels up through the tubes to the ovaries, setting up a salpingitis, peri-oöphoritis, or peritonitis, with all their attending ills. One of these cases may run an insidious course without developing any *well-marked* pelvic peritonitis, and present a history something like this: Trouble with lower bowel, rectum, bladder, menstrual disorders, soreness, with indefinite pains, tenderness on palpation, etc. Colicky pains are common if salpingitis is present. These pains are sudden and lancinating, in the region of the tubes, or possibly in the hypogastrium; sometimes suddenly ceasing, followed by a discharge of more or less bloody, serous, or purulent material from the uterus, often thought by the patient to be leucorrhœal. These pains are not infrequently thought to be colic of the uterus; but with this history, if a vaginal examination is made, a small tumor will frequently be found on one or both sides. This same process of inflammation continues, and finally glues the fimbrated extremi-

ties together, causing sterility. Again, no appreciable amount of fluid may be contained in the tubes, and yet the inflammation may have caused a thickening of the coats of the tube (interstitial salpingitis), which can be detected through the vagina as a sore cord. These conditions are amenable to no other treatment, in by far the majority of cases, save the removal of the uterine appendages, which renders the woman incapable of performing her mission in its fullest capacity as a childbearing woman. Hence we see the very imperative demand for such prophylactic measures as shall forestall such disastrous results, which are obtained by antiseptic conditions of the uterine cavity at all timcs, and especially in cases of abortion, by rapid dilatation with steel dilators (not by tents), a thorough, carefully executed curretting, followed by systematic drainage until the uterine cavity shall have assumed a normal condition capable of taking care of itself.

Since writing this paper I have noticed a paper by Winter, of Berlin, in which, after analyzing 100 cases, he arrives at the conclusion that "the decidua vera can be left undisturbed—only loose shreds should be removed—as but nine patients completely shed the decidua; hence I feel warranted in assuming that safety to the patient demands the careful use of the curette to examine the uterine cavity, and if any decidual shreds remain (as I am confident they do in by far the greater percentage of cases) remove them. I consider the curette safer than the finger, and more effective. The results of retained decidual membranes may not be observed at once, but even at the end of one, two, or more years its effects will be noted upon the ovaries and tubes."

Finally, the conclusions at which I arrive may be summarized as follows, viz.:

1st. An abortion is a pathological process, involving the premature expulsion of the fœtus and membranes from the uterine cavity, which, normally, have an existence of nine months before they shall have completed their physiological intention.

2d. That such expulsion is generally incomplete when left to Nature, thus exposing the patient to subsequent pathological conditions or possibly death.

3d. That every case should receive a careful examination by the use of the blunt currette in preference to the finger, as it is safe, easier of introduction, and more effective.

4th. Complete removal of all membranes, maternal and fœtal, offers the greatest protection and safety to the patient.

5th. Perfect asepsis and drainage is a necessary supplement to the curette.

6th. Ergot has little or no effect in the treatment of cases of abortion. If used at all it should be in the late stages to assist involution.

PREVENTIVE MEDICINE AMONG THE WORKING CLASSES.*

BY H. N. HALL, A.M., PH.D., M.D.,
OF CHICAGO

REALIZING that comparatively little is known by the American medical profession concerning the masses of poor foreigners who form so large a portion of our population, I feel that it might be interesting to look over a year's work among these people and the results obtained. It will be of special interest, inasmuch as the practice has been largely confined to the lower and poorer classes, who have apparently never sought a physician unless seriously ill, and then, in the majority of cases, consulting some native of their own country who has "come over" here and prefixed "Dr." to his name. We all know that the Government provides a service for the army and navy; that city governments provide a similar service for their police and firemen; while the railroads assess their employés in order that they may reap the benefits to be derived from this source; but it was not until last January that the attention of the manufacturer was called to this important matter.

In the fall of 1889, Mr. R. T. Crane, President of the Crane Company of Chicago, conceived the idea, in a charitable sense, of employing a physician and surgeon on a salary, to care for the 2000 to 3000 employés of his company, and on January 1, 1890, the service was inaugurated.

The following table will show the number of cases treated each month:

	Number of cases.	New cases.	Cases improved.	Cases same.	Chronic cases.	Sick men off.	Cases off.	Surgical cases.	
								Number of cases.	New cases.
Jan.	2041	1216	771	24	30	.....	58	159	82
Feb.	1325	695	585	23	22	263	8	136	54
March	1332	673	544	13	12	234	2	216	98
April	1310	834	355	16	5	124	...	379	89
May	1201	771	416	7	7	88	3	438	81
June	1391	905	471	2	7	117	14	525	117
July	1352	839	512	6	9	55	4	475	94
Aug.	1423	1107	304	4	8	28	...	531	106
Sept.	1648	851	782	3	5	46	1	654	129
Oct.	2055	1147	899	4	5	33	1	920	138
Nov.	1686	1117	563	5	2	38	2	729	140
Dec.	1927	1353	573	5	6	29	1	706	108
Total	18,691	11,508	6775	112	119	1055	94	5868	1236

Again, if we make quarterly enumerations in order that we may learn that period at which any one condition has been prevalent, we have the following:

	Jan., Feb., March.	April, May, June.	July, Aug. Sept.	Oct. Nov. Dec.	Totals.
Surgical cases	234	287	329	386	1236

Of these employés 200 are girls, whose ages average sixteen years. Some 800 are boys between the ages of fourteen and twenty years, while probably four-fifths of the entire number are either foreigners or are born of foreign parents. Of these we find that the machinists and well-paid mechanics are Germans, Norwegians, and Swedes. The mechanical workers, that is those who feed automatic machines, are Irish and Norwegian lads; while the moulders and laboring men, such as helpers, truckers, etc., are principally Poles, Bohemians, and Jews of all types, among whom are many Russians.

It might be well to explain that our object has been to *prevent* rather than *cure*, and that this plan has been very successful is demonstrated in the column of "sick men off." In January there were probably 400 men reported as sick at home, but as this excessive number was due to the epidemic of influenza, we will leave this item and begin with February, when there were 263 men who were reported as having lost at least half a day on account of sickness.

This number has been gradually reduced until June, when, on account of the excessive heat of that month, as well as from the influence of whiskey and immense quantities of beer consumed by these men, we find that there were 117 men at home sick. It might be interesting to state that many of these men who work at the furnaces at a temperature of about 140° F. have an idea that the more whiskey a man drinks the better he can stand the intense heat; but we know that the temperate man is seldom affected by the heat. From June the figures vary but very little in their downward course, and in December we see a very flattering result, namely, only 29 men reported as having lost any time at all on account of sickness. These results seem to demonstrate practically that after all *preventive medicine* is very beneficial to the poor man, who cannot afford to be sick, and who, on account of his surroundings, is far more liable to all the diseases to which flesh is heir than a more prosperous fellow-being who can afford a small house or several rooms in a clean and healthy neighborhood, rather than share the same quarters with many families in possibly a basement in some wretchedly unhealthy locality.

It should be explained that only 94 of these 1055 cases applied to us for medicine; the balance of the number were either taken sick at night or at a time when they could not find the company's physician, or some possibly felt that their ill feelings would not amount to anything and that they would be themselves again on the morrow, while many others, decided followers of fatalism, believed that if a man was destined to be sick he must be so, and that the "old fogyism," "a stitch in time saves nine," was a most atrocious fallacy. However, we find that of 11,508 different cases seen, only 94 have lost any time at all on account of the condition for which they received treatment—which proves conclusively that the old adage applies as well to medicine as it does to the chain-stitch seam of a man's trousers.

It will be noticed that the chronic cases have also been reduced in number. We find that the surgical cases required about five dressings each, while each medical case consulted us nearly twice.

In looking over the tables we find that the surgical cases, which have been principally of a minor nature, have increased during the latter part of the year, when the days have grown dark early and when the men have been rushed with their work. A natural result is that we have many fingers caught in the gearing, giving us badly lacerated members; but

very few of these, with conservative surgery, have required amputation.

Another common accident results from a boy's trying to shift a belt with his hand, when suddenly his arm is pulled under the drum. From this cause we have had four cases of inter-condyloid fracture. Two cases of fracture of the olecranon were the result of "sliding bases" when indulging in base-ball. In these cases, the feet being pushed forward, the weight of the body was thrown upon the hand, with the above result.

In order to protect the firm, a factory surgeon should be a strong believer in conservative surgery, and should refrain from doing any amputation, except as a very last resort, for upon the slightest provocation, even the loss of a finger-tip, whether the result of his own carelessness or not, the man will sue the company for heavy damages, and in many cases the jury, whose sympathy is always with the man, will return an unfair verdict against the company. There was one case last year which will illustrate the desire which many men have for an opportunity of suing a company. A man, after informing a fellow-workman of his intention, walked deliberately over to a very heavy machine, thrust his hand into the gearing, and had the member taken off at the wrist. The testimony, however, was so very much against him that his attorney advised him to refrain from instigating any damage suits against the concern.

There were two cases of fractured ribs, the result of muscular action, both cases being in blacksmiths. There have been a great many cases of burns from molten brass and iron, caused by a man's pouring the hot metal into his shoe or by the presence of water in the mould, when an explosion will occur and the metal flies in every direction.

In all of these cases nothing has given such universally good results and speedy recovery as cleansing the wound with liquid vaseline or olive oil and then dressing the surface with bismuth subnitrate. In fact, so very satisfactory have been the results accomplished with this agent that it has been used as a dressing in a large proportion of my surgical cases in preference to iodoform. It is a good antiseptic, an astringent, is cheap, and above all is odorless.

Pyoktanin has been relied upon in cases of ulcers or injuries and burns of the eye, but in general the results have not been sufficiently successful to warrant its universal use.

Aristol I have used in chronic ulcers with good results.

The strains and sprains are conspicuous during those periods when the men are out of doors indulging in sports, base-ball, wrestling, etc.

The anæmia, as would be supposed, was found principally among young girls and boys, who did not have sufficient strength to accomplish the work they had undertaken.

Amenorrhœa is found among the youngest girls. It seems rather strange that, although these girls are associated intimately with men of all classes, and are subjected to vice, licentiousness, the influence of cheap theatres, etc., they should menstruate so late in life, the majority being sixteen and seventeen years of age before the function is properly established.

Brass poisoning is conspicuous during the warm spring months, when the system seems rather run down after a hard winter, when the pores of the skin begin to open.

This condition is nicely controlled by nitro-muriatic acid. I do not pretend to know what the exact chemical action is, and it was only by accident—as, though we are loth to admit it, most discoveries are made—that I learned of its virtue. Early in the year a man in the brass foundry came to me with what I considered chronic dyspepsia. His troubles were confined to his stomach, where he complained of pains, etc.—though many of the men complain of pain in the chest, and some of them even have green hair. I put all these men on the strong acid with very gratifying results. The first man gained nine pounds in one week and claimed that he felt very well.

The fumes which the men inhale contain oxide of lime, antimony, and iron, about 40 per cent. pure copper, 5 per cent. arsenious acid, 10 to 15 per cent. sulphur, 15 to 20 per cent. sulphuric and sulphurous acid in combination, and 14 to 19 per cent. of water.

Diarrhœa and dysentery are conspicuous during the third period, although, on account of bad food, poor surroundings, meagre clothing, etc., these conditions are prevalent during the entire year.

The kidney troubles include nearly every affection that is common to that organ, and in the majority of cases the disease is the result, either directly or indirectly, of alcohol.

Skin affections result especially from the irritation caused by fine particles of brass lodging on the surface of the body or upon the action of the corrosive fumes arising from the hot metal.

There have been 7 cases of goitre under treatment during the last quarter; 3 of these cases (nearly 50 per cent.) succumbed to inunctions of a 20-per-cent. ointment of aristol, while 3 more were obstinate, refusing to disappear until 20-per-cent. solutions of carbolic acid were injected into the tumor three times weekly; the seventh case was so very obstinate that it was not at all influenced by these two agents, and not until electrolysis was resorted to did it disappear. There are, however,

very few cases which cannot be controlled by carbolic acid. It has proven an excellent remedy in our hands.

During the epidemic of influenza I found nothing which gave such immediate and permanent relief as *antifebrin* given in three-grain doses in hot whiskey, after dinner and supper and on going to bed.

Of 720 cases of that form of influenza known as "la grippe" under treatment last January, only 54 of this number lost any time on account of sickness at home. Of course, the antifebrin controlled only the nervous, febrile, and painful symptoms. The gastric form of the condition received in addition symptomatic treatment. Antifebrin has been used extensively in headaches of the girls, and although they have continued at their work, running in and out of *hot ovens* after taking the drug, there have been no evil results whatever.

Malaria and rheumatism are prevalent at all times, but conspicuously so during damp weather.

Nothing has given such good results in cases of bleeding piles as twenty-five-grain doses of powdered ipecac, repeated once or twice.

Typhoid fever and cases bordering on this condition are especially prevalent among the poor foreigners, who live huddled together like so many sheep, and from this cause we have had several deaths.

As a cause for all these conditions three influences are predominant:

Preëminently causation is due to the home surroundings, social habits, and alcohol.

Secondly, and as aggravative of the conditions arising from the above causes, are the climatic influences, and lastly, the industrial surroundings—to which latter influence can only be attributed the surgical cases and conditions which are peculiar to the men's occupation, such as nephritis and paralysis among the lead-workers, bronchial affections among the polishers and grinders, and gastritis among the brass-workers. To climatic and social influences can be attributed the majority of the conditions enumerated in the tables.

For instance, we find in a great measure that diseases analogous in their general characteristics group themselves singularly together at special periods, as if the result of fixed physical and chemical laws. During cold weather such conditions as bronchitis, influenza (colds), tonsillitis, all respiratory affections, are prevalent; while during the hot weather there are grouped together those diseases whose essential symptoms are exudations from intestinal surfaces or from the liver.

There cannot be a more worthy charity which a manufacturer can bestow upon poor mechanics and laborers than to provide somebody who will care for him when disabled by sickness. Most of these men have large families, who consume every penny long before it is earned, and naturally the man has very little money to spend for a physician's services or medicines; and even if he should do so, the quality of both, which he could procure in his immediate neighborhood, would be questionable.

Looking at the subject in another light, there are *very few* investments that will net a manufacturer greater returns than a medical service among his men; and, after all, why should not a manufacturer devote such sums as he may feel disposed to give to charity to his own men, who really earn the money, rather than lavish it upon the many so-called "charities" to which he is always expected to contribute?

State and Ontario Sts., Chicago.

CLINICAL SUGGESTIONS FROM CASES OF "LA GRIPPE."

By SAMUEL S. WALLIAN, A.M., M.D.,
of New York.

Ignoring the question of the nature and etiology of this prevalent and somewhat treacherous malady, whether of zymotic or telluric origin, a specific germ disease or an epidemic influenza, of an unusual and unaccountable type, the characteristic, persistent and decidedly serious complications and sequelæ of "la grippe" make its clinical study a matter of intense and immediate importance to every physician, as well as to every inhabitant of the country.

In most of the larger cities, as well as in the rural communities, it is at this moment epidemic, and is sending the death-rate to a figure which may well be a cause of alarm to the most conservative and indifferent of the profession.

It would be preposterous to assume that the rapidly increasing death-rate from pneumonia and other sudden and fatal forms of respiratory disease, from "heart failure"—which has become a popular as well as a professional fad—and from the various other manifestations of a condition of general vital prostration, which follow so closely in the wake of this prevailing malady, are attributable to an old-fashioned influenza, or periodical and rather eccentric "bad cold," which is to be annually expected and combated.

At the first announcement of the scourge it was greeted by the press and the public with a good deal of badinage and an effort at grim humor. It was presumed to be a rather disagreeable but comparatively harmless Russian joke, and the daily press found in it a stock source of humorous sarcasm. All this is changed. Funeral notices have crowded out the funny corner, and the question of how to

cope with the new foe to life is now admitted to be of the most serious importance.

The vital point is not so much as to technical origin and microscopical curiosities of the disease, but *what shall we do for our patients?*

The nostrum venders are reaping a rich harvest, measured in dollars, by proclaiming loudly that each of their mixtures, from Ayer's Pectoral and Antipyrine to Scott's Emulsion, is a specific for the disease. No doubt, hundreds of cases have been aggravated, or made unnecessarily fatal, by indiscriminate drugging, under the direction of domestic advisers and reckless counter-prescriptions. Nor has this ill-advised drugging been limited to the laity and the unscrupulous pharmacist. Routinists in the profession have done their share, have relied on those fatal make-shifts, the anodynes and antipyretics, and as a result have inexcusably swelled the death-rate, while adding nothing to our knowledge of the pathology or therapeutics of the disease. For this reason many of those who have treated a large number of cases have nothing of value to offer as a result of their experience. As is true in all new or uncommon manifestations of disease, better half a dozen cases in the hands of a thinker than a thousand under the monotonous *régime* of the mere routinist.

From the loaded condition of all the secretions it is evident in these cases that the blood is from some cause seriously poisoned. Whether that poison is produced by a microbe inhaled from the air—a mode of accounting for otherwise quite unaccountable diseases and infections now quite in vogue—or is absorbed from some other source, may some time be demonstrated. The first indication is prompt and efficient elimination by every available channel. Purgation is hardly allowable, in view of the extreme prostration which is so common a feature. Diuretics are both uncertain and inefficient, although they may sometimes be found auxiliary to other measures. The skin and lungs are unquestionably the most efficient organs through which to operate. In case of robust patients, an efficiently managed Turkish or Turko-Russian bath at the outset is one of the promptest measures at command. It relieves congestions, causes rapid elimination, and equalizes the circulation better than any measure I have tried. Few patients are too weak to bear this measure, if it be intelligently adapted to each individual case. When for any reason it is not available, I substitute the full hot bath, and direct that this shall be as hot as can well be borne for five or ten minutes, after which the temperature may be reduced, or the extra hot immersion may be followed by a momentary shower of quite cool water. To the hot bath, as a detergent, I add bicarbonate of potash or soda, or, preferably, refined borax and aqua ammonia, or eau de Cologne, which makes it both stimulating and refreshing. If the shower be omitted it should be replaced by a rapid splash, or hand-douche of cool, but not shockingly cold, water—which latter is too often heroically advised.

This is to be followed by a thorough and free use of measures which directly facilitate oxidation of the morbid elements existing—whether *absorbed* or *developed* we need not stop to inquire—in the blood. First of all, place the patient in a large, airy, and well-ventilated room. See to it that the room is not crowded with upholstery—thick, fluffy curtains, plush furniture, and heavy, absorbent carpets. It would be well to observe all the precautions which are deemed desirable in case of the more decidedly infectious disease. The readiest method of disinfecting and rendering the sick-room aseptic is by means of peroxide of hydrogen, which is to be thoroughly sprayed about the room every two or three hours. Simple as the process is, it becomes a most valuable adjunct to other measures. It not only disinfects in a most natural and efficient manner, it also liberates free oxygen in an extremely active or ozonized condition, and thus directly contributes toward the main object. Any good hand atomizer, which has either glass or hard-rubber tubes, will answer the purpose. Metal tubes are not allowable in connection with the peroxide. In extreme cases a constant spray of peroxide solution (10 to 15 vols.) may be kept up by means of any good nebulizer attached to an air-receiver, worked by a hand-pump.

Add to this free and frequent inhalations of pure oxygen, to the extent of from 15 to 25 gallons per diem. See to it that these inhalations are properly performed, and not left to the careless and inefficient manipulation of an inexperienced nurse or other attendant. To prevent sequelæ, these inhalations should be kept up for a week or two after convalescence has fairly set in. Oxygen will be found to do efficient service in restoring tone to the impoverished blood, and through this to the entire vital organization. It promotes digestion and assimilation, and has no possible drawbacks to its free and persistent use. Sometimes this method, the inhalation of this gas, proves ineffectual—as from the abnormal condition of the respiratory mucous membrane, coupled with imperfect inspiratory efforts on the part of the patient. In these cases it will be amply worth while to take the trouble to administer the gas *per rectum*, or, after Valenzuela, hypodermically. By either of these methods it is quite promptly absorbed, and soon shows its good effects.

181 ST STREET AND FORT WASHINGTON AVENUE.

CLINICAL MEMORANDA.

MEDICAL.

A Reliable Purgative Enema.—The following enema has proved so reliable and satisfactory in my hands, that I feel it is worthy of a brief note:

℞.—Sulphate of magnesia . . 2 ounces.
Glycerin . . . . 2 "
Oil of turpentine . . . ½ ounce.
Water . . . . . 2 ounces.—M.

Label, "To be used as an enema."

To move the bowels after abdominal section or after plastic operations on the female pelvic organs, it has been in constant use for many months. When used alone it has moved the bowels, as a rule, promptly; and has been equally effective when given as an adjuvant to some cathartic taken by the mouth.

Prior to the employment of this formula, I had used the simple enema of glycerin, and of glycerin and turpentine, which are distinctly inferior to the one above recommended.

The combined action of Epsom salts, turpentine, and glycerin is very effectual, not only in evacuating the rectum, but also in getting rid of flatus, the presence of which in the bowels is the cause of much of the pain present after abdominal section.

I have had the opportunity, upon two occasions, of testing the activity of this enema in cases of threatened obstruction of the bowels following operation. Other measures failing—including purgatives and large and small enemata—I have introduced a long, soft tube up the rectum, and given this enema into the descending colon, with the happiest results.

Now that the use of opium is banished from the after-treatment of cases of abdominal section, this enema has, in my hands, become the great anodyne—which fact is quickly realized by patients, who demand its frequent use.

When given through the rectal tube, its employment promises much in cases of partial obstruction of the bowels, and also in cases of obstruction due to paralysis of the bowel.

The enema is given best through a hard-rubber piston syringe.

Charles P. Noble, M.D.

Philadelphia.

Purpura Hæmorrhagica: with a Report of Two Cases.—These two cases are exactly opposite in their nature. Through the kindness of Dr. M. D. Ellison, of Canisteo, N. Y., I was allowed to see the following case:

Case I.—Mrs. S., aged thirty-three years, married, and had given birth to three children, two of whom are living, the elder being ten years of age. I saw the patient June 26, 1890, in the fourth month of her pregnancy. She was anæmic and poorly nourished, and complained of a great deal of pain in her limbs. There were a few purpuric spots on the forearms and legs, which seemed very sore. The patient was put on a nutritious diet and in good hygienic surroundings. Small doses of fluid extract of ergot, tincture of the chloride of iron, quinine, and dilute sulphuric acid were given, and a bath of alum and alcohol ordered. The hæmorrhagic spots were not constant, the old ones being absorbed and new ones appearing. The disease did not seem to be influenced by treatment, symptoms of cerebral anæmia developed, and the patient died July 3, 1890. There was no hæmorrhage from the mucous membranes.

Case II.—Willis S., aged two and a half years; apparently in good health; family history good, with the exception of an aunt on the mother's side, who died with a similar affection. When the child was weaned from the breast it was fed with milk from a farrow cow and suffered from indigestion for a period of six months; but when the milk was changed the child grew healthy and strong.

I was called at 4 P. M. on December 30, 1890, to see the boy. A history was given of a feeling of malaise for several days, the child being bright and playful in the morning, but during the afternoon would get tired, feverish, and fretful. He presented a slight hæmorrhagic spot at the femoral opening on left thigh about the size of a silver half-dollar.

I saw patient again at 7 P. M. and found that the spot had become larger, and in addition there were other hæmorrhagic spots on the inside of thighs and calves of the legs, which established a diagnosis. He was given ergot and iron up to the point of tolerance, was kept cool, and astringent washes were used. Stimulants and a most nutritious diet proved of no avail; the hæmorrhage continued, and the little fellow died at 11 A. M. the next day. The bleeding was confined entirely to the lower extremities, which were filled until they were hard with blood.

"Bled to death," we say, and yet not one drop of blood was visible outside the body.

If someone could devise a method whereby we could recognize the premonitory symptoms of this fatal form of the disease and establish a prophylactic form of treatment, it seems to me it would be a great achievement.

Case I., I am told, aborted a few hours before death and suffered much.

Case II. died without pain, and the mind was clear up to the last few minutes.

Roy Dunham, M.D.

Greenwood, N. Y.

Influenza.—During the present epidemic of influenza I find, as an antipyretic and analgesic, nothing better than phenacetine, or phenacetine and salol in combination. With very few exceptions, the temperature has been lowered and the pain greatly relieved after the administration of ten grains of phenacetine, or five grains of phenacetine and five of salol, followed by five grains of phenacetine, or two and a half grains each of salol and phenacetine every three hours. I usually give this for twenty-four hours, rarely finding it necessary after that time.

C. Emmerling.

Pittsburg, Pa

PATHOLOGICAL.

A Case of Abscess of the Liver Opening into a Bronchus.—Adam R., aged thirty-four years, single, born in Germany, a farm hand, was admitted to the Episcopal Hospital under Dr. Caspar Morris's care August 9, 1890.

Present illness began with an attack of dysentery one year ago last May; he has since had frequent lancinating pains over the hepatic region, and during the summer appeared to have suffered from irregular chills, fever, and night-sweats. Several months ago he noticed that his feet and legs were somewhat œdematous, and they have remained so. Upon his admission patient was very thin, and presented a peculiar, sallow, earthy appearance; conjunctivæ faintly yellowish, and the lancinating pains were still complained of.

Examination of heart and lungs was negative. Abdomen slightly bulging in the right hypochondrium, and there was marked tenderness to touch over the whole hepatic region. The liver dulness was eight inches in mammary, two and a half inches in median, and five and three-quarters inches in axillary line. Abscess of the liver was suspected, but fluctuation could not be made out.

On October 11th intense pain was complained of over the sixth right interspace, with sharp pricking sensations in epigastrium and right hypochondrium. On the 14th the pain was in the tenth space in the axillary region, and much aggravated by pressure. Urine gave no trace of albumin with heat and nitric acid test, but well-defined ring with tannic acid. Peptones 0.24. Spleen enlarged, measuring six inches vertically and about four transversely. Posteriorly the liver dulness measured seven inches, and anteriorly the dulness extended almost to the umbilicus. Great pain was referred to the free end of twelfth rib.

On November 23d there was diarrhœa with mucous and bloody stools. The pulse was irregular and intermittent. Estimated red blood-corpuscles at 3,262,000. White corpuscles not markedly in excess of normal.

On December 1st had slight cough attended with mucous expectoration, which on the 6th was much increased, and accompanied by free expectoration of brownish (blood-stained) sputa. With hypodermic needle I punctured the upper portion of the region that was found to be dull on percussion, and drew off some purulent matter and examined for bacilli, but found none present.

On December 12th he expectorated about eight ounces of greenish-brown matter. The patient was very weak with an intermittent pulse and complete anorexia. Death occurred on this day from exhaustion.

Autopsy: Body extremely emaciated. Anterior border of liver extends below umbilicus. Numerous firm adhesions between liver, diaphragm, and right kidney. The right lung also bound down firmly to diaphragm, and in trying to separate these adhesions a large abscess cavity was opened in the upper posterior portion of the right lobe, which was found to contain about a quart of foul-smelling pus. Only about half an inch of sound liver tissue remained at the upper posterior portion of the right lobe, bridging over the abscess cavity. The walls of the cavity were composed of shreddy false membrane and covered with much recent lymph, but a complete cicatrization had not occurred, though in places a smooth wall of protecting lymph had been formed. A fistulous communication was discovered passing from the abscess cavity through the diaphragm into one of the bronchi near the lower border of the lower lobe of the right lung. A small quantity of pus escaped from the cut end of the trachea. The *lungs* were emphysematous, and the right lung, particularly, a good deal congested, but it showed no signs of pneumonic infiltration. The *spleen* weighed twelve and a half ounces; irregularly lobulated. *Right kidney* firmly imbedded in false membranes and attached to lower border of liver; appeared fatty. *Heart* dilated; right auricle contained a large currant-jelly-like clot; left ventricle dilated and contained a large clot. Numerous ulcers in rectum and descending colon, dysenteric in type.

Though the diagnosis in this case had been pretty well established some weeks before the patient's death, the ignorance of the seat of the suspected purulent accumulation in the liver deterred me from advising a free opening. One or more exploratory punctures should have been made and the seat of the accumulation in this way determined, and it is possible that if this had been done soon after I first saw the patient in October, and free opening made and good drainage secured, his life might have been prolonged. An interesting feature of the case was the almost entire absence of fever, at least during the last month or two of patient's life. His appetite was unimpaired until within a very short time of his death.

HENRY M. FISHER, M.D.

MEDICAL PROGRESS.

Ipecacuanha to Increase Labor Pains.—DRAPES (*Les Nouv. Remèd.*) affirms that ipecac, in the form of wine of ipecac, in the dose of ten to fifteen drops, repeated every ten minutes, constitutes a powerful remedy to provoke strong contractions of the uterus in a case of uterine inertia or rigidity of the cervix, which threatens to indefinitely prolong the labor. After the second or third dose strong uterine contractions will come on, will repeat themselves at regular intervals, and tend to rapidly bring the labor to an end. That which makes ipecac in this condition superior to ergot of rye is that it never provokes tetanic contraction of the uterus, so frequent after the administration of ergot.

The Action of Hydrastin upon the Vascular System and the Uterus.—Authorities are divided upon the mode of the action of hydrastin on the vascular system. Some have observed an increased blood-pressure and slowing of the heart's action, whilst others affirm that the drug paralyzes the vascular system. The uterine contractions provoked by hydrastin are due, according to some, to the direct stimulation of the muscles and of the cardiac nerves; according to others, to the stimulation of the central nervous system. It was for this reason that Serdtseff had undertaken new experimental researches upon frogs (sixty-two experiments) and upon warm-blooded animals (fifty-seven experiments). These are the results obtained by this experimenter:

Given in a small dose hydrastin provoked, in frogs and in warm-blooded animals, slowing of the heart's movements, owing to a stimulation of the inhibitory apparatus, both peripheral and central. Small doses always increased blood-pressure; by larger doses it was lowered.

These differences depended upon the state of the vasomotor centre. Small doses were not followed by convulsions, and did not paralyze either the respiration

or the heart. He thinks, then, that if some observers have verified the paralyzing action of hydrastin upon the vascular system, it must be those who have given larger doses of the remedy. Regarding the influence exercised by hydrastin upon the uterus, the voluntary or rhythmic contractions of this organ would be increased in their strength, their number, and their duration.

Hydrastin does not act *directly* upon the neuro-muscular apparatus of the uterus, but *indirectly* by the intervention of the central nervous system, and that very probably by way of the vasomotors.

In sustaining these obtained results the experimenter counsels the use of hydrastin in all those cases of hæmorrhage where it would be, for one cause or another, unwise to await strong contractions of the uterine muscles, and where, in consequence, it is of the greatest importance to attack the bleeding through the vessels of the uterus.—*Les Nouveaux Remèdes*, February 24, 1891.

Treatment of Convulsive Tic.—Krueger is reported in *La Semaine Médicale* to have cured a case of bilateral convulsive tic, probably due to exposure to cold, and occurring in a young girl of a non-hysterical temperament in the following manner: After the disease had proved itself very obstinate, resisting for three weeks the bromides and valerianates, relief was finally obtained, both rapidly and completely, by the use of very hot poultices applied to the face, upon both sides, until profuse local perspiration was developed.

Atropine for Paralysis Agitans.—Moretti has treated three cases of paralysis agitans by hypodermic injections of atropine. The results obtained were very encouraging. He commenced the treatment by the injection of $\frac{1}{100}$th of a grain, and progressively increased the dose until $\frac{1}{30}$th of a grain was taken each day, divided into two injections.

Gargle for Acute Tonsillitis.—

℞.—Ammoniated tincture of guaiac, Compound tincture of cinchona } of each 6 drachms.
Chlorate of potassium . . 2 "
Honey . . . . . 6 "
Powdered gum arabic a sufficient quantity.
Distilled water enough to make 4 ounces.

From one-half to one teaspoonful of this should be used as a gargle in a little water every two or three hours.—*Journal de Médecine de Paris.*

A Gargle for the Relief of Fœtid Breath.—The *Revue Générale de Clinique et de Thérapeutique* gives the following prescription for the relief of this condition:

℞.—Saccharine, Salicylic acid, Bicarbonate of sodium } of each 15 grains.
Alcohol . . . . . 1 ounce.
Essence of peppermint . . 10 drops.

A teaspoonful of this is to be placed in a wineglassful of hot water, and used as a gargle once or twice daily.

The Treatment of Pulmonary Tuberculosis by Hypodermic Injections of Iodoform.—Gavoy, in the *Gazette Médicale de Paris*, details his method of treating pulmonary tuberculosis with iodoform. Morning and night, a hypodermic injection of 30 minims of the solution, of 1 part to 100 of iodoform in oil of sweet almonds, is given.

No febrile reaction occurs, and the results are very good. The cough diminishes rapidly, and the characteristic muco-purulent catarrh first becomes more liquid and then ceases. The character of the voice is also improved, and the lung becomes more permeable to the air. Inspiration is increased in depth, and the râles become more moist. Other symptoms showing the favorable influence of this treatment are a decrease in the night-sweats and a renewal of the appetite. The therapeutic influence of iodoform over carious bone and pus-corpuscles seems to point to the fact that it exercises an analogous action upon tubercular processes accompanied by resolution and necrosis of the lung.

Antipyrine in the Treatment of Gonorrhœa.—In the *Revue Générale de Clinique et de Thérapeutique* it is stated that Brindisi employs the following solution as an antiseptic lotion in the treatment of gonorrhœa:

℞.—Antipyrine . . . . 45 grains.
Sulphate of zinc . . . 4 "
Rose water, Cherry-laurel water } of each 2 ounces.

Label, "To be used as an injection."

Prescription for Tetanus.—*La Semaine Médicale* states that Mayer employs the following prescription in the treatment of tetanus:

℞.—Hydrochlorate of morphine . ⅙ grain.
Chloral . . . . . 15 grains.
Bromide of sodium . . . 20 "

Make into one powder, which should be wrapped in waxed paper; give from three to six of these powders each day.

Injection for Tubercular Diarrhœa.—

℞.—Olive oil . . . . . 6 drachms.
Guaiacol . . . . . 10 drops.
Water . . . . . 8 ounces.
1 yelk of an egg.

This injection is recommended for cases of tubercular diarrhœa.—*Journal de Médecine de Paris.*

Prescription for Rhachitis.—In the *Journal de Médecine de Paris* the following prescription is given for the treatment of rhachitis:

℞.—Phosphorus . . . . 1 grain.
Absolute alcohol . . . 5 drachms.
Spirits of peppermint . . 30 drops.
Glycerin . . . . . 2 ounces.

Six drops of this mixture may be given in water three times a day, and after the lapse of one week another drop may be added.

CURRENT LITERATURE.

SATURDAY, APRIL 25, 1891.

PYOKTANIN.

DR. O. WANSCHER refers to Professor Stilling's paper, in which the latter called attention to the antiseptic properties of the aniline dyes and named them pyoktanin, from their pus-killing properties. Experiments with the aniline dyes are now justifiable, for Merck has produced a non-poisonous aniline which can be given in doses of 15 grains to dogs, with no result other than to stain their fæces blue.

Wanscher confirms Stilling's statements regarding the pus-destroying properties of pyoktanin, but he is not certain that the good result following its use in two cases each of iritis and of choroiditis are to be ascribed to the antiphlogistic power of the pyoktanin. On the other hand, Carl and Braunschweig have disputed its antiphlogistic power, and also claim that it caused severe pain, shooting into the brow and the temple, and that great irritation with croupous exudate occurred upon the ocular conjunctiva after its use. Wanscher thinks these statements unjustified. He has found in a one-per-cent. solution of blue pyoktanin (methyl violet) an agent which fulfils the desire expressed by Billroth for a stain which will find and destroy its own peculiar bacteria without injuring the tissues. The results of Carl and Braunschweig he attributes in part to improper use of the stain. The pyoktanin, to be effective, must seek out the bacteria in the tissues; hence, it must be dissolved, clear, and easily absorbed. The more granular it is the more difficult will absorption be. Moreover, the application must be so made that no danger is incurred of transferring any pyoktanin from one patient to another, which can easily happen if the same brush is used for several patients. Pyoktanin in a half-dried condition destroys the bacteria of pus, but not those of croup and diphtheria. Possibly the semi-dried mass is irritating, just as powdered chlorate of potash acts as an escharotic, while a concentrated solution has no such action. Again, the pyoktanin must be employed repeatedly until the tissues are effectually stained. To this end ten or twenty drops at a sitting are often necessary, and they must be instilled every two or three hours, according to circumstances. Carl discards it as ineffective because he did not succeed in checking a serpiginous ulcer by using one drop a day.

For six weeks, Wanscher says, he instilled pyoktanin (blue and yellow) in nearly every case that applied. Fifty patients received upward of a thousand instillations. About twenty patients came daily to his clinic, instillations being employed generally four times a day; altogether there were three hundred instillations a day. He says in no case did he see irritation follow. None of his patients have complained of pain; and, on the other hand, he says he has undoubtedly rescued three eyes which would have been lost through gonorrhœa, and two others have recovered from it with full vision. Braunschweig has treated seventy patients with pyoktanin in two months, but it was not employed in a case of gonorrhœa. Wanscher reports his four cases in detail.

Besides the cases of gonorrhœa, he has treated by instillation of a one-per-cent solution of pyoktanin two cases of cataract operation, four iridectomies, one squint operation, one case of gonorrhœa of the lachrymal sac, two cases of specific choroiditis, one of simple iritis, two of suppurative conjunctivitis, superficial keratitis, etc. The result in these and in other eye and surgical cases in private practice has confirmed his good opinion of pyoktanin, especially of the blue pyoktanin.

In his private practice he says he has cured a gonorrhœa of the lachrymal sac which had persisted a year under other methods of treatment, even including galvanic stimulation of the mucous membrane of the canal. He has also employed it in the dressing after operation of a case of osteitis and necrosis of the tibia which had lasted twenty-five years. The result was favorable, and no irritation was produced. A walking case of gonorrhœa, associated with great dysuria, was abated with a one-per-cent. solution of pyoktanin. The same result was obtained in a case of balano-posthitis. A good result was also obtained in a case of ingrowing nail and inflamed corn. After operation a bandage soaked in a one-per-cent. solution was applied. The wound healed in a few days, notwithstanding the fact that the patient continued to go about.

Wanscher finds yellow pyoktanin less active than the blue. The color disappears quickly when used upon the eye, but more slowly when used upon the skin. Alcohol quickly dissolves the fresh stain.

In conclusion, he speaks of a one-per-cent. solution of blue pyoktanin as one of the most valuable of our therapeutic remedies for use in purulent ophthalmia.—*Therapeutische Monatshefte*, February, 1891.

ANTISEPTIC ACCOUCHEMENT.

IN the *Journal de Médecine* for February 25, 1891, LUCAS-CHAMPIONNIÈRE furnishes a condensation of the various antiseptic precautions observed in the different French maternities. In the service of Professor Pinard in the Baudeloque clinic, care is taken to clean the waiting wards daily with pieces of linen cloth moistened in a solution of the biniodide of mercury of the strength of 1 to 2000. The labor wards are cleaned in the same way several times daily. When the patient enters the maternity ward, if the stage of the labor permits, she is given a bath, and the external genitalia are washed first with soap and then with the biniodide solution. The woman then receives a vaginal injection of the biniodide solution, 1 to 4000, and a square of tow soaked in the biniodide is placed over the vulva. Every three or four hours a new injection of the biniodide is given, especially if there have been frequent examinations made; other injections are given after the birth of the child, and two hours

after delivery the woman is carried into the ward for puerperal women. The cord of the child receives a dressing of sublimated wadding, and the breasts of the mother are covered with boricized cotton. Immediately after birth the child receives an instillation of lemon-juice into the eyes. This prophylactic measure has given excellent results. The eclamptic or albuminuric women receive injections of a saturated solution of naphthol. During the puerperium, in case of fœtid lochia, vaginal and intra-uterine injections are given, and should there be fever which persists, the woman is isolated and placed under continued irrigation with phenic water, 1 to 60. In case of an operation upon the vagina or perineum, a piece of iodoform gauze is placed in the vagina and upon the vulva. After each operation the metal instruments are heated in the alcohol flame—except the cutting instruments—and then placed in a solution of phenic water, 1 to 20. Rubber instruments are kept in a glass containing the biniodide solution. The antiseptic substances employed are:

1. The solution of the biniodide of mercury, according to the following formula:

℞.—Biniodide of mercury, Iodide of potassium } of each . 7½ grains.
Water . . . 9 ounces 4 drachms.—M.

This solution is employed pure for the toilet of the hands after careful brushing and washing with soap. It is diluted with one-half of its volume of warm water for injections and dressings.

2. The phenic water employed is the strong solution, according to the formula of Lister, 1 to 20.

3. The vaseline which is used for making examinations contains phenic acid, 1 to 50.

Professor Pinard has never had a local or general accident of mercurial origin since he has adopted the employment of the solution of the biniodide of mercury. The solution has no disastrous effects upon the hands of the operators.

Guéniot, surgeon of the Maternity, employs as an antiseptic phenic acid, and has always obtained the best results. He uses the hundredth solution for the living tissues, and the twenty-fifth for the fumigations or the washing of the instruments. The concentrated solution may produce an erythema; the solution in use, the hundredth, is by no means dangerous, and has never produced poisoning, either as a vaginal or intra-uterine injection. When called to attend a patient in private practice, Guéniot employs a phenic solution of the following strength:

℞.—Distilled water . 9 ounces 4 drachms.
Phenic acid . . . 10 drachms.—M.

For living tissues this solution is diluted to about three times its volume with water, and is then used for washing the external genitals, for vaginal injections, and for the antisepsis of the hands of the accoucheur and his assistants. For disinfecting the beds, the soil, the walls, and wash-basins, sublimate solution is employed. This solution is of the strength of 1 to 4000. It is also occasionally used for washing the external genitals and for vaginal injections. A strong solution of phenic acid (10 drachms to 9 ounces 4 drachms of water) is used for the instruments. Examinations are made as rarely as possible, and the lubricating body is boricized vaseline. During labor, solutions of antiseptic materials of weak strength are injected into the vagina. Labor terminated, the eyes of the infant are washed with boiled water, or with a weak solution of sublimate, or one drop of a weak solution of silver nitrate, neutralized by salt, may be employed. The cord is dressed with a small piece of antiseptic wadding. The dressing of the mother consists of a tampon of iodoform gauze. During the following days, and twice daily, an abundant vaginal injection is given. In case of an operation, the following antiseptic precautions are taken: 1. Phenic fumigation of the operating ward by permitting a four-per-cent. solution of phenic acid to boil in the free air; 2. The instruments are boiled in a strong solution of phenic acid (1 to 25); 3. The sponges are composed of pieces of tarlatan boiled in the same solution; 4. Disinfection of the hands; 5. Dressing of the iodoform gauze of commerce.

Porak, in the Hospital Lariboisière, observes antisepsis largely as above. When a woman enters the hospital she is placed in a bath and cleansed with soap. The genital organs are washed in soap, brushed, and bathed in a solution of sublimate, 1 to 1000. After this disinfection compresses soaked in antiseptic solutions are placed over the vulva to prevent later infection. During labor, injections of sublimate, 1 to 2000, are used. Examinations are made as seldom as possible, and then only with every antiseptic precaution. Phenic vaseline is employed as a lubricant. Porak prefers, however, the following preparation:

℞.—Vaseline . . . 3 ounces 5 scruples.
Corrosive sublimate . . . 7½ grains.
Alcohol (to dissolve sublimate) . qt. suff.—M.

Intra-uterine injections are reserved for cases where a macerated fœtus exists, in cases of obstetrical interference, or where vulvar lesions are suspected. In case of a tear of the perineum iodoform gauze is used. The eyes of the infant are bathed in a concentrated boric solution. If the mother has a vaginal discharge, a few drops of this solution of silver nitrate is employed instead.

℞.—Distilled water . . . . 5 ounces.
Silver nitrate . . . . 15 grains.—M.

In case of retention of the membrane, fœtid lochia, or tear of the perineum after unsuccessful union by first intention, vaginal injections are used together with intra-uterine injections. The corrosive sublimate solution for instruments which do not amalgamate is as follows:

℞.—Distilled water . . 9 ounces 4 drachms.
Tartaric acid . . . . 4 scruples.
Corrosive sublimate . . 15 grains.—M.

The solution of 1 to 2000 is reserved for the hands.

SOCIETY PROCEEDINGS.

FIFTH FRENCH CONGRESS OF SURGERY.[1]

THE Fifth French Congress of Surgery opened its sessions on Tuesday, March 31st, in the Medical School of Paris, under the presidency of PROF. GUYON. Many foreign, as well as all the eminent French surgeons, were present at that meeting.

After an appropriate discourse by the President, DR. GUYON, the members immediately set to work.

DR. J. BOECKEL, from Strasburg, read a communication on "Resection of the Knee-joint."

The author prefers, in many instances, resection of the knee-joint to amputation of the thigh, in different pathological lesions. He founds his opinion on a series of 140 patients whom he has observed. The principal conclusions at which he arrived are: suppression of the bony suture, of the hæmostasis, and of drainage. The author thinks that resection of the knee can be performed at any age with safety, in very old as well as in very young people; in children, however, between the ages of five and seven years, resection is excellent, if the surgeon makes an intra-epiphyseal resection and is parsimonious in the excision of bony tissues. He has performed 23 resections of the knee in persons varying from forty to eighty-two years of age, and only twice was he compelled to do a secondary amputation. Age, therefore, is not a contra-indication.

As to the indications for the operation: 1st. In those operations which are obligatory, such as in all tuberculous articulations, he operates early; in these cases he has always found well-defined articular lesions.

If resection is a question in any case, he prefers to employ it rather than the contrary, as he has found that partial operative interference in very often insufficient.

In regard to the *modus operandi*, the author discards the bony suture, which is replaced by vertical suspension of the extremity during twenty-four to forty-eight hours, the excision of a band of skin, or deep catgut suture.

As regards hæmorrhage, all ligatures are omitted as a result of the vertical elevation of the extremity. Drainage is abandoned, which allows one to obtain a cure with one dressing.

Out of 61 operations performed during the last three years, 50 are radical cures without a fistula, 6 are cured with fistulæ; 1 secondary amputation after three months; 1 pseudarthrosis; 3 deaths—1 from influenza, 1 from cerebral accident, and 1 from tuberculosis ten months after operation.

DR. CHIRIAR, from Brussels, presented an interesting history of "Intestinal Obstruction by a Calculus." The patient was a very nervous woman, fifty-one years of age, suffering from a voluminous fibroid tumor of the uterus; she also suffered from severe constipation necessitating frequent purging. In August last she was suddenly seized with symptoms of complete arrest of solid matters and gas. On September 2d she was taken with vomiting, which was bilious at first, but soon became fæcal. On September 6th, Dr. Chiriar proposed surgical interference, which was opposed for two days, but finally accepted.

A sub-umbilical incision five inches long was made, through which the peritoneum was opened. A bloody serum oozed out; the left hand, introduced into the left side of the cavity, came in contact with a hard, movable tumor, which was easily drawn out of the wound; it was then found to be a calculus the size of a small egg, which was absolutely imprisoned in the contracted intestine. The intestine was carefully isolated with sponges and an incision was made from two to two and a half inches in length, through which the calculus was extracted. A Lembert suture was applied to the intestinal wound and the abdomen closed. During that day the patient had three normal passages, and on the fourth day was cured. The calculus weighed 18 grammes, and measured one and a half inches in its long diameter. The centre of it was composed of cholesterin and biliary pigment, while the periphery was calcareous.

In an operative point of view, the author insists on the necessity of carefully applying the sutures. These sutures are always made with catgut No. 1. The mucous membrane was sutured separately, while the serous coat was united by a double Czerny-Lembert suture; in this way complete union always takes place.

As soon as the calculus was removed from the intestine there was a powerful contraction of that part of the gut, which it was thought at first would necessitate an excision of a portion, but as it was thought to be of reflex origin it was left alone, and the consequences were most favorable.

PROF. PANAS, from Paris, next spoke on a case of "Orbital Angioma," which is very rare, as there are only about sixty cases reported as existing in the literature of the subject.

The best diagnostic signs are the coexistence of exophthalmus and a nævus or vascular spot on the eyelid, with a certain degree of softness and reducibility during the first two or three years of its existence.

In the history produced, the lesion had begun at the age of two years and the tumor had been treated by electrolysis and injections of Pagliari water; the tumor had diminished somewhat, but the exophthalmus had persisted. Vision remained good until the age of eight years, when she suffered from typhoid fever; she then presented a phlegmonous inflammation of the orbit, which necessitated enucleation. The author then found a small tumor, deeply situated, which contained pus. This pus was examined and found to contain the bacillus of Eberth, and he had then to deal with a spontaneous infection of the angioma by the bacillus of typhoid fever.

This case of *endo-infection* is not an isolated one, as during the past few months Dr. Panas has found five or six cases in which there was certainly an endo-infection consecutive to influenza. In the case in question, the slow circulation of the angioma had certainly produced an arrest and accumulation of bacilli which had developed in that place and had infected the orbital region.

At the second meeting of the Congress, on March 31st, the communications in answer to the question which had been announced for discussion were considered. This question was: On Surgical Interference in Affections of the Nerve Centres (primitive trephining of the cranium excepted).

PROFESSOR V. HORSLEY, from London, being unable to attend, sent his assistant, Dr. Boyce, who read the

[1] Held in Paris from March 31 to April 4, 1891.

communication; the principal portions of which are: That Dr. Horsley always made a very large trephine wound; the cutaneous flap is very large, as well as the bony opening. The resection is made with a circular saw, as follows: The segment of bone to be removed is indicated, the saw penetrating to about half the depth of the bone; in the centre of this segment a smaller piece of bone is removed, and the rest of the bone, up to the limit indicated by the circular saw, is removed with cutting forceps; as much as possible, all excised bone is put in position again before the wound is closed. As regards the determination of the exact spot to be removed, if there are no lesions visible indicating the diseased part, one can use with great advantage induced currents of electricity.

In regard to tumors to be removed, Dr. Horsley thinks that if after six weeks of internal treatment no good is observed, surgical interference is justifiable. Even in certain cases, where it is found that the tumor cannot be removed, trephining has been sufficient to cause certain troubles to disappear, such as headache, or optic neuritis —which are caused by cerebral compression; while in one case it was found that simple exploratory trephining was followed by atrophy of the tumor.

Prof. Lannelongue, from Paris, then read a paper on "Craniectomy in Microcephalus and in Children Presenting some Lack of Development, with or without Epileptic Fits, all of Cerebral Origin."

The results given are founded on a series of twenty-five cases. In regard to microcephalus, Dr. Lannelongue has found that in such children ossification is very much advanced and the fontanelles are very small, which indicate an *anticipated ossification*, and, as a consequence, the brain is also prevented from developing. Craniectomy is very useful in obstetrical compression which has brought on idiocy; also when there has been a prolonged compression within the uterine cavity as a result of a small quantity of amniotic fluid present.

Meningeal hæmorrhages, especially those of the convexity of the brain, bringing on hæmatoma, circumscribed pachymeningitis, and serous cysts, are cases for this operation.

The author has used two different processes, viz., linear craniectomy and the flap craniectomy. In linear craniectomy the incision is made along the superior longitudinal sinus and can be prolonged through the coronal suture, on the motor or Rolandic zone, toward Broca's centre. He has performed that operation on the occipital behind, between the lateral sinus and the occipito-parietal suture; finally, he also made a transverse and symmetrical craniectomy on the frontal bone by detaching the longitudinal sinus.

Flap craniectomy is the one preferred by the author, and by this he means removal of the cranial substance, which is made so as to leave flaps of bone, which remain sufficiently attached by a broad osseous base; sometimes the flap only involves one bone, the parietal or the frontal, more often the flap is "on horseback," so to speak, on two bones, the frontal and parietal. The flaps have the form of a ∪ or an inverted ∧, rectangular, horseshoe-shape, or T. The loss of substance is to the extent of 8 to 12 millimetres, the operation lasting from forty to forty-five minutes.

The operation is done as follows: The cranium is attacked at one of the extremities of the wound with a trephine, the rest is cut with the forceps. The dura mater is next detached and allowed to remain untouched, unless there should be lesions indicating pachymeningitis, in which case it would then be advisable to open the parts. If the dura mater is opened it must be sutured. As to the periosteum, it is preferable that it should not be touched. In two post-mortems made one and two months after the operation, both patients having died from croup, no bony regeneration through the dura mater was observed. Operative complications are not serious, for hæmorrhage is of slight importance, the meningeal artery and its branches being easily reached.

As to the results of the twenty-five operations, the author has twenty-four operative cures and one death, forty-eight hours after the operation, of acute septicæmia, or the continuous flow of the arachnoid fluid; three cases underwent a little suppuration, the longest one having lasted three weeks; no case of necrosis. The youngest child was eight months old, while the oldest was twelve and a half; thirteen were boys and twelve were girls. As to the after-results, the majority were improved both intellectually and in their ability to walk.

Dr. Th. Anger, from Paris, also presented a case of craniectomy which he performed on a girl eight years old. The previous history was that the child had walked at fifteen months; toward eighteen months the parents remarked a deficiency in the intellectual development, and at this time the patient was seized with nocturnal convulsions, which occurred as often as thirty times in one night. When Dr. Anger saw the child for the first time, these convulsions had not occurred for one year, but as regards intellectual power the eight-year-old girl was not more advanced than when eighteen months old, being unable to recognize her letters; she said "papa" and "mamma," but no phrase could be pronounced. She had not the least notion of cleanliness, and would urinate anywhere. When walking, her head was hanging and her gaze was never fixed.

Examination of the head showed that the left side was flattened, which stimulated the surgeon to operate upon that side.

The *modus operandi* was as follows: A linear incision was made from the frontal eminence to the lambdoid suture, a disc of bone was then removed by trephining, and the cranial excision continued along the above-mentioned line for twelve centimetres (four inches). The dura mater projecting was punctured with a hypodermic needle, but no fluid escaped; the gap was still further enlarged, and finally resulted in a loss of substance having an oval form, being eleven and a half centimetres in its antero-posterior diameter and four centimetres transversely; the skin was then sutured. No accident occurred, and eight days later the sutures were removed. The results of the operation were, that the next day the patient ceased to urinate and have her passages in bed; a few days later she began to ask to eat; then cried when told that her parents were absent; the look was frank, the athetose movements ceased, and the child walked and jumped. When she was brought home to her parents she recognized all her family, and her intellect has gradually gone on improving ever since the operation.

DR. DURET also presented two cases of trephining—one for an aphonia, which followed a fall on the head; the other for traumatic epilepsy, the accident having occurred several years before.

DR. JEANNEL, from Toulouse, presented a very interesting case of "Jacksonian Epilepsy," treated by trephining. The patient was a baker, thirty-two years old, who, in February, 1890, was suddenly attacked by apoplexy, which left behind it a certain paresis of the right superior extremity. Resumed his occupation, when, two months later, spasmodic movements appeared in his right upper extremity, which returned every two days. Anti-syphilitic treatment produced no beneficial results.

These epileptiform attacks occurred every second night, and convulsions were present, especially on the right side, lasting from eight to ten minutes, sometimes accompanied by delirium; he also presented a well-marked aphasia—very variable, however, for sometimes he only could say one word, while at others he could speak sufficiently for ordinary use. No depression of the cranium could be discovered on the left side, but it was found that, when fifteen years of age, the patient had received a stab wound just above the ear on that side; in fact, a small cicatrix could be seen in that location, but it was not adherent. The cranium was opened as usual, on the Rolandic line; the dura mater did not present any pulsation; beneath it, however, existed a soft, violet mass, which was adherent to the cerebral substance, and prolonged itself below and behind. The mass was extirpated with the curette, and an opening about the size of an almond was made; two punctures in the middle of the cerebral substance gave no results. The next day the spasmodic movements had ceased, but were replaced by a paralysis. Speech returned gradually, and to-day there remains only an incomplete paralysis, but, above all, there exists a contracture of the forearm; every fifteen days the patient has an epileptiform attack, during which he bites his tongue.

An interesting case of "Essential Epilepsy" was reported by DR. GIRARD, of Grenoble. The patient, a woman, aged twenty-nine years, had suffered since the age of fourteen with very frequent epileptic fits, with vertigo and unconsciousness. Out of six children, she lost five after convulsions. In November last she shot herself in the right temple with a revolver. When first seen she was found in a deep comatose state, the left arm being inert along the body; at forty-five millimetres from the external orbital or angular process there was a rounded perforation through which the arachnoid fluid escaped. She was trephined and the bullet and several pieces of bone removed. No suture of the dura mater nor drainage were employed; the skin was completely sutured. Union took place in seven days.

Operative results: The coma ceased the day of trephining. The next day the ideas of suicide disappeared, and for five months she had not had an epileptic fit, while vertigo had become very rare. Her menstruation has become regular. This trephining, performed for the injury, seemed to have cured the epilepsy.

DR. REGUIER, of Paris, also presented a case of "Trephining for Jacksonian Epilepsy due to Cystic Glioma." The history is: A child, aged ten years, was attacked, when five years old, with peculiar symptoms. A sensation of pricking of all the mucous membranes of the face, with abundant secretion of the conjunctiva and nose, existed. In 1888 she fell several times on the head and had a cicatrix on the left parietal region. The first convulsive fit occurred in April, 1889. These became more and more frequent until they occurred four or five times a day. They began in the face, the mouth and tongue being deviated to the right, and then the head. Then the convulsions extended to the arm and leg. No sensitive troubles. Prof. Charcot, who then examined that child, gave the following diagnosis: Partial sensitive motor epilepsy, corresponding to a probable lesion of the middle and inferior portion of the Rolandic convolutions.

She was trephined in the Rolandic region, where a gray-colored tumor of cystic appearance was found, but extending so far down into the cerebral substance that only its superficial portion was removed. The wound was dressed and healed. No change took place in the condition. Five months later the primitive trephined wound was again exposed, and the cyst removed with a curette. The next day the patient had six epileptiform convulsions; six days after a new attack with aphasia occurred, but all soon disappeared, and since then, three months and a half ago, she had had no attack and no other symptom presented. The tumor was a glioma with a cystic cavity in its centre; its situation was at the inferior extremity of the pre-Rolandic groove.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PÆDIATRICS.

Stated Meeting, April 9, 1891.

AUGUST CAILLÉ, M.D., IN THE CHAIR.

THE theme of the evening's discussion was "The Prevention of Diphtheria," and the Chairman introduced the subject by referring to the number of deaths reported to the Board of Health as occurring last year from scarlatina, measles, and diphtheria. There were 3000 cases of scarlatina with 350 deaths, 9000 cases of measles with 700 deaths, and 4500 cases of diphtheria with 1400 deaths. These figures, he said, represented about the average. He thought that in view of the fact that the mildest form of simple sore-throat might become a most severe form of diphtheritic sore-throat, the profession might do the community an incalculable benefit by improving the methods of prophylaxis. Knowing the character of the enemy, and the nature of its attack, we should now be able to protect ourselves against its inroads. By way of suggestion, he alluded to the great good that could be accomplished by cleansing the mouth and nose with mild antiseptic washes, improving the condition of the teeth, and rendering the mucous membranes generally less vulnerable to an attack of this disease. Dr. Caillé said that he admired the efforts that were being made by our Board of Health to prevent the spread of infectious diseases, but he had become convinced that municipal control in large cities was inadequate to cope with this great problem, especially as regards the public and private schools. Many families knew to their sorrow how much disease had entered their households since the little ones began to attend school, and he wished again to call attention to a plan which he had elsewhere described at length, by which,

under a system of daily medical inspection, the schools might be prevented from becoming, as they now are, centres of infection.

The systematic discussion of this all-important subject was opened by Dr. J. Lewis Smith, who first spoke of our present knowledge of the cause of diphtheria, the Klebs-Löffler bacillus. This bacillus causes the fibrinous exudation, but is local and superficial in its action, and does not in itself cause systemic infection. This infection is the result of a ptomaine which is formed by this bacillus, and which is taken up by the lymphatics and bloodvessels. Other microbes, as well as irritants not of microbic origin, sometimes give rise to the formation of a similar fibrinous exudation, but the action of the diphtheria bacillus is characterized by the production of this ptomaine, which by infecting the system gives rise to a peculiar paralysis, and to a nephritis attended by albuminuria, but with little or no dropsy, and sometimes attended by such symptoms of uræmic poisoning as vomiting and convulsions. Dr. Welch has cultivated this diphtheria bacillus, and by a series of inoculations with these cultures has produced diphtheria, so that this theory of the origin of the disease seems to be fully established.

In the decade following 1850, Dr. Smith said diphtheria first made its appearance in New York City, being spread by the sewers, which to this day are a constant and subtle agency in the dissemination of this disease. The speaker cited several instances in which diphtheria had been spread by domestic animals, and also where it had been carried by physicians to their own families. The bacillus was known to be very tenacious of life, and this was well shown in the case of a child who contracted diphtheria from examining the clothing of her mother who had died, two years before, of diphtheria. During all this time the clothing had been packed away in a chest.

Referring to the special subject of the evening, the *prevention* of diphtheria, Dr. Smith said that it should be constantly borne in mind that the physician not infrequently carries the disease himself, and hence his visits to such patients should be short, and when examining the throat he should be particularly careful to stand to one side of the patient, so that no particles of mucus may be coughed out of the patient's mouth and lodge upon his person or clothing. The neglect of this precaution, a physician had recently told him, had resulted in the death of his child. It was a good plan for the attending physician to carry with him tablets of bichloride of mercury, so that he might frequently and effectually disinfect himself, and if he were compelled to go from such a case to one of confinement, he should also change his clothing. During convalescence the patients should not be allowed to mingle with others for at least a month. The vexed question of the value of sulphur fumigation was discussed by the speaker, who decided against this time-honored method, and in support of this position he related an instance in which a ward in the New York Infant Asylum, which had become infected with diphtheria, was fumigated most thoroughly with an unusually large quantity of sulphur, and immedately after the fumigation the air of the room was examined biologically by Drs. Prudden and Cheesman, who found the diphtheria bacillus present in unusually large numbers. Washing the ceiling, walls, and floor with a solution of bichloride of mercury is much more effectual, and did not require that the room should be vacated. Families frequently move out of infected apartments without fumigating them, and hence it was not surprising that others moving into these rooms shortly afterward were often attacked by the disease.

Dr. Smith was heartily in favor of the daily inspection of our schools, and in addition, advised that the schools be disinfected once every month.

Dr. Joseph D. Bryant who was unable to be present, sent a letter, in which he spoke of the efforts which the Board of Health had been making during the past three years to stamp out infectious diseases, and admitted that although these endeavors had proved successful as regards smallpox, but little had been accomplished in connection with other infectious diseases. The ceilings and walls of the tenement houses, and frequently the decorations of our public buildings, were well calculated to harbor and spread disease-germs, yet no good would result from ordering the owner to remove the paper, scrape the walls, etc., for if the owner ignored this, the law was such that the only recourse the Board of Health would have, would be to vacate the house, and this meant sending the poor occupants with their infected goods to some other place. At the present time, rooms were fumigated with sulphur, but a better method was needed. The Board was in a better position so far as the disinfection of fabrics was concerned, for they had recently had erected near the Willard Parker Hospital, in accordance with the plans of Drs. Prudden and Biggs, a very efficient apparatus for the disinfection of fabrics, either by moist or dry heat. The Board would, if desired, take the infected fabrics, disinfect them in this apparatus and return them.

Dr. T. M. Prudden, taking up the subject from the standpoint of the bacteriologist, said that primary or true diphtheria was caused by the Löffler bacillus, which was very tenacious of life, and could be readily carried by the dust. There was also a form of pseudo-membranous inflammation, but this is due to the streptococcus. The diphtheria of animals he did not consider to be identical with that found in the human subject. As the life history of the Löffler bacillus was well known, our present knowledge indicated a line of prophylactic treatment; the medical profession should take the initiative step, and the health boards should then continue the good work. By the use of germicides the bacillus could be killed, and the frequent use of milder gargles and washes would prevent the proliferation and spread of such germs as had become detached from the pseudo-membranes and were liable to carry infection to other parts. Especially was this true when considered in connection with that very serious complication, aspiration pneumonia. An absolute and early diagnosis of diphtheria could be made by the biological culture method, and the provision for such examinations in connection with children's asylums would be of great service, both in preventing epidemics and in assisting in the inauguration of an early and efficient treatment. It was customary in many of these institutions to quarantine in one ward children suffering from various kinds of sore-throat until the diagnosis was certain, but this plan unnecessarily exposed children suffering from

simple tonsillitis, when in a condition to invite infection with diphtheria, to this disease. Such management could not be too strongly deprecated. The speaker had made a large number of biological analyses of air from hospital wards, and in view of the fact that the diphtheria bacillus can be readily carried by the dust, he wished to call attention to the pernicious habit of shaking the bedspreads in the wards. These spreads presented almost as large a dust-collecting surface as the floor of the ward.

DR. A. JACOBI spoke of the strange silence that had prevailed in medical literature generally upon the subject of the *prophylactic* treatment of diphtheria. In addition to caring for those sick with the disease, he thought it would be well to provide buildings or places of refuge for children temporarily sent from home to avoid the disease. In the last thirty years, in New York City alone, fully forty thousand persons had fallen victims to diphtheria, and many more were suffering from its effects, and yet in the face of these appalling figures, we are told that daily medical inspection of our schools is impracticable. When a single case of variola, or of typhus fever, is discovered in the city, the daily press prints the most sensational articles, but thousands are constantly dying of diphtheria, and nothing is done to stay the scourge. If the press would arouse from this apathy and work with the medical profession, it would be easy to establish this daily inspection of the schools.

DR. H. D. CHAPIN said that the schools naturally received considerable attention in such a discussion as this, and so it might prove opportune for him to speak of what he had seen in his tour of inspection of the public schools. In one of the primary schools, which is crowded with children, there is no place whatever provided for the children's clothes, and they are, therefore, compelled to pile them up on the back seat. When it is remembered that these garments are often wet, and that they belong to children coming from the dirtiest and poorest tenements, it was easy to understand how readily this custom favored the spread of infectious diseases.

DR. L. EMMETT HOLT spoke of the preventive measures which had been adopted in two institutions with which he was connected, and which had proved most efficient. In one of these, the New York Infant Asylum, where there were upwards of two hundred children under two years of age, sporadic cases of diphtheria had occurred every three or four months during the past three years, but in every suspicious case, prompt individual quarantine has been adopted, the child's clothing has been removed from the ward, the ward has been fumigated, and the walls washed with bichloride solution, the bedsteads have been washed with carbolic acid solution, 1 to 40, and the bedding has been steamed. The throats of the children in the ward who have been exposed are examined twice a day, and if there be much nasal discharge, nasal syringing is at once begun. As a result of these prophylactic measures, not a single *epidemic* has occurred during this period.

CORRESPONDENCE.

NEW ORLEANS.

THE fifty-seventh annual commencement exercises of the Medical Department of the Tulane University of Louisiana were held at the Grand Opera House of this city on Wednesday, April 1st. Judge W. W. Howe was the orator of the day, and delivered an able address, dwelling especially on the relation of the physician to the law and sanitation. The dean, Dr. S. E. Chaillé, made his report to the president of the University. The medical department had 405 matriculants this year, this being the largest number in the history of the University. There were 105 graduates in medicine and 13 in pharmacy.

Dr. C. D. Owens, President of the Louisiana State Medical Society, has called the annual meeting in New Orleans for May 13th. The Society was to have met last May in Baton Rouge, while the Legislature was in session, with the hope of having a bill passed for the regulation of the practice of medicine in this State. On account of the extensive overflows no meeting was held, but a sub-committee was appointed to prepare a bill for the Legislature. This bill passed one branch of the Legislature, but was defeated in the other by the homœopaths and a few regular physicians whose motives have never been known. The Society will renew its efforts, and it is hoped that we will soon have a State Board.

The profession here do not take much interest in the State Society. Few of them attend its meetings, even when they are held in New Orleans. The only medical society in New Orleans suffers in the same way. There are about 210 regular physicians in New Orleans, many of whom are members of the New Orleans Parish Medical Society, and yet it is seldom that there are more than fifteen members present at its meetings, which are held once a month. Such a state of affairs should not exist in such a medical centre as New Orleans, yet it does exist, and those members of the profession who are best able to remedy this evil seem to take the least interest in it.

MONTREAL.

SINCE my last communication lymphomania has affected us about as badly as it has other communities. While the precious liquid was unobtainable the excitement continued quite active, both among the laity as well as among the profession. In November two of our younger medical men hurried off to Berlin, well laden with letters from the Governor-general, Consul, Board of Health, and others, to be early in the field. A good deal of lay advertising had to be submitted to, in connection with this trip. On December 19th the first supply of paratoloid reaching Canada was put in use in the Montreal General Hospital. Selected cases, of skin, joint, and internal tuberculosis, were subjected to careful treatment and close observation. Alas for human hopes, in three months the treatment is abandoned as unsatisfactory and dangerous. The following are some of the sadly-interesting results reported at a recent meeting of the Medico-Chirurgical Society by Professor Roddick, the chief surgeon of the hospital: A patient, who had derived great benefit from cauterization of the interior of

the bladder through a supra-pubic cystotomy, remained in the hospital with trouble in one testicle; after a few injections of tuberculin the other testicle, apparently normal, or, at least, quiescent up to this time, showed signs of irritation, and went on to disorganization, requiring its removal. The bladder was unaffected by the injections. A child, with incipient knee-joint disease, could walk when first injected; very soon the joint gave great trouble, a destructive action made rapid progress, and the knee had to be excised. In the case of a man with tarsal bone disease of limited extent, under tuberculin therapy the trouble manifestly and rapidly extended, and the loss of the foot was the disastrous result. A case of lupus of the face of long standing, in a girl of eighteen years, was pronounced worse than before the injections. With such lamentable possibilities, he would be a rash man indeed who would use the fluid in private practice.

From the medical side of the hospital the reports are unsatisfactory, though not clearly bad.

This week our medical schools close for the session, and with the incoming month a large number of young medicos are let loose on the community. The following are the numbers of the medical graduating classes of 1891: McGill University, 49; Montreal School of Medicine, 24; Laval University, 13; Bishop's College, men, 3; women, 1. We thus have the first woman graduate of the province this year. The lady in question, Miss Ritchie, B.A., has had a brilliant training, having previously taken the honors course in art at McGill. As yet, old McGill gives no invitation to female professional students, the authorities of the University being opposed to co-education even in arts. Up to this time our city can only boast of one recognized female practitioner of medicine, a graduate of the Women's Medical School of Kingston.

Dr. E. H. Trenholme, the well-known gynecologist, on account of ill health, has had to remove to the more congenial climate of the Pacific Slope. This gentleman was a daring and original operator, and a physician of marked individuality. He constantly asserted his claim to be the author of Tait's operation, on the strength of an early reported successful case. This priority was acknowledged by Battey and some others.

Prof. George Ross, sub-dean of McGill, has been unable to fill the chair of practice this winter; his lectures, having been prepared, were delivered for him by other members of the faculty. Dr. Ross has found it necessary to limit himself, for the present, to consultation practice.

CHICAGO.

The twenty-first annual commencement exercises of the Woman's Medical College were held at Central Music Hall on March 30th. The degrees were conferred by Professor I. N. Danforth. The graduating class numbered 30. Two of the graduates, Drs. Maggie L. McCrea and Emma White, were appointed internes at the Woman's Hospital of this city. Dr. Blanche Denig, another graduate, received the appointment of interne to the New England Hospital, Boston, and Dr. Anne McFarland has been appointed superintendent of the Oaklawn Retreat, Jacksonville, Ill.

At a meeting of the Alumni Association in the evening, a bust of the late Professor William H. Byford was formally unveiled. It is life-size, and of Carrara marble. It is the handiwork of Lorado Taft. The bust presents a faithful likeness of the late Professor. Dr. M. J. Mergler made the dedicatory address.

The effort that has been made here to organize and build a hospital for the exclusive use of the colored people has kindled a flame of righteous indignation amongst the people of that race. The colored people are opposed to such a sectarian institution, for the reason that it encourages and keeps alive race prejudice, and they consider it in direct opposition to the spirit and genius of our American form of government. They say that the patients and inmates of the hospitals and benevolent institutions of this city are all treated alike, irrespective of race, color, nationality or religion, and why encourage the inauguration of such a movement?

An institution, to give instruction in medicine and surgery, to be known as the Illinois School of Medicine, was recently incorporated, with a capital stock of $10,000. The incorporators are physicians.

The annual commencement exercises of Rush Medical College took place March 31st, in the presence of a large audience, a class of 204 graduating, the largest in the history of this famous institution. A palpable cloud rested upon the faculty and class—the knowledge that a beloved associate and instructor lay dead in his darkened home, subduing every heart and softening the accent of every lip. The sudden death of Dr. Charles T. Parkes was a severe blow to "Rush," and it fell with added force, following so close upon the deaths of the President, Dr. James Adams Allen, Dr. Joseph P. Ross, and Dr. William H. Byford, all members of the faculty, who have died within this college year.

The ninth annual commencement exercises of the College of Physicians and Surgeons of this city were held March 24th. Professor S. A. McWilliams conferred the degrees. The graduating class numbered 42.

The Alumni Association of the College of Physicians and Surgeons held a special meeting recently with reference to reinstating Dr. W. C. Brinkerhoff. Two years ago Dr. Brinkerhoff was dropped from the membership of the Alumni Association for advertising in the daily papers special qualifications in the treatment of specific diseases. A year later he made application for a hearing before the Alumni with the object of eventual reinstatement. A hearing was granted, and the doctor and his friends, it is said, endeavored to convince the majority of the Alumni that there was no violation of the code of ethics, by a simple announcement in the press of the diseases which he felt qualified to treat. After considerable discussion, a vote on the motion to take up the application for reinstatment disclosed 13 against and 2 for it, 20 members declining to vote.

La grippe has been very prevalent here. At the Alexian Brothers' Hospital every ward is full, and several patients were turned away because of the lack of room. At the German Hospital, out of seventy patients, over one-third are suffering from *la grippe*. Out of the eight house physicians, six are unable to attend to their duties, and several of the nurses are too sick to be at their posts. St. Joseph's Hospital has accommodations for seventy-five, but here, as at other places, everything is crowded. At the Presbyterian Hospital much the

same condition of affairs exists. Out of one hundred or more patients, about twenty-five are *la grippe* sufferers, and a large percentage of the employés are under the care of physicians. At the Illinois Training-School for Nurses twenty-two persons are down with the prevailing malady. The county hospital is probably the most overcrowded of any of these institutions. Out of 350 or more medical patients, at least one-third are suffering from throat and lung troubles. The hospital is more than overcrowded, but patients are still received, an average of seven a day, and there is not a ward in the medical department which has not from fourteen to fifteen patients on the floor. There are fully 150 more patients at this institution than the hospital is intended to accommodate, but so long as the epidemic continues, an effort will be made to care for all, if possible.

According to the Health Office report the weekly mortality up to March 21st, from throat and lung troubles, was unusually large. Pneumonia caused the deaths of 170, bronchitis 81, diphtheria 23, and *la grippe* 19. This would indicate that outside the hospitals the disease is proving much more fatal than in them. Consumption carried off 46, making a grand total of 339 deaths during the week from bronchial and pulmonary troubles.

ST. LOUIS.

The annual summary of mortality of the City of St. Louis, which has just been issued by the Health Department, contains some interesting data.

The annual death-rate is given at 18.45. The total number of deaths reported is 8407, 405 more than the previous year. The mortality from different causes is distributed as follows, viz.: Total from zymotic diseases, 1547; from constitutional diseases, 1635; from local diseases, 3781; from developmental diseases, 969; from violence, 476; unknown, 1. There were 186 deaths from diphtheria; 140 from typhoid fever; 436 under five years old; and 104 above that age from diarrhœal diseases. 843 deaths are attributed to phthisis; 336 to marasmus, tabes mesenterica, and scrofula; 601 are referred to pneumonia; 332 to bronchitis; 469 to diseases of the circulatory system; 207 to meningitis and encephalitis; 444 to convulsions and trismus; 399 to other diseases of brain and nervous system; 230 to enteritis, gastritis, etc.; 253 to Bright's disease and nephritis.

4611 were male, and 3796 female; 3115 were under five years of age.

11,564 births were reported during the year, of which 704 were stillbirths.

The competitive examination for appointments as resident physicians in the City and Female Hospitals called out applicants from the several colleges as follows, viz.: St. Louis Medical College, 9; Beaumont Hospital Medical College, 6; Marion Sims Medical College, 3; Missouri Medical College, 4; St. Louis College of Physicians and Surgeons, 1. The following are the successful competitors, viz.: H. H. Born, H. W. Buvig, C. J. Orr, J. J. Seibold, J. A. J. James, W. H. Fuchs, J. H. Bell, J. P. Stock, H. D. Brandt, F. S. Haeberle, and E. C. Runge. Seven of these were from the St. Louis Medical College, three from the Beaumont Hospital Medical College, and one from the St. Louis College of Physicians and Surgeons.

The Missouri Medical College held its "Golden" (50th) commencement exercises Tuesday Evening, March 31st, and issued diplomas to ninety-four students who had completed their course and passed their examinations.

La grippe has visited our city in a very mild form this winter. There have been a good many cases, but most of them have been mild in their character, and the mortality has been very low, very different from that which has been experienced in Chicago.

Governor Francis has recently made two appointments to membership in the State Board of Health to fill vacancies caused by death, viz., John P. Harmon, of Johnston County, vice Wm. Gentry, deceased, and Dr. R. C. Atkinson, of St. Louis, vice James B. Bather, deceased; both appointments being for a term expiring July 2, 1892. Dr. R. C. Atkinson is at present a member of St. Louis Board of Health, having been appointed by Mayor Francis about four years ago.

I was about to call the attention of your readers to the recent failure of the attempt to secure the passage of a bill, introduced into the Legislature, for the purpose of requiring a three years' term of college work as a requisite for registration as a qualified practitioner of medicine in this State, when I learned that a full statement of the case had been prepared by Dr. C. A. Todd, who was an active member of the committee who had charge of the preparation of the memorial to the Legislature.

It is the earnest wish of the largest part of the teachers and other medical practitioners in this city and State, that it should be clearly understood where lies the responsibility for the recent failure to take an advanced position in medical education, which is desired by a large majority of the profession here.

LONDON.

Dr. Broadbent on Fatty Degeneration of the Heart; Dr. Thomas Oliver on Lead Poisoning.

The Lumleian Lectures annually delivered before the Royal College of Physicians by one of the senior Fellows, this year fell to the lot of Dr. Broadbent, who took Structural Diseases of the Heart for his subject. What he had to say about fatty degeneration may probably be of some interest to your readers. Deficient blood-supply through disease of the coronary arteries or from other cause he regarded as the most common and most important mode of causation, the atrophy of the muscular fibre thus produced being followed by the invasion of the fibre with fatty granules. Defect in the quality of the blood-supply, the quantity being unaffected, will also produce it, as shown in advanced stages of pernicious anæmia and in severe cases of typhoid fever; the heart in these affections suffers more than the voluntary muscles, because of the constant wear and tear to which it it is subjected. Diabetes and alcoholic excesses may produce fatty degeneration, either by impoverishment of the blood, or perhaps by myocarditis. Cases in which no causation can be made out may be ascribed to a defective assimilative action in the muscles of the heart, or possibly some unrecognized blood condition.

The symptoms at first may be those of dilatation, but in complicated cases dropsy is rare; the effect of the disease is defective pressure in the venous system, and

consequently syncopal, apoplectic and epileptic attacks are characteristics of the later stages. The syncopal attacks do not go on to complete loss of consciousness, but they generally last long, and are accompanied by coldness of the extremities and body surfaces. In the apoplectiform attack the patient is perhaps unconscious, with stertorous breathing, but examination of the pulse and heart will show the entire absence of sufficient tension to cause rupture of a vessel, and this will constitute the best means of recognizing the true nature of the attack; there may be transient loss of power on one side of the body; the patient is never quite the same after one of these attacks, and has increased liability to subsequent syncopal attacks. The epileptiform seizures are generally of the nature of *petit mal*, and are probably dependent upon the defective cerebral circulation from heart failure, the pulse in these cases sometimes being as low as 40. Dr. Broadbent does not believe in the greasy skin and sallow complexion traditionally associated with fatty degeneration; he has often seen patients maintain every appearance of health up to the last.

The most constant and significant feature of the pulse is that it is short and unsustained. It may vary much as to frequency, the most characteristic form, but, at the same time, the most rare is a very slow pulse, with extreme low tension. The impulse of the heart cannot, as a rule, be perceived, and the sounds are inaudable, or very weak, the first sound being short. If there is a doubt as to whether the signs are due to functional or organic disturbance, to subject the patient to slight exertion will probably suffice to solve the problem. If the heart is sound it rises to the occasion, the pulse, heart-beat, and sounds becomes more distinct, stronger, and more regular, whilst the fatty heart "goes to pieces," and the pulse becomes irregular, and shorter than ever, or may even disappear. If the diagnosis is certain, a fatal termination is merely a question of time and circumstances, on which latter, however, much will depend. The patient should have as much sun and fresh air as possible, but must not be exposed to severe cold. Exercise is good for him, but not exertion. His diet must be simple, and his meals regular, and constipation must be avoided.

Dr. Thomas Oliver has recently delivered the Gulstonian Lectures before the same body. He chose "Lead Poisoning" for his topic. He has contributed not a little to the elucidation of this subject in recent years. He says that the first effect of lead upon the system is to interfere with the function of the making of blood, and he has never in any case of lead poisoning failed to find a deficiency in the number of red blood-corpuscles. He regards swelling and ulceration of the gum as the necessary precursor of the blue line; it is more constant and more marked in the lower than in the upper jaw. He also finds that three months is about the time required for its disappearance after the patient is removed from all source of lead poisoning.

His views on the subject of lead paralysis are of special interest; after discussing the neuropathic theory he gives his decision against a peripheral origin, and in favor of a primary lesion in the cord. That this has hitherto escaped detection he explains on two grounds: one, that in the early stages the changes must be slight, sufficient time not having elapsed for them to develop; and, secondly, that so many patients recover. The paralysis attacks functionally related groups of muscles, and the precise parts of the cord in which the centres for these groups are situated is unknown, and must be very small, so that the detection of any lesion of it might easily escape.

Sir Andrew Clark has just been elected for a fourth time President of the College of Physicians, by an almost unanimous vote. He has well deserved the compliment, for he has been most zealons in the discharge of all the duties of his office, even going the length last summer of coming down from Scotland in the middle of his holiday in order to preside at a lecture which has always been delivered in the middle of August. He has done very good work outside the college, too, on behalf of the profession at large, in fighting in the cause of the army medical officers, and though his efforts have not been crowned with complete success, there is no doubt that many of the concessions recently made were owing to his powerful advocacy.

There is not much news in the world of medical politics; the scheme for reconstituting the University of London is still being considered by the senate of that body, but it is more than likely that they will not be able to find a compromise that will satisfy all the contending parties, in which case steps will be presumably taken to form a new university for London students, so it will be some years yet before we can get an accessible degree.

NEWS ITEMS.

A Hospital for Students in Vienna.—A hospital will soon be opened in Vienna especially to accommodate sick students. It has been established by the Students' Association, and contains thirty-eight beds—eight of which are for surgical cases, and nine others, in an isolated pavilion, are for cases of contagious disease. The attending physician is Dr. Redsenbacher.

Rush Medical College, Chicago.—To supply the place made vacant by the death of Dr. Charles T. Parkes in Rush Medical College, the faculty have elected as Professors of Surgery and Clinical Surgery Professor Roswell Park, of the Buffalo Medical College, and Dr. N. Senn, of Milwaukee, Wis. Dr. Park is expected to move here in a few days, and Dr. Senn has already taken up his residence here and is going to remain permanently. Dr. Daniel R. Brower has been elected Professor of Materia Medica and Therapeutics, in addition to the Chair of Mental Diseases, which he already holds. Dr. Sanger Brown has been elected Professor of Hygiene and Medical Jurisprudence. Drs. H. N. Moyer, J. B. Herrick, and J. H. Salisbury have been elected Adjunct Professors of Medicine; and Dr. Charles Warrington Earle Adjunct Professor of Obstetrics and Diseases of Children.

Just as we go to press we have a note from Dr. Park, in which he says that he has declined the election to the Professorship of Surgery in Rush Medical College of Chicago.

A German Medical College in Chicago.—It is said that Chicago is to have a new institution known as the

German College of Medicine and Obstetrics, with a capital stock of $50,000. The college will have ten professors, four to teach in the English language and make a specialty of obstetrics; the other professors will teach in German and have charge of the regular college course. Five years of study will be required before a diploma is granted. It is thought that eventually a college building will be erected near Humboldt Park. The money required will be provided by the incorporators and by the professors who are to occupy the chairs in the college. The professors have not yet been selected.

Milwaukee.—The Milwaukee Clinical Society has changed its name to that of the Milwaukee Medical Society, and is endeavoring to enlarge the scope and membership of the Society. It has elected Dr. S. W. French as president, Dr. U. O. B. Wingate as secretary, and a board of thirteen councillors, who have the general management. It will hold two meetings per month, on the second and fourth Tuesdays, except the months of July, August and September.

Obituary.—DR. WILLIAM C. HUNT, another old practitioner of Chicago, died on March 1st. He had been ill for more than two years, and was a classmate of Dr. Johnson. He was born at Litchfield, Conn., November 8, 1827, and went to Chicago at the age of twenty-one years. He attended Rush Medical College, from which he was graduated in 1851, afterwards becoming a member of the faculty of that institution.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 14 TO APRIL 20, 1891.

By direction of the Secretary of War, the following changes in the stations of medical officers are ordered: MARSHALL W. WOOD, *Captain and Assistant Surgeon*, is relieved from duty at Fort Meade, South Dakota, and will report in person to commanding officer Fort Preble, Maine, for duty at that post, relieving William B. Davis, Captain and Assistant Surgeon. Captain Davis, on being relieved by Captain Wood, will report in person to the commanding officer Fort Clark, Texas, for duty at that station.—Par. 11, *S. O. 85, A. G. O., Washington*, April 15, 1891.

By direction of the Secretary of War, a Board of Medical Officers, to consist of: HENRY MCELDERRY, *Major and Surgeon;* JAMES C. MERRILL, *Captain and Assistant Surgeon;* and W. FITZHUGH CARTER, *Captain and Assistant Surgeon*, is appointed to meet at West Point, N. Y., May 1, 1891, or as soon thereafter as practicable, to examine such cadets of the U. S. Military Academy as have been granted leave of absence until that date on account of physical disability, and to report upon their physical fitness to continue with the Corps of Cadets.—Par. 2, *S. O. 83, A. G. O., Washington*, April 13, 1891.

By direction of the Acting Secretary of War, leave of absence for six months, on surgeon's certificate of disability, is granted PASSMORE MIDDLETON, *Major and Surgeon.*—Par. 4, *S. O. 81, Headquarters of the Army, A. G. O.*, April 10, 1891.

By direction of the Acting Secretary of War, the leave of absence granted HENRY P. BIRMINGHAM, *Captain and Assistant Surgeon*, in S. O. 39, March 13, 1891, Department of the Columbia, is extended one month.—Par. 2, *S. O. 81, Headquarters of the Army, A. G. O., Washington*, April 10, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 18, 1891.

BEARDSLEY, GROVE S., *Medical Director.*—Appointed a delegate to represent the Medical Department of the Navy at the meeting of the American Medical Association at Washington, D. C., May 5th.

FLINT, JAMES M, *Surgeon.*—Appointed a delegate to represent the Medical Department of the Navy at the meeting of the American Medical Association at Washington, D. C., May 5th.

GRIFFITH, S. H., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Dolphin," and granted one month's leave of absence from date of detachment.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING APRIL 18, 1891.

BAILHACHE, P. H., *Surgeon.*—To represent the Service at the annual meeting of the California State Medical Society, April 8, 1891. Detailed as Chairman of Board for the Physical Examination of Officers Revenue-Marine Service, April 14, 1891.

VANSANT, JOHN, *Surgeon.*—Detailed as Chairman of Board for Physical Examination of Officers Revenue-Marine Service, April 14, 1891.

AUSTIN, H. W., *Surgeon.*—Detailed as Chairman of Boards for Physical Examination of Officers and Candidates Revenue-Marine Service, April 14 and 15, 1891.

GASSAWAY, J. M., *Surgeon.*—Leave of absence extended five days, April 15, 1891.

STONER, G. W., *Surgeon.*—To proceed to Alpena, Mich., on special duty, April 12, 1891.

MCINTOSH, W. P., *Passed Assistant Surgeon.*—Detailed as Recorder of Board for Physical Examination of Officers Revenue-Marine Service, April 14, 1891.

MAGRUDER, G. M., *Passed Assistant Surgeon.*—Detailed as Recorder of Board for Physical Examination of Officers Revenue-Marine Service, April 15, 1891.

PERRY, T. B., *Assistant Surgeon.*—Ordered to examination for promotion, April 6, 1891.

WOODWARD, R. M., *Assistant Surgeon.*—Ordered to examination for promotion, April 6, 1891.

GOODWIN, H. T., *Assistant Surgeon.*—Ordered to examination for promotion, April 6, 1891.

VAUGHAN, G. T., *Assistant Surgeon.*—Ordered to examination for promotion, April 6, 1891.

GEDDINGS, H. D., *Assistant Surgeon.*—Detailed as Recorder of Board for Physical Examination of Officers and Candidates Revenue-Marine Service, April 14, 1891.

PERRY, J. C., *Assistant Surgeon.*—Detailed as Recorder of Board for Physical Examination of Officers Revenue-Marine Service, April 14, 1891.

GROENEVELT, J. F., *Assistant Surgeon.*—To rejoin station (New York), April 13, 1891.

ROSENAU, M. J., *Assistant Surgeon.*—To proceed to Cairo, Ill., for temporary duty, April 13, 1891.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. FEL BOVIS INSPISSATUM—ITS IMPORTANCE AND USES AS A THERAPEUTIC AGENT.[1]

BY WILLIAM HENRY PORTER, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THIS old-time remedy, ox-gall, appears to have been sadly neglected in the mad rush for new remedies. Frequently it is omitted by writers upon therapeutics, while others grant to it only a passing notice. Yet, it is still retained in the pharmacopœias of the United States, Great Britain, Germany, etc., as one of the medicinal agents that can be used to relieve the sufferings of the human race.

In my experience it is one of the most valuable remedies that we have at our command. Without ox-gall it would be almost impossible to treat successfully and satisfactorily that great class of maladies commonly described under the title of functional derangements of the digestive and hepatic system. With the hope of being able to bring to light some satisfactory results that can be attained with ox-bile, administered either alone or in combination, this article has been compiled.

Primarily it can be asserted that all abnormal or diseased conditions, either acute or chronic in character, are largely dependent upon an imperfectly effected digestion and assimilation; that, so long as the physiological nutritive vitality is perfectly maintained, very few diseases either acute or chronic can gain access to, or originate within, the system and develop sufficient power to make their presence manifest. But whenever the vitality is lowered, then the system is quite prone to take up extraneous and deleterious substances, and to develop all forms of acute and chronic diseases, the character and intensity of the infecting agent determining in a large measure the final result. To combat successfully these damaging effects, the digestion, the hepatic and nervous functions, must be raised to, or even carried beyond, the normal standard, so that the vital powers may be maintained until the infecting agent can be subdued and removed from the system. Having accomplished this, Nature is placed in a position in which she is capable of sustaining the bodily functions, and, at the same time, of repairing the damage to the various tissues and glandular structures, until finally the human economy again becomes normal.

Assuming, in the first place, that all forms of extraneous and poisonous substances which are introduced into or are developed within the system are carried to the liver, and there acted upon by the chemico-physiological transforming power of the protoplasmic masses composing the cells of that organ, it is quite easy to see and comprehend how derangement, faulty action, or even an absolutely pathological condition, of these cells is developed. Any one of these three conditions will disturb normal action on the part of the liver, and will tend to lower the quality of the bile produced. This imperfectly formed biliary fluid, on reaching the alimentary canal, will be unable to assist, as it should, the digestive functions of the intestine; and, as a sequence, fermentation is rapidly excited within the bowel, producing many deleterious products, which pass through the entero-hepatic circulation and reach the liver, thus increasing the work of an already overtaxed organ. This, together with the damaging effects of the original poison and imperfect oxidation, explains the chief factors in the development of increased bodily heat in connection with all diseased conditions. In this manner the process continues repeating its injurious effects upon the system, until Nature, by her inherent power, grants relief by destroying or eliminating the poisons, or is aided in so doing by the skilful administration of some medicinal agent. In a certain percentage of cases, however, both the inherent power of Nature and the skill of the physician are held in abeyance.

Taking this view of the situation, the first indication to be fulfilled in the treatment of disease is to rid the system as rapidly and easily as possible of its original, old, and deteriorated bile, and quickly replace it with some of a better quality that has been derived from a young and healthy herbivorous animal. This line of reasoning has led me to use the inspissated ox-bile very extensively during the past ten years—with this conclusion: that fel bovis inspissatum is indispensable in the treatment of almost every pathological condition. This is especially true in all individuals who have passed their prime and are in the decline of life. After this extensive use of ox-bile as a therapeutic agent in all kinds of disease, and upon all classes of patients, I feel

[1] Read before the Section on General Medicine, New York Academy of Medicine, February 21, 1891.

warranted in speaking with some degree of certainty in regard to its physiological action and therapeutic power.

It is hard, if not impossible, to give a complete picture of the physiological action of fel bovis. The function, however, of the bile in the physiological economy,[1] as we understand it to-day, if fully comprehended, covers the chief physiological action of fel bovis inspissatum. The changes, however, which its presence in the alimentary canal and the system in general causes, together with the therapeutic indications for its use, will enable us to appreciate what can be attained by its administration.

In Brunton's most valuable work this statement is found: "Bile precipitates pepsin, and interferes with the digestion of albuminous substances in the stomach. It seems to irritate the mucous membrane and give rise to headache and vomiting. It does not aid the digestion of farinaceous food. It quickens the absorption of fats; it prevents to some extent putrefactive changes in the intestinal contents, and it quickens peristaltic action." My experience is somewhat in opposition to some of these statements, but if we stop and analyze the subject carefully the difference will probably be found to be apparent rather than real.

There is no doubt that bile which is of impure quality, regurgitated from the intestines, will irritate the mucous membrane, precipitate pepsin, and even retard, rather than favor, digestion; but new bile which is good in quality will not, as a rule, irritate the stomach, and it very materially aids in the perfection of the digestive process, especially after the removal of the old and deteriorated bile. In case an unduly irritable stomach is encountered, the distress which might be attributed to irritation arising from the presence of newly-administered bile in the stomach, can easily be prevented by adding one grain of cocaine to each capsule containing the fel bovis. My observations and clinical cases, which are not few, strongly favor the assertion that newly-acquired bile is not irritating to the gastric mucous membrane, and does very materially augment the digestive process effected in the stomach.

The first principle, however, in the treatment of all abnormal physiological conditions must not be forgotten, namely, that the old and useless bile must first be forced out of the system.[2] When this has been accomplished, the system is placed in a position to accept, utilize, and be benefited by a new supply of bile of improved quality. That the digestive and nutritive functions of the body are augmented is shown by a marked improvement in the general condition of the patient and by positive changes in the composition of the urine.

[1] THE MEDICAL NEWS, January 24, 1891, p. 90.

[2] Ibid., February 28, 1891, p. 245.

First. In a well-defined abnormal case, before ridding the system of its old bile and substituting a new supply, the amount of urine is usually found to be scanty, high-colored, hyper-acid, and of high specific gravity, ranging between 1025 and 1035. The amount of urea is decidedly diminished in quantity, with an excessive amount of uric acid, urates, or oxalates, and it often contains bile-pigment and biliary salts. Owing to the large quantity of uric acid such a sample will remain acid in reaction for days, weeks, or months, before alkaline fermentation is developed. When this does occur the products of its fermentation will be ammonium carbonate, free ammonia, carbon dioxide, ammonium urate, and the ammonio-magnesium phosphate crystals, together with a more or less complete disappearance of the uric acid crystals.

Second. Where the abnormality is less marked and the digestive and assimilative functions are more perfectly performed, but are not yet normal, the time elapsing between the discharge of the urine and the development of the alkaline fermentation is shorter. The duration of the acidity varies with the degree of the digestive and hepatic disturbances. The urine is less likely to contain bile than in the former case. The products of the alkaline fermentation are practically the same as in the former instance, excepting the formation of ammonium urate, which is usually absent.

Third. After expulsion of the old bile and the introduction of the new and improved ox-gall, the flow of urine becomes more abundant and normal in quantity, lighter in color, less acid, of lower density, and contains a larger percentage of urea with a corresponding diminution in uric acid, urates, and oxalates. When the normal standard is reached, the urine will change from its faintly acid reaction to that of alkaline fermentation in from twenty-four to forty-eight hours. The products of fermentation will now be what may be called normal, namely, ammonium carbonate in abundance, free ammonia, carbon dioxide, and an excessive amount of crystals of ammonio-magnesium phosphate.

By this method of prolonged study of the urine, we are enabled to determine with a wonderful degree of accuracy the perfection of the digestive, hepatic, and assimilative processes of the body. From its results we can tell whether our patients are improving in their nutritive condition or whether they are losing ground, no matter what symptoms may be presented. By it we have, as it were, a perfect key to the working of the chemico-physiological laboratory of the system. With these physiological laws in mind we are in a position to appreciate what can be accomplished by the internal administration of the fel bovis inspissatum. In fact, all the good that

can be obtained from the use of the bile must come from its action upon the digestive, hepatic, and assimilative functions of the body.

The administration of ox-gall is indicated under all circumstances where there is a faulty digestive action, poor nutrition, and abnormal urine. It should always be administered in the form of a capsule, which should contain from two to five grains of the inspissated bile, the former being the preferable dose, either alone or in combination with other medicinal agents.

When taken in this form it temporarily retards the flow of hydrochloric acid from the gastric mucous membrane, and stimulates a more copious discharge of a more active milk-curdling ferment. This temporary decline in the acid constituents of the gastric juice gives time for the milk-curdling ferment to precipitate the casein in the form of fine feathery flakes. When the acid and peptic secretion is reëstablished by the irritation of the precipitated casein there results a more rapid and perfect peptonization in the stomach of this proteid of the milk.

The truth of these statements can easily be demonstrated by administering some capsules containing ox-gall to an individual who cannot under ordinary circumstances digest milk, when he will cease to throw off the tough, leathery curds of precipitated casein, which he previously did. If an emetic is administered after a suitable time has elapsed since the ingestion of the milk, preceded by the fel bovis, the precipitate in the stomach is found to be composed of fine feathery particles, in which form it is most rapidly acted upon by the peptic ferment.

Ox-bile also stimulates a more active flow and an improved quality of pepsin, as is shown by the more rapid and perfect digestion in the stomach of all the different kinds of proteids. By producing this perfect peptonizing action upon the proteids in the stomach the amount of work to be accomplished by the pancreatic and intestinal juices is considerably decreased and a more perfect digestion of the remaining food-stuffs, which have reached the intestinal canal in an undigested state, will take place.

A certain amount of the bile which has been administered *per os* passes through the stomach into the intestinal canal and there helps in the digestion of all food-stuffs. It now takes the place of the biliary fluid which the liver is not capable of producing, or of the old and imperfect bile which has or ought to have been expelled from the system by a cholagogue cathartic. Once in the intestine, we are justified in saying that this newly-acquired bile decidedly aids in the diastatic and peptonizing actions which are completed at this point, and is a mighty factor in rendering the nutritive pabulum more thoroughly diffusible. It also prevents decomposition, and decreases in a large measure the amount of effete or poisonous elements that can be taken up with food-stuffs to the liver. In this manner a certain amount of irritative matter is prevented from gaining access to the system, and to that extent the amount of work imposed upon the glandular structures of the body is reduced.

The newly-added bile further acts as a natural stimulant to the muscular coat of the intestine as a whole, thus causing the general peristaltic action to be increased. Again, some of the ingredients of the bile stimulate the small muscles of the villi, and greatly augment the activity of their contained lymphatic vessels,[1] causing them to pump the fat more rapidly through and out of the epithelial cells —which form the external covering of the villi—and to discharge it into the deeper lymphatics, to be carried on to the general circulation.

It also stimulates the alimentary secretions, which help to lubricate the intestinal surface, favoring a more natural and easy onward movement of the contents of the gut, thereby tending to prevent or overcome any existing constipation.

The bile also stimulates the vital activity of the epithelial cells lining the alimentary tract throughout, and by so doing causes them to absorb more rapidly all food-stuffs which have been converted into a diffusible pabulum ready for absorption, discharging the peptones and glucose easily and quickly into the entero-hepatic circulation, while the fats pass through the lacteals to finally reach the circulation at the origin of the left brachio-cephalic vein.

By converting all the food-stuffs into a thoroughly and easily diffusible fluid, by decreasing to the minimum the products of intestinal fermentation, and by stimulating the activity of the gut in this way, we have produced a condition which favors the most rapid absorption attainable, with the least expenditure of force, and, as a result, there is carried to the liver and system at large a completely digested intestinal product—a nutritive pabulum which contains the smallest possible amount of effete or deleterious matter.

With this nutritive fluid a certain amount of the newly administered bile is also carried to the liver, where it is seized upon by the hepatic cells, and a portion retransformed into biliary fluid, which again reaches the alimentary tract by the natural channel. The balance, by its presence in the liver, aids very materially in those chemico-physiological transforming actions which are so extensively carried on by the protoplasmic elements constituting the hepatic cells. As a sequence of this phenomenon

[1] The Medical News, January 24, 1891, p. 90.

we have discharged from the lobules of the liver into the hepatic system of vessels a more perfect nutritive pabulum, and one that is almost entirely free from extraneous or poisonous matter—a nutritive fluid that can be quite easily utilized for the growth, development and maintenance of the body tissues, and for the support of the secretory and excretory glandular structures. All this is accomplished with a small total expenditure of oxygen, provided that the food-stuffs taken are chiefly of the CHNOS group; and at the same time there is formed, to be eliminated from the system by the excretory organs, the most complete products of tissue-waste, namely, urea, carbon dioxide, and water. This naturally decreases to a very marked degree the excretory strain upon the glandular organs, which have for their function the task of removing from the body waste products resulting from the chemico-physiological transformations produced as the result of vital action.

But one thing can follow such a chain of events, and that is a more or less rapid restoration of all parts of the body to a normal physiological standard, with a disappearance of all abnormal symptoms; in fact, a complete cure of whatever diseased condition may have existed at the time treatment was instituted.

In the light of this knowledge, ox-bile becomes one of the most potent, if not the only true, physiological antipyretic agent at our command. This statement is especially true as regards typhoid fever, and in all those diseases in which intestinal irritation is marked. In all infectious diseases, where some poison has been introduced into the system, either in the form of a microörganism, ptomaine, leucomaine, toxine, or some unknown quantity, the first deleterious effect of the infecting agent is to disturb the functions of the liver and of its bile-producing power, as evidenced by the coated tongue, the primary constipation, the clay-colored stools, the high-colored acid urine of high density with a diminished quantity of urea and an increased amount of uric acid, urates and oxalates—all of which indicate incomplete digestion and imperfect or excessive oxidation, and an impaired nutrition.

While ox-bile may not be able to kill the original germ or destroy the ptomaine, leucomaine, or poison which is producing the specific disease, it does furnish to the system a new supply of a very necessary agent, and one which the animal economy, by its own inherent power, is not capable of producing, and without which the bodily functions cannot be perfectly performed. The fel bovis prevents intestinal fermentation, improves the digestive act, and decreases the amount of damaging material which can be absorbed from the lumen of the gut. It also increases the total amount of the nutritive pabulum which is to be carried into the system.

With the absorption of food-stuffs a certain quantity of this newly-introduced bile is also carried to the liver, and very decidedly aids in the action of the hepatic cells, all of which tends to reduce irritation, improve oxidation, assimilation, and the nutritive powers throughout the system. When this has been accomplished the animal economy is capable of destroying or removing the original poison which, before this, tended to multiply and become more intense in its action.

In this way the bile becomes a truly antipyretic agent and decidedly lowers bodily temperature; but while it may not be able to completely reduce the temperature, it nevertheless keeps it within living bounds, sustains the vitality of the system until the disease has run its course and has been eradicated from the body. It will not cure the disease, but it will very decidedly shorten the duration and diminish the intensity. Another good effect from the action of ox-bile in the treatment of typhoid fever is the small amount of tympanites present after its use. It also diminishes diarrhœa, and the cerebral symptoms are milder under its influence. There is also noted a more copious flow of urine, more urea, less uric acid, urates, and a diminished liability to albumin or casts.

For the past few years several of my colleagues have been following this plan of treatment with me, and so far there has not been a single death among our typhoid patients. The duration of the disease has been shorter and the attack milder as compared with many that we have seen in the past. This favorable showing has been limited to a small number of cases, not more than fifty in all. If carried into the hundreds it may be found to give no better results than many other lines of treatment; but theoretically, and from the results so far obtained in the practical line, and from its being in keeping with well-established physiological laws, it ought to continue to yield good results in the majority of instances. In so far as ox-bile prevents intestinal fermentation and improves nutrition, it will lower the temperature in all febrile conditions.

In the treatment of nephritic diseases it is the chief agent to be relied upon to enable the system to improve the digestive and hepatic action and the nutrition at large, and that of the kidney protoplasm in particular. By establishing a more perfect assimilation throughout the body, it very decidedly decreases the amount of excretory work to be accomplished by the renal epithelial cells. This achieved, the albumin and casts disappear from the urine and the renal excretion returns to a perfectly normal standard. The rapidity with which this change can be effected is almost beyond comprehension. The renal lesion is cured, physiologically speaking, although the kidney remains irreparably

damaged from a purely histological standard. This distinction between a physiological and a histological cure has been too often overlooked, and many diseases are classed as incurable because the pathological condition cannot be completely eradicated, while the damaged organ can be made to perfectly perform its functions and remove every trace and symptom of disease from the system.

To enumerate all the good that can be accomplished by proper feeding and the internal administration of ox-bile would be tedious. Enough has been given to fully illustrate the physiological principle of the action of fel bovis, which can easily be applied to a greater or less degree in dealing with all kinds of pathological problems.

One more action and use, however, must not be forgotten in connection with ox-bile, and that is its great power and activity in softening and removing fæcal matter from the colon, in connection with chronic constipation or where impaction has occurred. The fel bovis alone, or perhaps better in combination, as in the following formula, will soften and remove quite effectually impacted fæces and stimulate the lower bowel to action when all other means have failed. It is also a very powerful agent for bringing away the gas and relieving troublesome tympanites:

℞.—Inspissated ox-bile	. . .	℥j.
Glycerini	. . . . .	℥iv.
Ol. ricini	. . . . .	℥ij.
Aquæ	. . . q. s. ad	℥viij.—M.

Sig.—This added to a pint, or better still, a quart of warm soapsuds; the larger amount can be retained when slowly injected into the lower bowel.

After several copious injections have been administered and retained for a time and have come away without producing the desired effect, we are justified in assuming that the colon is free. This has been verified with sufficient frequency in the dead-house to warrant the statement that it will invariably soften and remove fæcal matter from the colon. Of course, excepting a tight stricture of the colon or an occlusion of the lumen of the gut, which cannot be passed by the enema.

TWO CASES OF EMPYEMA.

By G. R. TROWBRIDGE, A.M., M.D.,
Assistant Physician to the State Hospital for the Insane, Danville, Pa.

In The Medical News for February 21, 1891, Dr. Goggans has a most interesting and practical article on the "Surgical Treatment of Empyema," and if not trespassing too much, I would like to supplement his article with a rather meagre, I regret to say, report of two cases of empyema, which came under my care while resident physician in the Rochester (N. Y.) City Hospital.

I shall be obliged to give the histories of the cases from memory, as I have no data at hand; but both cases were so forcibly impressed on my mind that, although I shall not be able to give minute facts, yet I can give enough of a general outline of each to illustrate my point, viz.: the result of prompt surgical interference in one case, and the result of no such treatment in the second:

Case I.—Male, Italian, about thirty-five years of age. Was admitted with a history of having caught cold; some fever, cough, dyspnœa, and but little expectoration. On examination it was found that the left chest gave evidences of a large accumulation of fluid, and from the previous history it was decided that this fluid was of a purulent character, and that its evacuation was necessary. The man was in good general physical condition, and consequently the case was one from which the best of results could be expected. In order to confirm the diagnosis of empyema the aspirator was used, and several ounces of pus were drawn off. It was then decided that the best course to pursue was to make an incision and establish free drainage, and afford opportunity for irrigating the pleural cavity. Dr. Charles Dewey, the visiting physician, operated, making the incision in the intercostal space, as low down as possible, and without interfering with the ribs, in order that the freest drainage might be obtained. The operation was followed by no unfavorable symptoms, and I think this was in a measure due to the aspiration, on the day before, which allowed partial expansion of the lung.

The after-treatment of this case was to me the interesting part, and the method pursued was, to the best of my knowledge, the idea of Dr. Dewey.

A rubber drainage-tube, about ten inches in length, was introduced into the cavity as far as possible (about four or five inches), leaving about the same length outside the chest-wall. This was secured in place by threads sewed through the tube, which were attached to the chest-walls with strips of adhesive plaster. A glass tube, about four inches in length, was tightly fitted to the rubber tube, and to the other extremity of the glass tube was attached a second rubber tube, which extended over the edge of the bed to the floor, the end resting in a glass jar, which was partially filled with a 5 per cent. solution of carbolic acid. An antiseptic dressing was placed over the wound and around the tubing where it entered the chest, so that it was next to an impossibility for air to enter, as the tubing which passed into the pleural cavity was large, and fitted so snugly that the patient complained of it.

Twice a day for a week or ten days after the operation the pleural cavity was carefully but thoroughly irrigated with a solution of bichloride, 1 to 3000, the tube being disconnected at the glass connection, but before this was done it was carefully pinched between the fingers until the connection was made with a fountain syringe.

Of course the progress was slow, as empyema is

not as easily cured as acquired, but the patient made a good recovery, with but few unfavorable symptoms, and with but slight diminution in lung power and capacity. He returned to the hospital some months after his discharge, and stated that he was in as good health as he had ever been, and suffered no inconvenience in his chest.

The measurement of his left chest, on expansion, was slightly less than that of the right, but there was no perceptible difference in action.

CASE II.—Male, barber, about twenty-five years of age. Admitted with history of having taken cold; chills and fever, increasing dyspnœa, which was very marked at time of admission, and short, hacking cough.

Patient said he had been to see a doctor (?), but had steadily been losing ground. Was expectorating a large amount of extremely foul pus. Heart-beat was rapid, but fairly strong. General physical condition greatly impaired.

The right chest gave evidences of fluid throughout its entire extent, and with the history and the purulent expectoration, empyema with a pleuro-bronchial fistula was diagnosed.

During the first night he spent in the hospital it was necessary to remove him from the general ward, as the odor from the pus expectorated polluted the air of the ward, and annoyed other patients.

On the next afternoon Dr. W. S. Ely, visiting physician, made an incision into the pleural cavity, and immediately there was an escape of large quantities of pus and air, the latter confirming the opinion that there was a connection between the pleural cavity and the trachea. The dyspnœa was greatly increased after the operation, as the sound lung would not act as well after the removal of the pus. Patient failed rapidly, and died on the following morning. The autopsy showed that the right lung was pressed so closely against the spinal column that it was impossible for air to have entered it at all, and even after the relief of the pressure caused by the pus there was no expansion. There was a fistula connecting directly with the bronchus which admitted a lead-pencil. The walls of the pleural cavity were covered with a purulent exudate.

These are, to my mind, two illustrative cases, the first showing what may be accomplished by active measures, and the second, what may occur if the condition is not recognized and properly treated. In all probability, both cases were pleurisies with effusions, and gradually changed into empyemas.

Fluid in the pleural cavity is a condition which every practitioner should be able to recognize and properly treat, but how often this condition is carelessly passed over as a "cold," "malaria," etc.

Often obstinate cases of pleurisy with effusion occur, which will give way to no form of treatment except the repeated use of the aspirator, and occasionally not even to that.

In empyema the best form of procedure, according to most authorities, is incision, free drainage and careful antisepsis. I do not see why we should hesitate to remove pus from the pleural cavity any more than from an abscess. .

All authors agree that surgical treatment is the only proper procedure in the case of empyema.

Austin Flint[1] says: "In the treatment of suppurative pleuritis, no reliance is to be placed on measures to cause absorption of the purulent liquid. If the pleural cavity contain pus in considerable quantity it will not be absorbed; but if life be sufficiently prolonged, and thoracentesis be not resorted to, it will, sooner or later, make its way either into the air-passages or through the thoracic walls. Hydragogues, diuretics, blisters, etc., will not only prove unavailing, but they do harm by impairing the powers of the system. Thoracentesis should be performed as soon as the purulent character of the liquid is ascertained. Aspiration may be employed and repeated, but in many cases, owing to the reaccumulation of pus, this mode of performing thoracentesis will prove unsatisfactory. An opening should be made at the bottom of the pleural sac, allowing the pus to escape freely." This author goes on to state that this incision must be kept open by means of an "oakum tent," and the cavity cleansed with a solution of carbolic acid. This method is somewhat crude, as "oakum tents" and "carbolic acid solutions" are methods of the past, as the general tenor of the operation is toward surgical treatment.

Alfred L. Loomis[2] makes the following statement: "In the treatment of this affection it is useless to attempt to produce the absorption of the purulent accumulation by remedial agents. Its removal can only be accomplished by mechanical means—either by aspiration or by making a permanent opening in the chest-walls." Loomis advises the use of the drainage-tube, but does not favor irrigating the cavity, even though the pus becomes fœtid. The author may have been unfortunate in the irrigating process, but I do not think it possible for a perfect drainage to exist without this part of the treatment.

Wyeth, Erichsen, and, in fact, the majority of modern writers, advise thoracentesis, though all have their special "hobbies" in the minute details.

Dr. Goggans, in his article, advises repeated aspirations before resorting to the "open operation," but I think, in a measure, this depends on the character of the pus and the condition of the patient. A difference of opinion exists in regard to the advisability of aspiration or the "open operation," different writers claiming better results for each, but one fact is agreed upon by all, viz.: that the pleural cavities in these cases should be emptied. I think Dr. Goggans is right in opposing the view taken by Dr. Schede, of Hamburg, who favors resection of

[1] Practice of Medicine, page 142.

[2] Practical Medicine, page 161.

the rib. This seems to be unnecessary, unless the drainage-tube is compressed by the ribs, in which case it would certainly be advisable to remove a portion of bone; but unless this occurs, it seems useless to weaken the chest-wall.

Dr. A. R. Elliott, of this hospital, while in general practice, saw a case of empyema with a bronchopleural fistula, the sequelæ of typhoid fever and pneumonia, which recovered without surgical interference; but, of course, this is one in a thousand cases.

I think Dr. Lydston's case (quoted by Dr. Goggans) tallies very well with my second case, in being one of those which is unrecognized or neglected. In this case the man had been on board a trans-Atlantic steamer from the outset of the disease, and apparently nothing of any account had been done for him.

Perhaps my second case might be called a pyopneumothorax, but I report it here, as there must have been a purulent accumulation in the pleural cavity some time before the formation of the fistula.

I trust those who read this article will not think I am trespassing, but empyema may occur in insane people, and physicians in insane hospitals should be as much interested in diseases of the chest, abdomen, etc., as in mania, melancholia, circular insanity, or general paralysis.

ON THE REFORM IN NUMBERING PRISMS.

By SWAN M. BURNETT, M.D., Ph.D.,
of Washington, D. C.

Some time ago I had the opportunity of seeing a manuscript submitted for publication which dealt with a new method of designating anomalies in the refraction of the eye. The system consisted essentially in the adoption of a varying index of refraction in the media as expressive of the varying refracting power. The points were well taken, the argument was logical, scientific, and conclusive; but I do not believe the system ever came, or is likely to come, into general use, for reasons which are too apparent to require mention.

When I first saw the proposition to use what is called the centrad as a method of designating prisms, this ingenious system of marking ametropia instantly came into my mind, probably because of its analogous cleverness and ingenuity. For I hasten to say that the centrad *is* an ingenious conception, as are all the conceptions which originate with Dr. Dennett; and as a work of ingenuity I admire it as much as anyone can. But in this work-a-day world, where we have to deal with only average intelligences, and where prejudices of tradition and custom and the inertia of established habit are the greatest obstacles we have to advancement in all lines of scientific study and work, any radical innovation which requires a reëducation from the very foundation can hope for success only when it possesses a practical advantage over all competitors, which can be easily demonstrated to the most ordinary comprehension. That, in my opinion, the centrad does not possess such advantage in the numbering of prisms I have stated in my paper in the January number of the *Ophthalmic Review* and given my reasons therefor. Those interested in the question I would refer to the paper itself as expressing in general the arguments which I conceive to be valid against it and the minimum angle of deviation, and those in favor of the prism-dioptry.

The object of this present communication is to reply as briefly as possible to some strictures on that article, made by Dr. Randall in the issue of The Medical News for April 4th.

Among other things, he says: "The prism-dioptry, which is a tangent measurement, declines in value with each increase of the angle." What he should have said, and what he probably meant, is that the tangent, being a growing function, *increases* with the value of the angle until the latter reaches 90°, when the tangent is *infinitely great.* There is nothing that is absolutely contrary to the truth in that simple proposition, but it has the defect of not telling the whole truth. He makes the mistake of assuming that we are compelled to regard the deflection caused by a prism on a plane at any given distance in the light of a tangent. Now, as I have stated in the paper referred to, we are compelled to do nothing of the kind. We can, without surrendering any scientific principle, regard the deflection as a displacement, measurable in a linear manner on this plane, without regarding its reciprocal as expressed in sine, tangent, co-sine, co-tangent, degree, minute, or second, or in any other way that may be fancied. The absolute difference, however, between the multiples of the sine, tangent, and arc, for even a prism of 10°, which is higher than is, or should be, used in practice, is really insignificant:

Tang. 1°=0.01745.	Arc 1°=0.01745.	Sin. 1°=0.01745.
Tang. (10x1) 10°=0.17633.	Arc (10x1) 10°=1745.	Sin (10x1) 10°=0.017365
Diff., 0.00183 less.	No difference.	Diff.=0 00085 more.

How simple and easy it is to explain to even the uninitiated that a No. 1 prism is one which causes a deflection of one centimetre on a plane at a distance of one metre; No. 2, two centimetres; No. 3, three centimetres, and so on. That represents exactly and truly the amount of work done by the special prism so designated, and that is precisely what we want to know. We care nothing, practically, about its reciprocals expressed in angles, any more than in co-sines or co-tangents; and yet we can find these if, from curiosity or for scientific reasons, we so desire, from the ordinary table of sines, co-sines,

etc., just as we now have to find these reciprocals from the angle. And the fact that the angle of twenty prism-dioptres is not exactly twenty times the angle of one prism-dioptre is a matter of no practical consequence whatever, because we have not, nor need we have, anything to do with angles, any more than when we are dealing with spherical and cylindrical lenses—which, after all, are only series of prisms of constantly-varying deflection.

What is our standard for refracting lenses? One which causes a deflection of all parallel rays to a point on a plane at a metre's distance. What should be our standard for prisms in harmony with this? Naturally, one which causes a certain deflection at the metre plane; and what more appropriate and in keeping with our accepted standard of linear measurement than to have this unit deflection one centimetre? This is in consonance with the C. G. S. system, which is assumed as the basis of the centrad. The prism-dioptry is not only strictly scientific and exact in what it professes to do, namely, to give the deflecting power of any given prism, but it is marvellously simple in principle, is in perfect harmony with the metric system of numbering spectacle lenses, and is easily practised by anyone having a metre measure and a centimetre scale.

We are taken to task by Dr. Randall, because we asserted that neither Dr. Dennett nor any of the advocates of the centrad had offered any practical method of measuring the power of prisms according to the radian system. He says: "Dr. Burnett has befogged himself by importing into the centrad system the 'minimum deviation,' which has no place there. Like the prism-dioptre, the centrad is a prism which at one metre distance deflects the ray of light falling at right angles upon one of its faces through the space of one centimetre, the only difference being that the centrad is measured on the arc and not on the tangent."

When we read that paragraph we wondered if Dr. Randall had re-read Dr. Dennett's original paper recently and was aware of what Dr. Dennett actually proposed in his centrad system. Dr. Dennett says nothing at all about measuring one centimetre on the arc at the metre's radius. He expresses his unit only in reciprocal angles, and says: "We define the ideal centrad as an achromatic prism that produces in light passing through it in a direction perpendicular to one of its faces a deviation of one one-hundredth of a radian, or 0.57295°." This was the basis of our remark that the centrad could not perform any function which was not now equally well performed by the minimum angle.

Those of us who advocate prism-dioptry are glad to have its principles acknowledged and accepted, but not exactly in the way Dr. Randall has done. To Mr. Prentice alone belongs the credit of having proposed as a standard prism one which produces a deflection of one centimetre at one metre's distance, and no advocate of the centrad ever hinted at it until after the appearance of Mr. Prentice's paper in the *Archives of Ophthalmology*. We owe the simplicity of that idea to Mr. Prentice; let us not deprive him of whatever honor belongs to the conception. But if the advocates of the centrad desire to abandon their original idea of the reciprocal angle and will accept the curvilinear deflection of one centimetre at a metre's distance as a basis of numbering, the difference in principle between that and the prism-dioptre would not be great. The difficulty, however, as was foreseen by Mr. Prentice and myself, is that the curvilinear measure is not so easily or readily made as the purely linear, and the practical advantage we saw was greatly in favor of the latter. It is so much easier to measure deflections on a plane than on a curve.

We would like to enter here into more detailed consideration of the relation of the prism-dioptre to the metre-angle, but as Dr. Randall has acknowledged the great practical value of Mr. Prentice's work in that particular, we will defer its discussion for a future paper, in which we hope to show how the whole matter of convergence can be made simpler and more easily studied by means of the prism-dioptre than it is now by means of the clumsy metre-angle.

In the decentring of lenses the prism-dioptry system shows up to the greatest possible advantage, as has been demonstrated thoroughly by Mr. Prentice in his paper in the *Archives of Ophthalmology*. In regard to this Dr. Randall naïvely remarks: "I question if this be correct, although I fail to detect any fault in the argument."

When he does we trust he will let us know.

Dr. Randall's desire to make the centrad supercede the angle in measuring strabismus and in designating the direction of the axes of cylinders we cannot but regard as vain, knowing as we do the antipathy to change from even a bad system already established in the working of an art, although it be a scientific one, which prevails in the minds of the profession at large; when the reform comes, we fancy it will not be in the line of the centrad.

We quote, finally, this Parthian shot: "Dr. Burnett's assumption that the centrad is indivisible, and that only exact whole numbers can be employed, is gratuitous, to say the least."

Dr. Burnett never entertained any such opinion, and is not able to find any expression pointing to such an opinion in anything he has written on the subject.

ON THE RELATION OF ATMOSPHERIC ELECTRICITY, MAGNETIC STORMS, AND WEATHER ELEMENTS TO A CASE OF TRAUMATIC NEURALGIA.[1]

BY R. CATLIN,[2]
U. S. ARMY.

IN the relationship of atmospheric electricity to pain, it is shown that by a comparison of 120 daily curves taken on neuralgia periods with the mean of the same number for *ten consecutive days* of each month, pain seeks identity with both lower positive curves and with the negative, and with fluctuations of great amplitude.

For the influence of May storms on pain the maximum auroral period of 1882–83 was selected; of this period, seven of the greatest magnetic storms were chosen. Accompanying each was pain, and in the majority of cases pain of unusual intensity prevailed. The great storm of November, 1882, the greatest of which we have a record, shows the relationship to be unequivocal. In the other cases the magnetic storm was coincident with other causes, which may or may not have had something to do with pain, but in four cases no dry or wet cyclone was in any way connected with the trouble.

The comparison of the weather elements—such as pressure, temperature, force of wind, humidity, relative and absolute, days of rain, depth of rain, hours of sunshine, number of storms, and ozone—with pain—covers a period in no case of less than five years. Of these the increasing temperature curve, the hours of sunshine curve, and the absolute vapor curve, operate to diminish pain, while all the others are identified more or less with pain. In the monthly products for fourteen years it appears that the "depth of rain," ozone, and "number of days of rain," in this order, but almost equally, constituted the best standards for pain measurement. By generalizing on the extremes through all these years, by taking the twelve months of greatest pain and the twelve of least pain, the above conclusions are verified, and the law stated in general terms, as follows:

Maximum pain bears a direct proportion to storm frequency, and an inverse proportion to temperature and elastic force of vapor; and minimum pain bears an inverse proportion to storm frequency, and a direct to temperature and elastic force of vapor; while depth of rain accompanies the number of storms and maximum pain. Charts of *relative storm frequency* and *geographical pain* charts are thus ralated.

What are known as "*spells*" or "*types*" of weather, lasting from one to three weeks, probably due the relative position of the great anti-cyclone areas, have their influence on pain condition. This fact was recognized early in the history of this case in 1869. Increased amount and intensity of pain accompany these "spells," particularly at their beginnings. Covering a period of fifteen years the *relative ratios of the monthly products of pain* were as follows: February, 176; March, 175; January, 174; December, 168; November, 164; April, 161; May, 160; July, 159; June, 154; September, 153; and October, 153. The ratios were determined by dividing the total number of hours of neuralgia of each month by the total number of hours in the month for the whole period of fifteen years.

Perhaps the most difficult and complex part of the problem is in offering an explanation of the diurnal fluctuations of pain.

The record of hourly beginnings of pain covers a period of more than eighteen years; and the curve of the record of hourly beginnings of storms and the amount of rain of each covers a period of sixteen years.

The daily pain curve exhibits 3 pain maxima; the first at 11 A.M., the second at 2 P.M., and the third at 7 P.M. The part of the curve at 6, 7, and 8 A.M. has almost an inverse counterpart in 8, 9, and 10 P.M., but in the curve from 9 A.M. to 7 P.M., there is a very important minimum at 12 M. and 1 P.M., then a subordinate minimum at 3 P.M., very like that at 10 A.M., followed at 5 and 6 P.M. by a distinct minimum.

By placing on the pain curve the storm curves for the sixteen-year period, it becomes manifest that while the absolute values of the rain depths and number of storms on the pain curve do not show a full correspondence, it is, however, clear at once that there is a relative value between the two and the pain.

In all discussions of this subject to this time, only instrumental records, such as synoptic charts, thermograms, etc., have been brought into use, but it is clear that the physical effects produced by the temperature on the southeast side of a cyclone is very different from the same record-temperature on the west or the northwest side.

It is found that the eastern edge of the neuralgic crescent lies more than six hundred miles, or about twenty-three hours to the east of the centre of the "lows," but no two cyclones or rain conditions are exactly alike, and have different kinds of rain, and when we consider that there are two atmospheres—one of a dry, gaseous air, and another one distinct, of aqueous vapor, with the latter never thoroughly intermixed with the former, and never in a state of equilibrium—we partially realize how impossible it is in any given storm to get a complete record by instruments, or of those which are the best pain-

[1] Presented at the Boston Meeting of the National Academy of Science, November, 1890.

[2] See letter of Dr. Mitchell, p. 506.

producers, for without apparent instrumental cause they vary much in this respect.

No local hygrometric reading can give anything more than a vague approximation of the quantity of vapor or its mixture in a vertical column of air.

A typical neuralgic atmosphere, anticipating a cyclone, may be a dry air with a diminishing light, variable wind, and a pale, delicate, bluish whiteness in the atmosphere, more marked toward the horizon, and in the first stage more marked in the western horizon. The sickly whiteness may increase for from twenty to sixty hours, with an increasing discomfort when exposed to the peculiarly penetrating power of the sun's rays, but during all this typical condition there is nothing which has measured the changing aspect of the air, nor its changing condition of heat permeability, nor the absolute vapor, except at the surface, nor the distinctive character of the cyclone heat in the southeast quadrant, nor the direction of the upper and cross currents of wind, nor, above all, the modifications of the diurnal and "semi-diurnal" effect superimposed on the cyclone movement. It, therefore, seems important, in studying the hourly phases of pain, that meteorological charts should be supplemented by a descriptive narration to complete the record, and a closer study of the effect of diurnal change on weather.

OCULAR SIGNS AS AIDS TO DIAGNOSIS.[1]

BY E. OLIVER BELT, M.D.,
OF WASHINGTON, D. C.

As all rational treatment of disease depends upon a correct diagnosis, any information that will aid in quickly forming correct conclusions regarding the nature of an affection will, I think, be welcome to the busy practitioner; and knowing that the eye and its appendages are frequently the seat of the local expression of general disease, and of special disease of other organs, or portions of the body, it is my purpose to give a brief summary of the most important of such ocular signs, and the deductions to be made from them. We will first consider affections of the conjunctiva, lids, cornea, iris, and lens, as seen by the unaided eye; and, secondly, those diseases revealed by the use of the ophthalmoscope, and the testing of the field of vision.

When a physician is called to the bedside of a patient, examination of the pulse and the tongue for indications regarding the circulation and digestion is of so much importance as to have become routine practice. To this routine should be added at least a cursory observation of the condition of the eye. Dr. Rosse, in a paper on "Cerebroscopy,"[2] meaning thereby the "method of diagnosing cerebro-spinal disease by studying the alterations of the eye," says: "This new science, though still incomplete, has done so much to advance the diagnosis of nervous diseases that the advocates of cerebroscopy place it in the first rank of the methods of exploration employed by physicians; and remarks, without exaggeration, that it is for diseases of the brain and spinal cord what auscultation and percussion are for diseases of the chest, for it is now quite possible by this method to see in the eye what is taking place in the brain."

It takes but a moment to notice whether the conjunctiva be clear or jaundiced, the palpebral portion congested or pallid, the lids puffy or discolored, the cornea clear or cloudy, the pupils dilated or contracted; whether there is perfect movement of all the muscles of the eyeball and lids, and whether vision is affected in any portion of the field.

Beginning with indications afforded by the conjunctiva and lids, we need no better evidence of hepatic derangement than the icterode conjunctiva, nor of anæmia, than the pallid mucous lining of the lids. Phlyctenular diseases of the conjunctiva and cornea are indications of lowered vitality and a strumous condition. Œdema of the lids, unaccompanied by inflammation of the eyeball, points to diseases of the heart or kidneys; this condition, however, may result from the use of certain drugs, as arsenic, it being frequently the first intimation of poisoning by that drug. It is also a useful guide in the therapeutic administration of arsenic. A succession of styes denotes a lowered condition of the general health, or derangement of the stomach or reproductive organs. Marginal blepharitis also indicates lowered health or an error of refraction. Protruding eyeballs, a rapid heart, and enlarged thyroid gland are familiar symptoms of Graves's disease.

The chief diagnostic sign given us by the cornea is interstitial keratitis. As a result of syphilis Nettleship says: "That diffuse, chronic keratitis, affecting both eyes of children and adolescents, is, when well characterized, almost invariably the result of hereditary syphilis, is proved by abundant evidence."

As a rule, the characteristic Hutchinson teeth are seen with this condition. In the old we sometimes notice painless ulceration of the cornea, which signifies a lesion of the fifth nerve. Arcus senilis is often an accompaniment of fatty heart, and an indication of fatty degeneration of other tissues of the body. The iris frequently gives us indications of unsuspected syphilis and premonition of gout and rheumatism for weeks before there are other manifestations of these diseases.[1] About 70 per cent. of the cases of iritis are due to syphilis. It usually affects both

[1] Read before the Medical Society of the District of Columbia, March 18, 1891.

[2] Reference Handbook of the Medical Sciences.

[1] THE MEDICAL NEWS, December 27, 1890.

eyes, which is an important fact to remember, as unilateral iritis is generally due to rheumatism, which causes about 15 per cent. of all cases. A gumma of the iris is a positive indication of syphilis.

The condition of the pupils frequently gives us the first intimation of brain or spinal disease, and in cases of poisoning it assists in determining the nature of the poison, and the antidote.

Nettleship[1] says: "Reflex iridoplegia (the Argyll-Robertson pupil) is one of the most valuable of the early signs of locomotor ataxy." Inequality of the pupils seems to be very frequently a precursor of insanity. Aside from dilatation caused by paralysis of the third pair of nerves and the local influence of mydriatics, according to Meyer and other authorities, the pupils are found dilated in hysteria, in hypochondria, in the later stages of meningitis, in hydrocephalus, etc. Sudden dilatation of the pupils during the administration of chloroform is a very important danger signal.

Contraction of the pupils, according to Swanzy,[2] is found in the early stages at least of all inflammatory affections of the brain and its meninges, in tobacco amblyopia, at the beginning of an hysterical or of an epileptic attack, in the early stages of intra-cranial tumors situated at the origin of the third nerve, or in its course. In cerebral apoplexy the pupil is at first contracted, according to Berthold, who points out that this contraction is a diagnostic sign between apoplexy and embolism, in which latter the pupil is unaltered. In lesions above the dorsal vertebræ myosis occurs. Some authorities regard myosis as one of the earliest signs of tabes, while others do not. In acute mania the pupil is usually much dilated, and when this mydriasis is changed for myosis, approaching general paralysis may be prognosticated.

The pupils are dilated in poisoning by strychnia, ergot, belladonna, stramonium, hyoscyamus, duboisia, cocaine, and aconite; and are contracted by lethal doses of opium, jaborandi, physostigma, tobacco, etc. Loss of accommodation, with or without dilatation of the pupils, frequently follows diptheria, and may be the only positive evidence that the sore throat was diptheritic. Changes in the lens are sometimes of diagnostic value, as rapidly forming cataracts in persons of middle age are indications of diabetes mellitus. In one patient under my observation, suffering with that affection, cataracts formed and matured in both eyes in about six weeks. Muscae volitantes generally indicate disordered digestion, but this affection is not to be confounded with floating bodies due to changes in the lens, vitreous, and choroid, which are generally of a serious nature.

[1] Diseases of the Eye.
[2] Ibid., pages 274-275.

Among the indications revealed by the opthalmoscope we may mention symmetrical disseminated choroiditis with opacities in the vitreous as being almost pathognomonic of syphilis. In this affection the retina is often involved with the choroid. But the retina gives us useful indications in a number of other affections. Notably, in Bright's disease impaired vision is often the only marked symptom. According to Wells,[1] disease of the kidney may be unknown and unsuspected until the ophthalmoscope reveals the presence of the characteristic albuminuric retinitis. During the latter months of pregnancy amblyopia may be the first symptom intimating the probability of albuminuria. Blindness following delivery is more often from loss of blood.

Idiopathic retinal hæmorrhages are of decided significance, especially in the old, where they are often precursors of cerebral apoplexy. In illustration of this point I recall a case which came under my observation a few years ago, at the Presbyterian Eye and Ear Hospital, Baltimore. A prominent physician of the South, about eighty years of age, but in apparently excellent health, had been awaiting patiently the maturation of a cataract; suddenly vision in one eye was reduced to perception of light, and concluding that the cataract was mature, he came on to have it removed by Professor Chisholm. Instead of finding an opaque lens, however, we found extensive hæmorrhages into the vitreous. In less than a week after returning to his home he died suddenly in his office of apoplexy.

Retinal hæmorrhages are not unfrequently seen in organic disease of the heart, and sometimes they result from menstrual suppression. In the absence of glaucoma, when pulsation of the retinal arteries is observed, we might suspect insufficiency of the aortic valves, aneurism of the aorta, Graves's disease, or chlorosis. Amblyopia in certain cases may lead us to suspect tobacco-poisoning, especially if accompanied by central scotoma for red. Optic-nerve atrophy is often the first intimation of locomotor ataxy.

Optic neuritis, loss of sight in portions of the field, and paralysis of certain ocular muscles, frequently give us such aids as to enable us to diagnosticate with comparative certainty not only the presence, but often the location of cerebral lesions. According to Gowers,[2] neuritis is present at some period in at least four-fifths of the cases of tumor of the brain. He says the value of optic neuritis as an indication of the existence of an intra-cranial tumor is very great, and that it may be the only unequivocal sign of the intra-cranial disease. Nettleship says: "Although pointing very strongly to organic disease within the skull, neuritis is not of itself

[1] Diseases of the Eye, 1873, page 373.
[2] Medical Ophthalmoscopy, page 164, 1891.

either a localizing or differentiating symptom." In conjunction, however, with other symptoms that are frequently present it is of much value in localization.

Neuritis limited only to one eye, generally indicates disease of the orbit. Loss of half the field of vision (hemiopia) is one of the most important aids in the localization of cerebral lesions. When binocular it indicates disease at or behind the optic chiasma. In the majority of cases the hemiopia is homonymous, that is, the right or left lateral half of each field is lost. Loss of the right half of each field points to disease of the left optic tract, or of some part of the left occipital lobe, or in the fibres connecting these parts. Temporal hemiopia points to disease at the anterior part of the chiasma. When lateral hemiopia co-exists with hemiplegia the loss of sight is on the paralyzed side. Swanzy[1] says: "We may conclude that the hemiopia depends upon occipital lesion, if it be unaccompanied by hemiplegia, motor aphasia, or paralysis of cerebral nerves;" also, that contraction of the pupil in a case of hemiopia, when the light is thrown on the blind half of the retina, indicates that the lesion causing blindness is back of the corpora quadrigemina. The absence of this reaction indicates that this lesion involves the corpora quadrigemina or the optic tract. Sometimes there is incomplete hemiopia, that is, only one quadrant of the field of vision is affected. Hun[2] reports a case of this kind, in which the left lower quadrant in each field was blind, and where the autopsy showed a lesion strictly limited to the lower half of the right cuneus. Remember the fact that loss of a certain half of the *field* means loss of function of the opposite half of the *retina*.

Paralysis of the ocular muscles also aids in locating cerebral disease. Complete paralysis of the third nerve, without any other paralysis, is almost always due to lesion at the base of the brain, on the same side. Hemiplegia of one side, coming on simultaneously with paralysis of the third nerve of the opposite side, is a common sign of disease of the crus cerebri. When paralysis[3] of the third nerve occurs with hemiplegia of the opposite side of the body and other cerebral symptoms, it is usually due to pressure on the nerve where it runs beneath the cerebral peduncle. According to Nothnagel, this localization is still more certain when paralysis of the facial and hypoglossal nerves exist on the same side as the hemiplegia.

Paralysis of the sixth nerve, according to Swanzy, simultaneous in its onset with hemiplegia of the opposite side of the body, indicates a lesion of the pons, usually a hæmorrhage on the side corresponding to the paralyzed nerve. By itself paralysis of the abducens is of little value in the localization of cerebral disease from the fact that it is so often of peripheral origin.

There are many other ocular signs which aid in diagnosis, but I think this summary embraces most of those which have been verified in the clinic and by autopsies.

THE GREAT VALUE OF OPENING THE EUSTACHIAN TUBE IN DISEASES OF THE HEAD AND EARS.

BY LAURENCE TURNBULL, M.D., PH.G.,
AURAL SURGEON TO JEFFERSON MEDICAL COLLEGE HOSPITAL, ETC.

THIS case, with the one which follows, was sent by a friend, and must be my apology for this brief paper. The writer was called in consultation in Germantown, in the vicinity of Philadelphia, to see a case of deafness with other distressing symptoms. The following history is given by the attending surgeon:

G. A., aged thirty years, of full habit and sanguine temperament, fond of field sports, horses, etc., was driving with his coachman, and on making a sudden turn near Bala station the carriage was overturned, the gentleman falling on his side and striking the left ear and side of the head on a hard body, producing symptoms of concussion of the brain and profound deafness of the same ear, with distressing tinnitus aurium. He was treated most judiciously by his attending surgeon for ten days, but with no relief from the noise or deafness.

When called in I found the patient in bed with his head wrapped up and a poultice over his ears and very much distressed about his hearing. On examination, there was found a swelling situated back of the ear. The auditory canal was inflamed, and the membrana tympani opaque and dark from some material in it, and bulging. The surgeon had hesitated to puncture until I had seen the case. I suggested the use of the Eustachian catheter and inflation through it as perhaps a safer method of procedure. This was done both for the noise and also to give the patient a good, refreshing sleep. Pus, mucus, and blood passed in this way, first by the catheter, and after the free opening into the pharynx, was expectorated as if from an abscess; after some weeks of treatment all evidence of any foreign body was removed, the hearing improved, but the noises did not altogether disappear. The patient was able to take a trip to the West, still keeping up the use of remedies for the noise, which gradually disappeared, and he is now entirely cured.

The following case of Bayer, of Brussels, is analogous to the one above reported:

Male, aged thirty-three years, highly nervous temperament, and a great traveller; was out riding, and after being violently thrown from his seat, again

mounted. Upon dismounting he had to be carried to bed, and became unconscious; now and then pointed with his hand to the left ear. Had subsultus and all the symptoms of pressure. An examination of the auditory meatus showed everything to be in order and was negative. Catheterization suddenly restored the patient to consciousness, and he told this story: That he felt something snap or give way in the left ear when he was so violently jolted. His recovery was slow and he was very nervous; his left arm trembled frequently, and the intellectual functions were impaired for some time. Unconsciousness lasted nearly thirty hours in all. Nervous shock seemed to be the cause of the trouble, which was concussion of the brain, or it might have been auditory, especially as catheterization induced sudden and positive relief.

ORIGINAL LECTURES.

RANULA—SUBCUTANEOUS SECTION OF THE FEMUR FOR THE CORRECTION OF DEFORMITY FOLLOWING COXALGIA—EXCISION OF RIBS FOR EMPYEMA—NECROSIS OF THE HUMERUS—EXCISION OF THE KNEE.

A Clinical Lecture
delivered at the Children's Hospital of Philadelphia.

BY H. R. WHARTON, M.D.,
OF PHILADELPHIA.

[Reported by DR. WILLIAM H. MORRISON.]

THE first case which I have the pleasure of showing you is one of

RANULA.

By ranula we mean a tumor in the floor of the mouth in front of and under the tongue, with thin walls covered with mucous membrane and filled with fluid contents of a syrupy consistency. Its origin is supposed to be in a dilatation of the submaxillary or sublingual duct. This unquestionably constitutes one variety of ranula, known as acute ranula. Recent investigations have, however, shown that in the majority of cases the tumor is really a retention cyst of one of the mucous follicles in the floor of the mouth. The affection occurs both in adults and in children, but is more common in the latter. The floor of the mouth is often much raised by the tumor, and even the tongue may be lifted up. When large, it may cause a depression of the submental tissues, and the floor of the mouth may be raised to a level with the lower incisors. The affection is not dangerous, except where there is marked dilatation of the ducts and the tumor increases so much in size that it pushes the tongue upward and backward, interfering with the entrance of air into the lungs.

The treatment may be conducted in several ways. Simple puncture of the cyst does not usually result in a radical cure. Another method of treatment is by the introduction of a seton into the sack of the ranula. The fluid escapes and the seton sets up inflammatory action, and the ranula may be cured in this way; but the time required is longer than by the method that I shall speak of, and which I consider the best; that is, excision of a portion of the wall of the ranula. This is done by seizing the mucous membrane with forceps and cutting out a portion of the wall with scissors. The amount removed should be considerable, and if the ranula extend to the opposite side of the mouth, it is well to take a section out on the other side. The fluid contents are then squeezed out, and you may touch the inner surface of the sac with a solution of nitrate of silver or tincture of iodine, or a piece of the solid stick of nitrate of silver may be passed into the cavity and the walls lightly cauterized. Cure of the condition generally follows this operation. The patient suffers little pain, and the only after-treatment necessary is to keep the mouth perfectly clean. This may be done by a mouth-wash containing chlorate of potassium, glycerin and myrrh, or one of boric acid, carbolic acid, glycerin, and water. We cannot use the ordinary antiseptic solutions, such as carbolic acid and bichloride of mercury solutions, when operating on the mouth. We wash the parts with pure water, and depend upon that. It is impossible to keep the mouth aseptic after operation. In operating on these cases it is more satisfactory to use the mouth-gag, so that the jaws are held apart and sufficient room is obtained. There will probably be considerable swelling for a few days, but this will diminish as the parts heal.

SUBCUTANEOUS SECTION OF THE FEMUR FOR THE CORRECTION OF DEFORMITY FOLLOWING COXALGIA.

The next case is one of hip disease of some standing. The child is six or seven years of age, and has suffered for several years from coxalgia. The disease ran a rather quiet course. The case was probably not treated for some time, but an accidental complication arising, the boy was brought to us, and treated in the ordinary way. The limb was extended by a weight, and lateral support by means of sand-bags was employed. The child has developed no inflammatory complication, and the reason I bring him before you is to do an operation to remedy the deformity which results from the cure of the disease. A great many of these cases of hip-joint disease, in which recovery takes place, are left with the limb slightly flexed on the pelvis and with a slight amount of abduction. This is the characteristic deformity following cured hip-joint disease, even where special apparatus is employed to prevent it. The deformity causes a certain amount of shortening of the limb, and interferes, to a certain extent, with progression. There is, in this case, limited motion at the hip joint.

To remedy this deformity, we have two operations. One is excision of the head and neck of the femur; the other, subcutaneous osteotomy of the neck of the femur, or of the shaft of the bone just below the lesser trochanter. The latter operation is the one which I consider the better in these cases. It is attended with little risk, and results in a satisfactory cure of the deformity. The operation was devised by Mr. Adams, of London. It consists in making a section of the femur with a small saw passed through a wound on the outer side of the thigh. The operation suggested by Adams was section of the neck of the thigh-bone. This is a good operation in certain cases of deformity, and especially in those cases which seem to be of rheumatic origin, where there is little change in the shape of the head and neck of the bone; but in coxalgia, where the disease has destroyed

the head of the bone and involves the acetabulum, the operation is not so good as the modification devised by Gant, which consists in a subcutaneous section of the femur below the lesser trochanter. As I have said, the operation is attended with little risk. I know of only one case in this city which did badly after this operation; but that one eventually recovered with a cure of the deformity. This was early in the history of the operation, before it was properly understood. A small puncture is made with a strong tenotomy knife on the outer side of the thigh. Then the tissues are divided with a blunt-pointed knife around the bone and this is followed by the introduction of a special saw, known as Adams's saw, and the bone is divided. The small wound is closed with a compress, and generally heals without trouble.

The deformity in these cases is due, in a measure, to the action of the psoas and iliacus muscles, which are inserted into the lesser trochanter. When the bone is divided below the trochanter, the limb can be brought into its normal position, thus leaving a wedge-shaped gap, which becomes filled with new bone in a short time. If, however, the neck of the bone is divided, while you may correct the deformity, the action of the muscles will tend to reproduce it. That is the objection to Adams's operation in this variety of case. In some cases there is a slight amount of hip-joint motion; in others, there is complete ankylosis. In either event, the operation is a proper one.

The first thing to do is to locate the position of the greater trochanter. There is sometimes a little difficulty in doing this, for its position is, of course, changed by disease of the head of the bone. Having located the trochanter, I make a section of the soft tissues a little below it. The knife is passed down to the bone and the saw introduced by its side. The saw is then passed over the upper portion of the bone and brought to a right angle with it. The section of the bone is then made with short cuts of the saw. Having divided the bone I bring the limb into its proper position. I have really produced a compound fracture of the femur, which, before the days of antiseptic surgery, would have been an unjustifiable procedure simply for the relief of this deformity. Over the opening made I apply a compress of bichloride gauze dusted with iodoform, and held in position by a few adhesive straps. The treatment now will be that of fracture of the femur, the patient being kept in bed, and extension by a weight, with lateral support by sand-bags, employed to keep the limb in position. The child will be kept absolutely flat on his back for four or five weeks. By that time union is generally quite firm, and the small wound, through which the section was made, has generally satisfactorily healed long before. There will probably be some shortening of the limb, which can be overcome by the use of a high shoe. In some of these cases, there is a tendency for the lower fragment to ride up. In such cases we apply a sand-bag over the anterior surface of the femur for a few days after the section.

EXCISION OF RIBS FOR EMPYEMA.

The next case is one of empyema of some duration. I first saw the patient last summer, and made openings between the ribs, introducing large drainage-tubes. The result was satisfactory for some time. The general condition improved, and he was sent to the convalescent branch of the hospital in the country, and in the fall the discharge from the tube had almost ceased, and his general condition had much improved. The drainage-tubes were gradually shortened and withdrawn. There was left only a small sinus, which I thought might be connected with a localized caries of the ribs. The boy then left the hospital, and, some weeks afterward, in playing, received an injury over the seat of the original trouble. This was followed by fever and return of the symptoms connected with the chest, and the patient was again brought to the hospital. We dilated the drainage wound, introduced a tube and found a large collection of purulent matter. The patient was then kept under observation, and the chest drained and washed out, every second or third day, with antiseptic solutions. We also washed out the cavity with a solution of peroxide of hydrogen. The case has now come to a point where some decided operative interference seems advisable. I propose to-day to explore the wounds, expose the cavity, and if I find any considerable space between the costal and pulmonary pleura I will excise a portion of one, two, or three ribs, as may be deemed necessary. This case was also complicated by an attack of scarlet fever a few months ago. It is unusual in children that excision of the ribs is necessary for the cure of a cavity resulting from empyema. I have generally found that in children free drainage with large drainage-tubes, with thorough washing out, will bring about a satisfactory result. The elasticity of the chest-walls will generally allow the parts to sink in, and bring the two surfaces in contact, so that healing will take place if drainage is maintained. It is only after a faithful trial of less heroic measures that I have deemed it advisable to excise a portion of the ribs.

In excising the ribs, we first turn up a flap of the chest-wall, including the skin, superficial fascia, and muscular tissue, exposing the ribs. Then we explore the cavity and see in which direction it extends, and then remove a portion of one rib, or of several ribs, as the case may be. We can divide the rib with the Hey's saw or with forceps. I prefer to weaken it with the saw and then complete the section with bone-forceps. The only hæmorrhage that is to be looked for is from the intercostal arteries. This we may have to control with the cautery. I removed about an inch and a half of the rib without injuring the costal pleura. I find that the cavity extends upward over the diaphragm, and I shall also take out a like amount of the rib above. Hæmorrhage is then controlled by the application of ligatures, and the cavity thoroughly washed out with a solution of bichloride of mercury, 1 to 4000. A large drainage-tube is next inserted, and an antiseptic dressing applied. The tube will be allowed to remain three or four days, and then the cavity will be again washed out. The dressing consists first of protective, over which a wet bichloride-gauze dressing is applied; over this is dry gauze dressing covered with bichloride cotton, and a bandage is applied to secure the dressings, but not so tightly as to interfere with the respiratory movements.

NECROSIS OF THE HUMERUS.

The next case is a boy, six or seven years old, who presents, at the upper part of the left arm, an opening

through which protrudes a portion of necrosed bone. The history of the case is that four or five years ago there was an inflammatory affection of the bone, which terminated in the formation of an abscess, and since that time there has been a constant discharge from the opening. Recently there has appeared in the sinus a mass of dead bone. This is often the history of these cases of inflammatory affections of the bone which are not subjected to prompt surgical treatment. The disease originally starts as an inflammatory affection of the periosteum or of the bone; abscess is apt to follow, and then exfoliation of the bone takes place gradually. In long-standing cases there is generally a firm, well-developed involucrum surrounding the dead bone, which has its origin in the periosteum. The whole shaft of the bone may be dead and surrounded by this involucrum. The more chronic the case the more extensive and hard is this bone-sheath. These long-standing cases, in which the dead is separated from the living bone, are favorable cases for operation. The necrotic process in the bone is limited, and the dead bone is ready to be thrown off, and in many cases the only thing that prevents spontaneous extrusion is the large size of the sequestrum, and the fact that the sheath of new bone surrounds it.

I shall first apply Esmarch's bandage, which renders the operation bloodless. The dead bone is then exposed and the involucrum chiselled away, leaving a cavity with sloping edges, which can be filled with granulations. The cavity should be kept packed, so that it will heal by granulation from the bottom. When the wound is thoroughly healed a depressed cicatrix is left. This is an evidence that the necrotic process is arrested, and that the wound has healed in a satisfactory manner. I have not had an opportunity to examine this case before, and it may be that the cavity is very small, and all that will be necessary will be to remove the sequestrum and pack with bichloride or carbolated gauze. In these operations on the arm, care must be taken to avoid injuring the musculo-spiral nerve, which crosses the arm about its middle. In a recent case, where I removed the whole shaft of the bone from the upper to the lower epiphysis, I avoided all risk of injury to this nerve by dividing the tissues above and below the region of the nerve, and then raising the tissues under the nerve so as to cut away the bone and make the cavity continuous, allowed the soft parts containing the muscle sheath to form a bridge over the true cavity. Having applied the Esmarch's bandage, I cut down on the sequestrum and separate the periosteum from the bone. Then with a chisel I enlarge the opening in the new bone and remove the sequestrum. The cavity extends downward some distance, and I enlarge the opening so as to have a cavity with sloping edges, which can be readily packed. All overhanging portions of bone are removed, and the cavity scraped with the osteotrite. The wound is then washed and packed with bichloride gauze. A piece of protective is first put in the wound. This prevents adhesion of the packing to the surface of the bone, and facilitates the redressing. The dressing is completed before removing the Esmarch's bandage. This dressing will be allowed to remain undisturbed for a week, and the case will then be redressed in the same manner, and we will expect to find the wound at that time covered with healthy granulations.

EXCISION OF THE KNEE.

I now bring before you a girl, four or five years of age, who is suffering with a chronic inflammatory affection of the knee-joint. The appearance presented is that of ordinary gelatinous or tubercular arthritis of the knee. The disease has existed for some time. The parts are much swollen, but as yet there are no discharging sinuses. The limb is useless, as far as its functions are concerned, and the time has arrived when some operative treatment should be instituted. In these cases of arthritis of the knee-joint, we do not recommend operation in the early stages. We are generally satisfied to employ some form of dressing or splint which will produce fixation, and treat the case locally by the use of resolvent applications and, at the same time, direct treatment to the constitutional condition of the patient. Many cases recover with considerable impairment of joint motion, and yet with useful limbs as regards locomotion. When the disease advances and there are marked degenerative changes, when the ligaments are involved and displacement of the articular surfaces occurs, with erosion and destruction of the cartilages or of the articular surfaces of the bone, then the case is one in which operative treatment is indicated. In these cases we have two operations. One, which has been recently adopted, is that of arthrectomy, which consists in exposing the joint, trimming out the diseased tissue, closing the wound, and suturing the lateral ligaments and the divided ligament of the patella. The limb is then placed on a fixation splint and an endeavor made to get union with a certain amount of motion. In some cases I have seen excellent results from this operation. In cases, however, where there is extensive destruction of the joint with probable necrosis of the articular surfaces, this operation is not apt to give good results. It is better adapted to cases before the bone is extensively involved. In instances like the present, I think that excision of the knee-joint is safer and a more satisfactory procedure as regards permanent cure. In this operation a transverse incision is made across the knee-joint, the ligamentum patellæ divided, and the joint opened. The condition of the bony surface is then examined, and as much bone removed as will take away the diseased tissue, and place the limb in its proper position. In this operation we do not aim to get a movable joint; we hope to get firm bony, or fibrous, union. The limb is more useful with bony union, as there is less tendency to subsequent deformity. After the operation the limb is kept on a bracketed wire splint, which permits removal of the dressing and redressing without disturbance of the limb. The incision which I prefer is a transverse incision passing below the patella; it starts at the inner condyle of the femur and extends over almost to the external condyle. The incision is carried down to the deep fascia, and then the flap dissected up until we have exposed the whole of the patella. We then divide the lateral ligaments and expose the articular surfaces of the tibia and femur thoroughly. Any hæmorrhage that occurs will be arrested by hæmostats temporarily, and the vessels will be tied after section of the bone is completed. As I open the joint, pus escapes in large quantities. The inflammation has also extended into the bursa above the knee-joint. The articular surface of the femur

is carious, but the tibia does not seem to be diseased to any marked extent. I remove a section of bone from the femur and also from the tibia, taking care that the sections are made so that when the bones come together, the limb will be in its proper position. I do not use the Esmarch bandage in this operation, because the amount of blood lost is not great, and where this bandage is employed in excisions the consecutive hæmorrhage may be quite troublesome. Having placed the bones in proper position, I curette the bursa above the knee-joint thoroughly, and drain it with a large tube. In some cases we may suture the bone, in other cases use ivory pegs or steel nails to fasten the bone together. In the majority of cases the splint affords all the fixation necessary. I also trim away the degenerated tissue around the knee-joint. The wound is thoroughly irrigated with the bichloride solution, a drainage-tube passed into the bursa and one across the front of the knee, and the edges of the wound brought together with sutures of silkworm-gut. The usual antiseptic dressing is then applied, and the limb secured to the bracketed wire-splint. [This case was dressed for the first time upon the tenth day after the operation, at which time the temperature was normal; the wound was solidly healed except at the points where the drainage-tubes protruded; these were removed with the exception of the one extending into the bursa above the patella, which was allowed to remain, and the case was redressed in the same manner as at the primary dressing.]

EXTROVERSION OF THE BLADDER—SYPHILITIC ORCHITIS—SYPHILITIC PERIOSTITIS.

A Clinical Lecture,
delivered at the New York Post-Graduate Medical School and Hospital.

BY HENRY DWIGHT CHAPIN, M.D.,
PROFESSOR OF DISEASES OF CHILDREN.

GENTLEMEN: The infant I present to you is one year old; it is fairly nourished, although showing slight evidences of rickets. At the lower part of the abdomen, just above the pubes, you notice a reddened mass, just below which is seen the penis, which is in a condition of complete epispadias. An examination of this case shows it to be one of those comparatively rare instances of extrophy or extroversion of the bladder. The reddened fungous mass consists of the posterior wall of the bladder, which is prolapsed through an opening in the abdominal wall. There is an entire absence of the anterior wall of the bladder. On either side, and at the lower part of this mass, careful inspection will show the orifices of the ureters. Passing a probe in, as I do now, we can follow these canals for quite a distance on either side. These cases are often accompanied by inguinal hernia, and this child has a double hernia of that description. The testicle is absent on one side; in not a few instances we have a non-descent of both testicles. In some of these cases, the deficiency in the abdominal wall may be several inches in extent, although usually not so extensive. There is invariably a condition of inflammation of the mucous membrane of the protruding bladder on account of friction from the clothing and from decomposition of the urine. There is also to be noted a distinct umbilical hernia. In some of these cases, non-union of the pubic bone may likewise be noted.

Examination of the urine shows the kidneys to be healthy. The urine dribbles away constantly, and when the bladder is pressed upon, a few drops nearly always escape. If these cases are not kept extremely clean, the skin will be excoriated from the constant dripping and decomposition of the urine.

This unfortunate deformity is usually met with in the male, but it may be occasionally seen in the female, when the nature of the deformity is of the same kind. The measures taken to relieve these cases are not accompanied by much success. The prognosis is not very hopeful, as a complete cure is out of the question. Every means must be taken to lessen the irritation to which the exposed parts are subjected. A pad of antiseptic cotton or gauze can be placed over the bladder, and gentle pressure employed. The surrounding parts can be dusted with bismuth, oxide of zinc, or lycopodium. If the children live long enough to walk about, a rubber urinal, having a cup fitting over the opening in the abdominal wall, can be employed, and the urine collected in a receptacle attached to this cup.

Two varieties of operation have been proposed and employed in these cases. The first consists in making the rectum serve as a receptacle for the urine. To accomplish this, the ureters are brought into connection with the rectum by threads. The results, however, of this procedure have not been good, as kidney disease is very apt to ensue, and the urine produces considerable disturbance in the rectum. A more radical operation consists in closure of the abdominal opening by means of a plastic operation, allowing the urine to pass through a small opening. Where the abdominal opening is small, the edges of the skin may be freshened and covered with flaps which are derived from the adjoining tissues. Various surgeons have devised different plastic proceedings; Pancoast derived his flaps from the inguinal region, and united them in the median line with their epithelial faces inward. Other surgeons have worked with flaps of integument derived from the scrotum, perineum, and groin. The operation itself is not unattended with danger, as it has been estimated that about 20 per cent. of the cases have died from peritonitis, sepsis, or exhaustion from loss of blood. As in this case the extroversion is very extensive, and the general condition of the child not very good, I think it best to defer operative measures, particularly as the function of urination is well performed, and the child is fairly comfortable. If these cases live to adult life the condition is a pitiable one; they constantly carry about with them the offensive smell derived from decomposing urine, which is dribbling continuously from the ureters. It is likewise impossible for them to perform the sexual act, although the desire is present.

The next case is an infant of two years. His mother has brought him for "a hard lump" in the scrotum. There are several conditions to be noted in connection with swellings of the lower groin and scrotum at this age. We may have hydrocele of the tunica vaginalis, hydrocele of the cord, an undescended testicle, or an inguinal hernia. An examination of this case shows that we can easily eliminate most of these conditions, as it resolves itself into some change that has taken place

in the testicle. It is an extremely hard, somewhat diffused mass that evidently involves the whole testicle. It may be either tubercular, syphilitic, or sarcomatous. The mother gives a history of having had two miscarriages just previous to the birth of this infant. There is present in one of the eyes a plain case of interstitial keratitis. Besides this the mother gives no history of previous syphilitic manifestations in this infant. Syphilitic infiltration of the testicle is of slow growth. The mother has noticed that this condition has been present for several months, and thinks it is gradually increasing in size. In cases of tubercular disease of the testicle, hard, irregular nodules may generally be felt, which may simply undergo a slow, caseous degeneration, or finally suppurate. There is apt to be pain in the testicle. The abscesses, which are commonly formed by suppuration in the nodules, may be multiple, originating from several foci. Handling the testicle in the case before us produces absolutely no pain. Sarcomata may be occasionally seen during infancy, both of the simple and multiple variety. The tumor may reach a large size, and at the beginning be accompanied by great pain. We shall put this case at once upon the iodide of potassium, and can give a very good prognosis.

The boy I now present to you is ten years of age. The mother has had eleven children: the first six were born at term and have been healthy. Then she had two miscarriages, the first at six and a half months, and the second at seven and a half months. The next infant was born healthy and remained so, and the patient before us was the next child. He has always been delicate, and during infancy was said to have suffered from marasmus. He grew stronger when about three years old, and has been thoroughly well since with the exception of colds. Three weeks ago the mother noticed a swelling over both tibiæ. The skin over these bones was slightly reddened, and somewhat painful upon deep pressure. He did not complain particularly of the pain, but limped about, attending to his ordinary duties. The condition has been growing steadily worse until last week, when he was first brought to the clinic. Since then a decided improvement has been noted, for during this time I have been employing fairly large doses of iodide of potash. This may be considered one of the late manifestations of hereditary syphilis. An ordinary idopathic periostitis would have been accompanied by much more active and urgent symptoms. There would have been rigors, followed by vomiting, headache, and possibly delirium, with a high temperature. Such a periostitis is apt to be accompanied by an osteo-myelitis, and the prognosis is always serious. The treatment is principally surgical, as free antiseptic incisions must be early made in order to relieve the pressure and prevent sepsis. Syphilitic periostitis is controlled, on the contrary, by simple medical treatment, the iodide of potash usually relieving it in several weeks. It involves particularly the tibia and humerus. The specific periostitis is likewise usually multiple and very apt to be symmetrical. If one tibia is attacked, the corresponding bone on the other side will probably also be involved, and the same is true of the ulna and radius. There may be a deposit, accompanying the periostitis, which will change considerably the shape of the diseased bone. Hereditary syphilis is often accompanied by proliferation of new bone, which is, however, of inferior quality. The pain accompanying inflammatory changes is worse at night, this phenomenon being the same in hereditary as in acquired syphilis. In some cases of hereditary syphilis, a low caseous inflammation takes place at the junction of the epiphysis with the diaphysis. This may even go on to suppuration, and is known as osteo-chondritis. Among the rarer forms of bony change may be mentioned dactylitis, which may involve the bones of either hands or feet. This, however, is usually seen in very young children. It begins generally in the periosteum or in the fibrous tissue about the joint. Resolution nearly always takes place.

MEDICAL PROGRESS.

Treatment of Simple Chancre.—In the *Revue Générale de Clinique et de Thérapeutique*, CASTEL, after pointing out that the danger of this lesion resides in great part in its virulence and in the facility with which re-inoculation is possible, proceeds to consider the best applications for its relief. After reminding us of the fact that Ricord habitually employed the charcoal and sulphuric acid treatment for this purpose, and obtained from its use very extraordinary results, he draws attention to the more recent methods of treating the disease, also calling attention to the use of Canquoin's paste. Diday and Fournier recommend the employment of a solution of nitrate of silver, and the latter has found that the application of a 3 per cent. solution produces very excellent results. The lesions should be dressed with a tampon of absorbent cotton dipped in this solution and renewed three times a day. With this treatment simple chancre should be cured in from three to six weeks, and it may be advisable to apply not only antiseptic washes, but oxygen water and solutions of chloral or Labarraque's solution. According to Rollet and Mauriac the following applications are also very useful:

℞.—Water	6	drachms.
Lemon-juice	1½	"
Laudanum	45	minims.
Goulard's extract	1	drachm.

Or,

℞.—Water	1	ounce.
Citric acid	45	grains.
Hydrochloric acid	45	"
Perchloride of iron	45	"

Treatment of Paralysis of the Bladder.—HOCHE divides the treatment of paralysis of the bladder into that which is palliative, and consists in the regular evacuation of this viscus by means of a catheter employed with every antiseptic precaution, and also the curative. The bladder should never be allowed to become distended. For the curative treatment, he uses injections of strychnia and subcutaneous injections of ergot, with cold douches and compresses to be applied to the perineum. Finally, electricity may be resorted to, and under these circumstances the application of the current should not last over ten minutes. The positive pole should be placed over the vertebral column, and the negative pole over the hypogastrium. If the positive pole is introduced into the bladder the negative pole should be put over

the pubes, and the current should not be applied over three or four minutes.—*L'Union Médicale.*

The Dose of the Bromides.—SIMON recommends that for infants under the age of one year the appropriate maximum and daily dose of each of the bromides should be three grains, which should be given in two doses and should be well diluted. Larger amounts may, of course, be given in the event of severe convulsions. For a child of two years the daily dose may be six grains, divided into two doses and given in a vehicle which will be pleasant to the taste, and which should be present in large quantity to prevent irritation of the stomach. The dose should also be given immediately after a meal. For a child of three years, fifteen to thirty grains may be given, divided into three or four doses, during the day. The drug should be stopped every other week. After the age of three years Simon thinks that large doses may be employed and believes that from this age on great tolerance is reached, and that gastro-intestinal troubles are diminished.—*Revue Générale de Clinique et de Thérapeutique.*

The Treatment of Purulent Ophthalmia.—The *Revue Générale de Clinique et de Thérapeutique* gives the following treatment for this troublesome condition: During the initial stage, when the secretion is transparent, antiseptic irrigations of phosphoric acid or the application of compresses soaked in a very cold solution of corrosive sublimate are of value. When the disease is well developed the treatment is both cauterant and antiseptic. The cauterizations are to be made, if possible, twice a day by dropping into the eye a solution of nitrate of silver in the proportion of 1 : 25, or better still, by the direct application of the nitrate of silver stick. After this the eye should be immediately washed out with a solution of common salt to prevent an excessive action of the nitrate of silver.

As an antiseptic irrigation phosphoric acid, naphthol, and corrosive sublimate may be employed, and in the cavities it may be well to employ compresses soaked with solutions of these drugs. For the relief of chemosis scarifications may be employed, and for corneal ulcers cauterizations with nitrate of silver followed by the use of iodoform ointment are valuable. During the period of decline in the disease it is well to continue the applications of the solution of nitrate of silver in the strength of one per cent., as well as the irrigations and antiseptic compresses. If the suppuration continues and there is much pain, relief may be obtained by the application of the following prescription:

℞.—Extract of opium . . . 1½ grains.
Boiling water . . . . 1 pint.

Sometimes the following collyrium is useful:

℞.—Nitrate of silver . . . . 1 grain.
Deodorized laudanum . . . 10 drops.
Distilled water . . . . 3 drachms.

Treatment of Anasarca.—According to *L'Union Médicale*, PECHOLEIN recommends the following application for the treatment of anasarca:

℞.—Veratrine . . . . . 15 grains.
Iodide of potassium . . 30 "
Lard . . . . . 1 ounce.

This is to be made into an ointment and applied with friction.

Liniment for Gout.—The *Lyon Médical* states that the following liniment is useful in the treatment of gout:

℞.—Collodion, Sulphuric acid, Salicylic acid } of each . 1 drachm.
Hydrochlorate of morphine . 15 grains.

This is to be painted over the part affected every few hours.

Application of Ichthyol.—According to the *Revue Générale de Clinique et de Thérapeutique*, UNNA employs the following preparation of ichthyol in the treatment of diseases of the skin:

℞.—Ichthyol . . . . 25 parts.
Starch . . . . . 50 "
Carbolic acid . . . 2½ "
Water . . . . . 22 "

The ichthyol and carbolic acid are dissolved in the water while hot, and the starch added.

Solution for the Removal of Freckles.—

℞.—Chloride of ammonium . 1 drachm.
Hydrochloric acid . . 1 "
Glycerin . . . . 1 ounce.
Fresh milk . . . . 2 ounces.

Dissolve, and apply night and morning to the part of the skin which is affected.

Treatment of Fissured Tongue.—

℞.—Carbolic acid . . . 37½ grains.
Tincture of iodine, Glycerin } of each . 3 drachms.—M.

Paint the affected parts.—*Journal des Malad. Cutan. et Syph.*

Treatment of Erysipelas.—This is the treatment TALAMON also employs in cases of pustular variola. It consists in spraying with Richardson's apparatus for a minute the outer ring, both within and without the erysipelatous swelling, with the following solution:

℞.—Corrosive sublimate, Tartaric or citric acid } of each 15 grains.
Alcohol (90 per cent.) . . 1½ drachms.
Sulphuric ether enough to make . . . 3 ounces 1 drachm.—M.

This solution being caustic should not be thrown into the eyes nor in proximity to the nostrils. Spraying should be repeated two or three times a day.

Cayet considers this as the best remedy employed against erysipelas. If it is used in the beginning, the inflammation will yield during the first day, and the disease will be terminated by the fourth day.—*Revue Général de Therapeutique et de Clinique.*

Statistics of Chloroform Administration.—GURLT, in *Le Mercredi Médical*, reports the statistics of 60 observers from July 1st until December 31, 1890. Of these 60

observers, 3 were Austrians, 3 Russians, 2 Swedes, 1 a Hollander, 1 a Belgian, and the rest Englishmen. The report embraces 24,265 cases of narcosis by chloroform. Bardeleben, who had already reported the statistics of 12,000 narcotizations at the Charity Hospital from 1878 to 1890, found 7 cases of death. These 24,265 narcotizings resolve themselves as follows: Of the total number, there were 22,656 narcoses by chloroform, with 71 cases of asphyxia and 6 deaths; 470 by ether, with no asphyxiations or deaths; 1055 by a mixture of ether and chloroform, with 5 asphyxiations and no deaths; by ether and alcohol, 417 cases, with 4 asphyxiations and no deaths; by bromide of ethyl, 27 cases, with no asphyxia and no deaths.

This statement shows 1 death in every 3776 administrations of chloroform alone, 1 asphyxiation in every 319 administrations of chloroform, 1 in every 211 administrations of ether and chloroform, and 1 in every 104 administrations of ether and alcohol. In the majority of cases chloral was given first, and the chloroform and inhaler of Esmarch were used. In 2732 narcotisms the duration averaged one hour; in 278 cases it was much longer, and in 3 cases it was 150, 155, and 180 minutes. At the Charity one cubic centimetre of chloroform was used for each minute of narcotism. According to Morian, the quantity of chloroform employed with Kappeler's apparatus is only one-sixth of the amount used with the ordinary apparatus. In his private clinic he uses 25 grammes of chloroform for each narcotization. The largest doses have been 150 to 180 cubic centimetres. The mixture was composed of 100 parts of chloroform, 30 parts each of alcohol and ether. He has used concurrently with the chloroform injections of morphine.

Bruns thinks the technique of narcotism susceptible of improvement. New experiments on etherization are necessary. Ether excites the heart's action, while chloroform lowers it. Moreover, ether protects against death from cardiac syncope.

Actinomycosis.—DOYEN reports, in *Le Mercredi Médical*, that he has observed two cases of actinomycosis in men. In the first a tumor was present, adherent to the periosteum at the angle of the jaw, and fluctuating, which, upon section, permitted a ropy liquid with but little color to escape, holding in suspension half a hundred actinomyces. In the second a large abscess had become chronic, having disintegrated the muscles of the tongue and caused symptoms of dangerous dyspnœa. These two patients—one treated by extirpation of the tumor and the other by curetting and packing—both recovered.

Chloride of Ethyl as a Local Anæsthetic.—As a substitute for ether spray as a local anæsthetic, M. Monnet has introduced a method of freezing by means of chloride of ethyl, which is highly spoken of by Dr. C. Rédard, clinical professor at the Geneva School of Dentistry. Chloride of ethyl is a colorless liquid possessing an ethereal odor, with a boiling-point of 50° F. It is hermetically sealed in glass tubes containing ten grammes, one end being drawn out into a fine point. When required for use the point is broken off with a pair of forceps, or by hand, at the narrowest part, which is marked by a file-scratch on the glass, and the warmth of the operator's hand is sufficient to cause a very fine jet of the chloride to be projected on the part to be anæsthetized. One great advantage claimed for this method is that no apparatus is required, and its use is advocated in such cases as tooth-extraction, neuralgia, etc.—*The Lancet*, April 11, 1891.

Chronic Rheumatism and the Nervous System.—A novel and suggestive, if somewhat revolutionary, theory in reference to the dependence of chronic rheumatic joint-changes on a morbid condition of the central nervous system is advocated in a work by Dr. Wichmann, of which an abstract is furnished in a recent number of the *Centralblatt für klinische Medicin*. The author began his work six years ago, with a view of explaining the nervous symptoms associated with rheumatic joint affection, and the dependence of these upon a central cause was first suggested by the occurrence of symmetrical phenomena, such as patches of erythema, subcutaneous nodules, etc. Charcot has explained the occurrence of contractures in rheumatism by supposing that there is an inflammation of the articular nerves, the influence of which is transmitted to the centres in the cord, there giving rise to irritation of the motor roots; and the fact that the contracture is usually in the flexed position is explained by the greater power of flexors as contrasted with extensors. But it is pointed out that this would not explain the occasional occurrence of extensor contracture, and that, moreover, in other conditions giving rise to joint affection, such contractures do not take place. As further supporting the theory of a central lesion for those conditions, attention is directed to the occurrence of arthropathies in tabes and other spinal conditions, and it is contended that a feasible explanation of the vasomotor and trophic disturbances—such as "glossy skin"—as well as of the disturbance of sensibility, is offered by such a hypothesis.—*The Lancet*, April 11, 1891.

Application for Diphtheria.—According to *L'Union Médicale*, SIMON recommends the following application in cases of diphtheria:

℞.—Salicylic acid . . . 7 to 14 grains.
Alcohol, a sufficient quantity to dissolve acid.
Glycerin . . . 1½ ounces.
Infusion of eucalyptus . 2 "

A small piece of absorbent cotton is to be wet with this mixture and applied to the throat and false membranes. The application may be made every three to eight hours during the day, and one or twice during the night. If the false membranes are very adherent they may be touched up two to four times a day by a solution composed of perchloride of iron and glycerin, of each three drachms. It may also be advisable to irrigate the nostrils and throat with boric acid solution in the strength of four per cent. Internally, he advises the administration of tincture of chloride of iron, in the dose of ten to twenty drops every twenty-four hours, according to the age of the patient. One drop may be given each hour in a little wine or broth.

CURRENT LITERATURE.

SATURDAY, MAY 2, 1891.

THERAPEUTICS OF DIPHTHERIA.

THE remedies recommended for the treatment of diphtheria are legion; most physicians come to have the greatest confidence in some one. There comes a time, however, when the favorite remedy fails, and then search is made for a better. Professor F. Löffler refers to these well-known facts, and declares the reason to be that hitherto we have not had accurate knowledge of the cause of diphtheria. Statistics to show the value of a remedy are untrustworthy, because many call a simple inflammation of the throat, with slight exudation upon the tonsils, diphtheria.

Löffler asserts, without qualification, that the bacillus described by him is the cause of the disease. Upon these bacilli the effect of different remedies should be studied. This has been done in different ways, which Löffler briefly mentions, by D'Espine and De Marignac, Babès, and by Boer and Behring.

To combat the diphtheria bacilli two things are required: First, to prevent the bacilli from settling upon the intact mucous membrane of the healthy, and upon the parts of the mucous membrane as yet unattacked in those having diphtheria. This can be done by bringing the healthy parts of the mucous membrane in contact with agents which either prevent the development of the bacilli, or, still better, in a very short time kill whatever bacilli are found upon the parts. It goes without saying that the remedies employed must not injure the mucous membrane, nor, by frequent local applications, occasion any injurious action upon the body in general. Second, the bacilli developed in thick heaps in the superficial layers of the mucous membrane must be destroyed, in order to prevent an extension of the process to unaffected parts, and also to prevent the transmission of the disease to others by the throwing off of bacilli capable of infecting them.

The bacilli grow best at a temperature of 99.3° Fahr., upon a blood-serum mixture, composed of four parts ox-blood serum, and one part accurately neutralized bouillon, to which is added one per cent. each of peptone and cane-sugar, and five-tenths per cent. of salt. Experiments to test the efficacy of remedies should be carried out upon bacilli grown under these conditions. Löffler takes ten cubic centimetres of the blood-serum mixture, places this in a test-tube held in an oblique position, so that the surface of the serum reaches to about the upper third of the glass. A platinum wire is then dipped in a pure culture of diphtheria bacilli and drawn across the surface of the serum in a number of places. In from twenty to twenty-four hours the whole surface of the serum becomes covered with a moderately thick coating of bacilli. In the tube, so prepared, a short time after it has been inoculated with bacilli, the fluid to be tested is poured so that it reaches to the upper border of the serum. The quantity is ten or fifteen cubic centimetres. The duration of the contact of the fluid to be tested with the bacilli was made to correspond with the usual duration of the act of gargling. The fluid was poured off immediately after being poured in, or was allowed to remain in contact with the bacilli for ten seconds. After this submission to the action of the agent, the test-tube was placed in an incubator, and examined in several (usually eight) days. The checking of the growth of the bacilli, if any, indicates the degree of efficiency of the agent. The bacilli was not washed out by the mere pouring in and out of fluid; this was proved by trial with distilled water. The conditions present in this case, it will be observed, represent those present when bacilli have just been deposited on a healthy mucous membrane.

If the bacilli are allowed to grow in the serum for several days they form a coating frequently half a millimetre thick. This corresponds with the coating produced by the growth of the bacilli in the most superficial layers of membranes. The duration of the action of agents upon such cultures was limited to twenty or thirty seconds. After the fluid was poured off, a culture was attempted from the depths of the thickest part of the layer.

The scope of Löffler's researches may be judged from the fact that he experimented with corrosive sublimate, cyanide of mercury, metallic mercury, nitrate of silver, chloride of silver dissolved in subsulphate of sodium, potassium permanganate, potassium chlorate, saturated lime-water, aqueous solutions of chlorine, bromine, and iodine, iodine trichloride, chloride of lime solution, iodine-iodide of potash solution, alcohol, allylalcohol, benzylalcohol, ether, chloroform, carbolic acid, salicylic acid, resorcin, pyrocatechin, hydrochinon, tropeolin, benzol, xylol, toluol, anisol, phenetol, pseudocumol, cumol, oil of turpentine, anilin, thymol, creosol, sulphate of creosol, and thirty-eight ethereal oils. The results of the action of these agents are given in some detail. Some of them were effective when the bacilli were upon the surface, in freshly-prepared tubes; but they were ineffective after the bacilli had formed a membrane.

Löffler's general results may be inferred from his recommendations. As a prophylactic at times of threatening danger, healthy persons should, he says, gargle, for five or ten seconds, every three or four hours, with a 1 to 10,000 or 1 to 15,000 solution of corrosive sublimate, or, perhaps better, because the taste is less disagreeably metallic, with a 1 to 8000 or 1 to 10,000 solution of cyanide of mercury. Chloroform water (1 part chlorine in 1100 parts water) and thymol (1 part dissolved in 500 parts of 20 per cent. alcohol) may also be used. Mosler's method of gargling, accurately described in the *Deutsche med. Wochenschrift*, 1881, No. 1, gives the best results. In the form of vapor, such remedies as oil of citron and oil of eucalyptus are especially active.

When a person is affected with the disease, in addition to gargling with the weaker solutions as mentioned, he should gargle, every three or four hours, with agents capable of destroying the cul-

tures. The most appropriate of the latter class, according to Löffler, are solutions of corrosive sublimate, 1 to 1000; 3 per cent. carbolic acid, dissolved in 30 per cent. alcohol; and alcohol and oil of turpentine, each with 2 per cent. carbolic acid. The throat may also be painted thoroughly and repeatedly with 5 per cent. carbolic acid, 2 per cent. bromine, or 1 per cent. chlorine solutions. Concentrated aqueous solutions of creosol, especially *o*- and *p*-creosol, also deserve mention.—*Deutsche med. Wochenschrift*, March 5, 1891.

NEPHRITIS IN PHTHISICAL PATIENTS.

Dr. C. von Kahlden says there is frequently found in the kidneys of phthisical patients a pathological change which is generally limited to the cortex. The kidney may either be normal in size or slightly enlarged. The surface of the kidney is usually smooth and pale yellow; the capsule can be easily stripped off; the cortex is normal or slightly thickened, and always shows a characteristic slightly yellow color. The medullary substance, like the organs in general, is usually pale and anæmic.

The microscopic appearances are best studied from preparations which have been hardened in Flemming's solution. The changes, which are principally degenerative in character, affect primarily the parenchyma. The interstitial infiltration and proliferation seem to be largely secondary, and dependent upon the degree of cell-destruction; and as evidently the fatty epithelial cells may be replaced for a time by newly-formed epithelial cells, this explains why the symptoms of proliferation in the interstitial tissue are, on the whole, so insignificant. The degeneration and the interstitial changes always occur in foci. The degeneration affects both the glomeruli, and especially their endothelium, and also the convoluted tubules.

The rather large fatty cells, seen frequently in the bloodvessels of the kidneys, are in part doubtless endothelial cells, as their partial connection with the vessel walls proves. Whether these cells come also from other organs, and especially whether they enter the circulation after the parenchyma of the lung is destroyed, must remain undecided; the latter has been supposed to be the origin of similar fatty cells found in the kidneys in pneumonia.

That these changes are chronic is shown by the thickening of the capsule, the atrophy of individual glomeruli, and the transformation in many cases of the club-shaped epithelium of the uriniferous tubules into short cylindrical or cubical cells. The duration of the disease cannot be told by the appearance of the kidneys. Accurate clinical observation, too, is often unreliable, for the disease continues for a long time almost without symptoms. Œdema is very rarely found, even after death. Albumin seems to be present only transiently and in insignificant quantity. Moreover, if slight œdema does occur, it could be attributed to disturbances in circulation, and the albuminuria to hectic fever.

Von Kahlden regards the disease as a chronic parenchymatous nephritis. As to the connection which exists between it and phthisis, he thinks it probable that the nephritis is caused by a ptomaïne produced by the tubercle bacillus. The fact that it is a degenerative process agrees with this supposition.

Both Becquerel and Rayher have declared that tuberculosis and Bright's disease are frequently associated. Peacock found phthisis in 30.7 per cent. of one hundred and seventeen cases of kidney disease; Frerichs met with six cases of phthisis in forty-two cases of Bright's disease; while Bamberger places its frequency at 15 per cent. Von Kahlden goes still further, and declares that degeneration of the kidney epithelium is rarely absent in phthisis which is progressing to any degree. He admits, however, that it may be so insignificant, that the microscopic changes can only be recognized by special attention and care. The fact that hypertrophy of the heart is generally absent accounts for the relative insignificance and focal distribution of the anatomical changes in the kidneys, and also for the general anæmia.—*Centralblatt f. allgem. Pathologie und path. Anatomie*, February 1, 1891.

THE TREATMENT OF MALARIA.

Laveran finds that in the contest between the organism and the hematozoons, the leucocytes play an important *rôle*. It is a well-recognized fact that if an insoluble and finely-pulverized substance be injected into the blood of an animal the leucocytes rapidly invade this powder and charge themselves with its elimination from the blood (Ponfick, Hoffman, Langerhaus).

The researches of Metchnikoff prove that the leucocytes not only invade inert powders and the dead bodies of microbes, but also, in a great number of cases, the living pathogenic microbes, and that this property, known as *phagocytosis*, plays a very important *rôle* in the evolution of infectious diseases and in the phenomenon of immunity. The cells of the splenic pulp and those of the endothelium, of the connective tissue, and of the pulmonary epithelium participate in this power. He has also concluded that the paroxysm of the fever persists during the life of these microbes in the blood, ceasing only when the parasites become the prey of the phagocytes. Especially is this marked in relapsing and malarial fever. The resistance which the microbes exert against this action of the leucocytes may be of long duration if they be lodged in the spleen or in the marrow of bone.

Wyssokowitsch has noticed that the spores of the *bacillus subtilis* lodged in the spleen were still living at the end of three months, an interesting fact in a point of view of the study of latent microbism.

Metchnikoff, Golgi, Gamaleia, and others insist upon the destructive action of heat upon the microbes, while, on the contrary, cold diminishes the activity of the phagocytes. It is well known that an organism placed in the best general condition will resist most successfully the inroads of the pathogenic microbes, whilst all debilitating causes militate against the cure of malaria. Laveran himself has observed in animals whose blood contained hæmatozoa, that under the influence of an abundant ali-

mentation the microbes disappeared, while inanition favored their development. The anæmic diseases—over-fatigue, ill nourishment—are attended with frequent relapses of the fever, and the salts of quinine themselves seem to become powerless in preventing these relapses. On the contrary, under the influence of only a good regimen and rest, frequently the condition of malarial patients will ameliorate, the anæmia grow less, the relapses less frequent, and a cure may occur without the intervention of a more active medication, simply because the organism has been placed in the best hygienic condition.

All the tonics have, consequently, a favorable action upon the progress of the disease, and foremost among these may be placed wine, coffee, and arsenious acid. Arsenic taken in small doses is of great service in the treatment of rebellious fevers with the malarial cachexia. If given in large doses, however, relapses of fever will often be produced, and the condition of the patient aggravated. Hydrotherapy is valuable, always used as a tonic medication. It succeeds sometimes when other medications have failed. It is well to know, however, that the first treatment may provoke a relapse; hence it is necessary to proceed with prudence, beginning with short and lukewarm douches before arriving at cold douches, not touching at first the spleen, and prescribing some doses of quinine at the same time. One can readily understand that a cold douche, especially if applied over the splenic region or following a paroxysm, will cause contraction of the splenic vessels, driving the hæmatozoa into the circulation. The malarial patients who in thermal stations—Vichy, for instance—take these waters both internally and in the form of baths, often have relapses at the beginning of the treatment, when they do not proceed with prudence. The change of climate is often beneficial to these patients, because the great heat of malarial climates is very debilitating, giving rise to exhausting sweats, nights without rest, and dyspepsia—all of which are corrected in a better climate. Quinine is of invaluable service in the treatment of these fevers, especially acting as a specific in the chronic forms. It has a very powerful destructive action upon all microbes, especially upon the protozoa, to which group the hæmatozoa belong. These rapidly disappear from the blood of patients who are submitted to a course of quinine medication. The spherical bodies and the flagellate forms disappear first. The treatment must be continued for some time to insure entire destruction of the microbes. It is probable that the phagocytes invade more readily the hæmatozoa when they have been killed or benumbed by the salts of quinine, but that the activity of the phagocytes is not directly influenced by the quinine.—*La Médicine Moderne*, February 19, 1891.

STRANGULATED HERNIA.

DAYOT, FILS, in the *Archives Générales de Médicine*, February, 1891, reports a series of observations upon the various forms of strangulated hernia. In the space of four and a half years he and his father have performed colotomy twenty-two times to remedy the accidents arising from strangulation of a hernia. In thirteen instances the intestine was absolutely sound, and in most of the cases they were able to reduce the hernia and terminate the operation by the radical cure of the hernia. In three instances the termination of the case was in death—one an old woman of seventy-five years, who succumbed upon the fifth day to a pulmonary congestion, the wound being on the way to complete union; two men, who were quite exhausted, with grave general symptoms, died in collapse, notwithstanding their surgical intervention. The remaining cases were cured entirely and did not merit special attention other than that among them was a congenital hernia of the peritoneo-vaginal-testicular variety, with a large concomitant hydrocele absolutely transparent. The patient, who was thirty-three years of age, had had this hernia since the age of fifteen years, and had already suffered from the accidents of strangulation, which, however, had yielded to taxis. They also operated upon an umbilical hernia in a woman fifty years of age, the hernia being of twelve years' standing. The tumor was as large as a small fœtal head, moderately tender, uniform and resonant. The skin covering it was violaceous, of an elastic consistency, with disseminated points of induration. Very moderate and brief attempts at taxis proving fruitless, colotomy was performed, and at the end of twenty-five days the cure was complete. Upon making the incision a large quantity of sanguinolent ascitic fluid was discharged, and palpation revealed multiple indurations of the sub-umbilical region resembling chronic peritonitis. They believed that there was a hernial peritonitis, attributable, at least in a certain measure, to the peculiar congested state of the peritoneum. The displacement of the intestinal arch by the circulatory troubles which were produced had without doubt favored the predisposition to serous inflammation. This hernial peritonitis had not only produced a simple irreducibility of the tumor, but it had in addition determined intestinal obstruction with all its clinical characteristics. This had arisen from the great thickening of the tunics, the binding together of the two portions of the intestinal loop by false membranes, and a total increase in the volume of the tumor, so that, in spite of its large dimensions, the ring had become insufficient to contain the pedicle without compressing it.

From the experience derived from the series of observations made, they have come to recognize the great danger of temporizing. Without waiting to diagnose between the pseudo-strangulation of Malgaigne and true strangulation, they have at once resorted to herniotomy to settle the doubt which might exist. The most frequent cause of the intestinal occlusion, in their experience, has been external strangulation with acute or subacute course, necessitating prompt interference on the part of the surgeon. Intervention has become the rule, and this line of conduct, which was very clearly outlined in the thesis of Boiffin (1887), applies itself as well to umbilical hernias as to the other forms of hernia. The statistics of herniotomy

for strangulated umbilical hernia have been much improved since the employment of antiseptic methods. In operating in cases where the bowel has become gangrenous, the diseased portion has been removed and the healthy borders of the artificial anus thus formed have been stitched with care to the walls of the hernial sac, at the level of its neck. All penetration of stercoraceous material into the peritoneal cavity is thus prevented. Enterectomy has been the operation selected, in the majority of cases, in preference to enterorrhaphy, although the two may be combined. If enterorrhaphy be first performed it may have to be supplemented by an enterectomy.

SOCIETY PROCEEDINGS.

FIFTH FRENCH CONGRESS OF SURGERY.[1]

(Continued from page 474.)

PROF. VERNEUIL presented a most interesting case of "Spinal Fistula Giving Passage to Arachnoid Fluid." The patient was a young lady. Sixteen months before he saw her she felt a severe pain in the sacral region, which was followed by the gradual development of a tumor, which, when it acquired the size of a small orange, suddenly burst, allowing a quantity of pus to be discharged; pain immediately disappeared, but the abscess discharged until she presented herself to Dr. Verneuil.

He found at two inches from the median line in the right sacral region a fistula which was in communication with a denuded portion of bone situated on the posterior surface of the spine on a level with the third vertebra. The surgeon now explored with the thermo-cautery; and strange to say, instead of finding a denuded portion of bone, his finger penetrated into a depression which was the third posterior sacral foramen. This seemed enlarged and rough, and was, therefore, curetted. The next day, however, it was found that the patient's dressing was perfectly soaked with a reddish serous exudation. He was then told that there had been, on several occasions before this, sudden drenching by a liquid coming from the fistula, and this had been followed by coma a few days later. This Dr. Verneuil had also the opportunity of witnessing; for on the fourth day after exploration she was found in a state of deep coma, without fever or vomiting, but in a singular state of oppression. This liquid was collected with absorbent cotton and examined chemically. It was found to contain cholesterin, a little fat, albuminoid substances, earthy and alkaline phosphates, a little urea, and sugar. Hence, this is a clear case of fistula arising from an acute abscess of bony origin, which gave vent to arachnoid fluid, bringing on cerebral symptoms without other effects on the general system.

DR. BAZY, of Paris, presented the history of two cases in which he made an exploratory opening into the spinal canal. The first one, in November, 1886, was made on a woman for a hydatid cyst compressing the cord and giving rise to motor and sensory symptoms in the lower extremity. The woman died, three weeks after operation, from suppurative nephritis: the catheter was passed several times a day by the nurse without order from the surgeon.

In another patient, twenty-nine years old, syphilitic and hysterical, suffering from paraplegia, with contracture during extension, anæsthesia, etc., it was not settled by our best men in neuro-pathology whether the symptoms were those of hysteria or of a tumor compressing the cord. It was then decided to perform an exploratory operation, which was done, and it gave negative results. The operation, being made aseptically, gave rise to no accidents. The author insists on the fact that when the dura mater has been opened, this membrane should be carefully united without drainage, to prevent exudation of the arachnoid fluid.

DR. DOYEN, of Rheims, presented a case of trephining for serous cyst, in a young man, aged sixteen, who, since the age of seven, had been suffering from epileptic fits, left hemiplegia, and great weakness of intellect. A large cranial projection appeared on a level with the squamous portion of the temporal bone on the affected side. Specific treatment having given no results, the patient was cured two months after trephining, when intra-cerebral albuminous cysts, containing more than 350 grammes (12 ounces) of liquid, were found.

DR. PICQUÉ, of Paris, presented a patient, a lady, nineteen years of age, who shot herself in the frontal region. She was comatose for six days, when she recovered all her faculties. Still there was persistent headache on the right side. Exploration demonstrating penetration of the ball, the diagnosis of intra-cerebral abscess was made. A large trephine was applied, and the frontal bone was found perforated, as well as the dura mater. The cerebral surface appeared intact, except at one part, where the gray substance formed a hernia. The cerebral substance was incised with the knife, allowing a great deal of pus to flow out. The bullet, however, could not be found. In five weeks the patient was absolutely cured, and finds herself well today.

DR. BROCA, of Paris, presented three cases of trephining. He divides the indications for the operation into three classes, and has a history for each: 1. An exterior lesion, which indicates the point upon which to operate. 2. The endeavor to find a cerebral lesion of known or unknown nature, the seat of which can be diagnosticated, by putting together the symptoms produced, according to our present powers of cerebral localization. 3. Operation without the guidance of localization; the nature of the lesion having, however, been diagnosticated, and, from our anatomo-pathological knowledge, we know its usual seat and where to attack it.

In his first case Dr. Broca had one sign of localization —an athetose contracture of the upper extremity; but according to the history of the disease and form of the head, he diagnosticated intra-ventricular hydrocephalus, and thought that the first surgical indication was to relieve the excentric compression of the brain by evacuating the liquid. Using Keen's process, he opened and drained the left lateral ventricle, as the contracture was situated in the right upper extremity.

The second case was an infantile spasmodic brachial monoplegia. The athetose contracture of the left upper extremity certainly resembled the preceding case, but the history of the disease and form of the head pointed

[1] Held in Paris from March 31 to April 4, 1891.

to infantile cerebral sclerosis. Moreover, for the past four years the child had suffered from attacks of Jacksonian epilepsy, which certainly had their starting-point in the thumb. Trephining was resorted to, and a cyst was found on the motor centre of the thumb—that is, at the postero-inferior extremity of the centre for the upper extremity. Epilepsy has almost totally disappeared, the patient only suffering from agitation and a few convulsive movements during the night.

His third case was one of complicated fracture of the skull, which had been trephined at the time of the accident. The immediate result was good, but a few months after, the patient suffered from Jacksonian epilepsy of the inferior maxillary and left upper extremity. He still had a cranial fistula. Dr. Broca removed an infected piece of bone in contact with the dura mater, and the fits have become much less frequent and are becoming less and less marked.

DR. MICHAUX, of Paris, presented the history of a case of "Non-traumatic Meningeal Hæmorrhage Cured by Trephining." This man was brought to the hospital in a state of apoplexy, with left facial hemiplegia and paralysis of the right superior extremity. During the following days the paralysis extended to the right lower extremity; epileptiform convulsions then set in and became more and more frequent. The patient presented no sign of fracture of the cranium nor bleeding at the ear, nose, etc.; neither sub-conjunctival, pharyngeal, nor cranial hæmorrhage was observed. But it is learned that the patient was an inveterate absinthe-drinker. Several months ago he was compelled on two occasions to give up his occupation on account of intense headaches and vertigo. His urine contains 0.65 grammes of albumin and only 2.50 grammes of urea.

The operation was performed on the left side along the Rolandic line; two inches of bone were removed by the trephine and the dura mater was incised. Immediately, large black clots, about two tablespoonfuls, were thrown out. Iodoform dressing was applied. The patient has improved rapidly since the operation, most of the symptoms having disappeared, and the remaining ones are doing so gradually. This was certainly a case of spontaneous hæmorrhage of alcoholic or uræmic origin.

DR. MANOURY, of Chartres, presented the history of a case of "Craniectomy," which demonstrated that the favorable results obtained after the operation are not very permanent. He operated on a microcephalic girl of four years of age, who, at the age of three months, had her fontanelles completely closed. At six months convulsive movements in the two upper extremities appeared. She had never been able to walk or stand, because of a permanent contracture of the muscles of the posterior region of the leg. The child does not masticate her food.

She was operated upon, and an antero-posterior groove four inches long made in the left parietal bone, extending from the coronal suture to the lambdoid. As soon as the operation was over, the little patient became very calm, and did not cry any more. The upper extremity ceased to move, the head became straighter, and the look was more intelligent. The hand could be moved, and the child could masticate its food. The contracture of the gastrocnemii ceased, and the patient was able to remain on her feet. This favorable stage lasted two months, when the former symptoms all returned to their previous state, and mensuration of the cranium did not indicate the least increase in its dimensions from the time of the operation five months previous.

DR. TOISON, of Douai, spoke on a new mode of performing sections of the cranium. The objections to the mode usually employed are, that after trephining there is a permanent loss of bony substance, as the reinsertion of the disc of bone is not practicable by every surgeon. Wagner's process, says the author, is a great advance, as it consists in a temporary resection of an osteo-cutaneous flap, which is returned to its place as soon as the cerebral operation is over. Dr. Toison has repeated the experiment, made by Julius Wolff in 1863, on rabbits. He found that in dogs there was a very firm bony union two or three months after the operation, provided that no suppuration took place; the dura mater, however, does not seem to take part in this consolidation. The speaker has found that sections made by a saw become much more firm than those made with a chisel. He has applied this process to human surgery, and passes a thin flexible saw between the bone and dura mater, through four little perforations which have been made at the four angles of the bony flap which is to be uncovered; when the last point of attachment remains, it is fractured by introducing a small chisel under the rectangular piece of bone; this process has also the advantage of abolishing the hammering of the cranium.

DR. LEDRU, of Clermont, read a paper on "Extirpation of a Rectal Epithelioma through the Anus." The operation was performed after having previously well dilated the parts; but the disease soon recurred, and as the patient refused all other interference, the speaker used an application on the epithelial ulcerated surface of a layer of Conquoin's paste (chloride of zinc, 32 grammes; wheat-flour, 24 grammes; oxide of zinc, 8 grammes). A great deal of pain was experienced at first, but afterward all went well, and two months later there was not the least sign of recurrence of the trouble.

DR. BERTHOMIER, of Moulins, read a paper on "Osteo-myelitis of the Ribs," in which he said that osteo-myelitis developed itself in the ribs as in the long bones; there are often found two points affected on a level with the epiphyseal joints. One is anterior and is well known, presenting itself as a projection on a level with the chondro-costal articulation; while the other point affected is posterior, on a level with the head of the bone toward the pleural cavity, and presents all the symptoms which might be mistaken for a pleuritic effusion, dulness, murmur, ægophony, etc. These two points infected, communicate with each other, although exteriorly we find no trace of such propagation.

The following case illustrates very well the above-mentioned fact: A patient who had been suffering for six days from osteo-myelitis, presented when first seen a well-defined tumor of the size of a very small orange on a level with the chondro-costal articulation of the fifth right rib; second, behind or posteriorly along the spinal border of the scapula, there was a zone of about ten centimetres, where there existed dulness, murmur, and ægophony, while exteriorly there was no trace of

inflammation; third, the least trace of inflammation existed in the middle of the rib—no dulness, no murmur, no ægophony. The surgeon then aspirated the projecting tumor at the chondro-costal articulation, and washed the cavity out with a bichloride solution. Percussion and auscultation in the posterior region immediately after demonstrated the absolute disappearance of the dulness, murmur, and ægophony.

DR. TUFFIER, of Paris, gave his personal experience in "nephrorrhaphy." He has performed the operation fourteen times, and the symptoms which have encouraged him to operate were: first, pain; second, gastric symptoms; third, neurasthenia. All these three symptoms constitute the clinical types of the movable kidney. The painful variety is the most frequent and most favorable for treatment, as in ten of his patients the pain disappeared after operation, while in the four others it was greatly diminished. The dyspeptic variety is rarer, he having had two cases, with one failure. This variety is often accompanied by hepatic lesions. The neurasthenic variety is not very frequent, and comprises all neurasthenic symptoms, including hysterical attacks; in three cases he had two successes.

As regards clinical forms, Dr. Tuffier divides the movable kidney into two varieties; first, the simple movable kidney; second, the complicated movable kidney. The simple movable kidney is of traumatic origin; it is a real dislocation of the kidney, and gives the best operative results. The complicated movable kidney is a slow and progressive displacement, accompanied or followed by a descent of the abdominal viscera: the abdominal parietes are soft, depressible, and there may exist a hernia, a rectal or uterine prolapse, or the stomach may be dilated; the abdomen in those cases is better treated by orthopedic means.

Out of fourteen operations, Dr. Tuffier lost one patient by tetanus on the eleventh day, when the lumbar wound was already closed, the thirteen others having been cured. The painful symptoms have disappeared. He concludes by saying that nephrorraphy is one of the most efficacious amongst renal operations; as, out of a series of 149 operations collected, the mortality has only been 3.4 per cent. It is also very successful, for out of 73 typical operations there were 80 per cent. of complete cures or certain ameliorations.

PROF. HEYDENREICH, of Nancy, read a paper on "Partial Excision of the Pubic Bone for the Removal of a Vesical Tumor." He recommends partial excision when the vesical tumor is very deeply situated; he then resects a fragment of bone two centimetres long and four centimetres broad without danger to the pelvis, by following oblique lines passing outside, or even inside, the spinous process. He says that whenever a surgeon finds difficulty in reaching a deep-seated tumor he need not hesitate to perform this operation, which only takes a few minutes.

DR. PONCET, of Lyons, read a communication on "A New Process of Suturing Tendons." The following operation was done on a young laborer who had the tendo Achillis cut by the stroke of a spade. He was untreated for forty days; at the end of that time the cutaneous wound was closed, but the two ends of the tendon were one inch apart. The operation was performed as follows: A V-shaped incision was made on the posterior aspect of the heel and the flap was dissected up; afterward a vertical calcaneotomy was made by detaching a posterior slice of the calcaneum about one centimetre thick, the osseous fragment being rendered absolutely movable. Then this osseous fragment was pushed up, and the two ends of the tendon were sutured, while the lower end of the bony fragment was fixed to the bone by means of an aseptic ivory peg; the cutaneous flap was next sutured into position. This method, the author thinks, could be applied to certain cases of tearing away of the ligamentum patellæ or the tendon of the triceps brachialis.

CORRESPONDENCE.

DEFEAT OF THE OBLIGATORY THREE YEARS' COURSE BILL IN MISSOURI.

To the Editor of THE MEDICAL NEWS,

SIR: An attempt was made this winter by the friends of reform in medical education to secure the enactment of a law in Missouri defining the term "medical college in good standing" in the existing Medical Practice Act, to mean a college requiring, among other common conditions, that the applicant for graduation must have attended at least three annual collegiate courses. The Missouri Practice Act is copied from that of Illinois, and conveys the same powers to the State Board of Health which have enabled the Illinois Board to set on foot at home and abroad such a grand reform in medical education. The Missouri Board declined assuming the responsibility of following this famous example, but by resolution referred the matter to the General Assembly then in session. A bill was accordingly introduced in the House, was *unanimously* recommended by the House committee, and eventually passed by the gratifying vote of 85 ayes to 22 noes. The bill was subsequently lost in the Senate by a vote of 14 noes to 10 ayes. Legislation was crowded into the last few days of the session, so that the bill came up in the Senate at the very last, leaving no time to obtain a reconsideration. The defeat in the Senate was entirely unexpected, though very powerful political influence was felt to be inimical on purely personal grounds.

The reform movement originated in St. Louis. Encouraged by the appearance in the Illinois State Board of Health Report of the names of most of the medical colleges in Missouri favoring the three years' course (at present all but one do appear), a committee was formed, under whose auspices a circular was mailed to the profession of the State. A large number responded favorably, the negatives being so few as to cut no figure at all. These names and addresses, together with the names of the three years' colleges, were printed in the form of a memorial and presented to the Legislature; also a statement to the effect that in no other part of the civilized world were diplomas issued under at least four years' attendance upon college work; that the right of the States to regulate medical education had been affirmed in the Supreme Courts, both State and national, since the welfare of the people requires protection "against the consequences of ignorance and incapacity as well as of deception and fraud"; that all over the country reform in medical education is being agitated, and in a number of

States already laws have been enacted requiring the three years' course, etc. Of the fourteen medical institutions in Missouri granting diplomas, only one, at the present time, opposes the bill. This, the Marion Sims, was lately organized, graduating this year its first class. Its prospectus opens by declaring that the "chief object" of its organization is "the elevation and securement of an approximate perfection of the standard of medical instruction in the West." Its dean has just sought to further this laudable object by bitterly opposing at the Capitol the Three Years' Bill. By the aid of political friends high in office, and by working on the prejudices of some, he has succeeded for the time: conduct which Secretary Rauch, of the Illinois Board of Health, in a recent address on Medical Education (Missouri Medical College semi-centennial celebration, March 31st), tersely characterized as "dishonorable, unprofessional, and mercenary."

The sum of the argument (!) raised against the memorial presented in the Legislature was this: To require attendance upon a course of three years would work a hardship upon "the poor young man"—it would be class legislation—therefore undemocratic, a most deadly sin. Of course, the voice of civilization demanding better medical training, the decision of the Supreme Court of the United States pointing out the duty of the State to protect its people "against the consequences of ignorance and incapacity"—such testimony as this can have no weight in the grand scheme quoted, "The elevation and securement (!) of an approximate perfection of the standard of medical instruction, etc."

CHAS. A. TODD, M.D.,
Of the Committee on Memorial.

WEATHER ELEMENTS AND TRAUMATIC NEURALGIA.

To the Editor of THE MEDICAL NEWS,

SIR: I herewith send you a paper by Captain Catlin, of the United States Army, who was injured by a round shot in battle in 1864, which accident resulted in an amputation below the knee. [See page 489.]

From this time he suffered more or less from constant neuralgia. Seeing in one of my books a reference to the effect of storms upon this condition, he applied to me for relief. I requested him to keep a record of the influence of storms upon his neuralgia, and the result of this was three papers: One by myself in conjunction with Captain Catlin, based upon his information, to be found in the *American Journal of the Medical Sciences*, April, 1877; the second by Captain Catlin, with a short introduction by me, *American Journal of the Medical Sciences*, June, 1883; and finally the long and very elaborate paper on the effect of storm and electrical conditions upon pain, as well as of the influence of ozone. This paper will appear in full in the *Proceedings* of the American National Academy of Sciences. As, however, it will be a long time before it can be published, and as it is of great length and of a purely scientific character, I asked him to make a brief abstract of it, which I herewith give to the medical public with this short explanation.

If anyone is especially interested in this subject, a reference to the original document will enable him to trace out this research, which was only made possible by the circumstances of the situation. In other words, there was injury, traumatic neuralgia, acquaintance with electrical conditions, and the possession of such patience as is necessary to a study of this kind.

S. WEIR MITCHELL.

SUPERNUMERARY DIGITS.

SIR: In THE MEDICAL NEWS for March 16, 1889, page 307, I reported a case of supernumerary digits, and in THE MEDICAL NEWS for April 13, 1889, page 418, two more cases are reported by Dr. W. F. Drewry, of Petersburg, Va. On September 29, 1889, I attended Mrs. C. (the mother of the case I have already reported) in her third confinement. The labor, although slow, had nothing uncommon about it, but the child, a male, had a supernumerary digit attached to the outer side of the left little finger. It measured about one-fourth of an inch in length; was furnished with a nail; and was attached to the little finger by a thin pedicle.

When the child was about two weeks old, the supernumerary digit was removed without any difficulty.

Mrs. C.'s first baby was born without any such deformity; the second was born with two supernumerary digits; and the third was born with one. The first child having been born without these extra digits, why should the second and third have been born with them? As the second was born with two, why had the third only one? The second and third having supernumerary fingers, why did the first escape?

M. A. DE WOLF SMITH.
NEW WESTMINSTER, BRITISH COLUMBIA.

NEWS ITEMS.

New Jersey State Medical Examining Board.—The following questions were asked by the New Jersey State Medical Examining Board at their meeting on Thursday, April 9, 1891:

OBSTETRICS AND GYNECOLOGY.

George W. Brown, M.D., Examiner.

1. Describe the uterus.
2. What is the corpus luteum?
3. Name the contents of the broad ligament.
4. Describe the fœtal circulation.
5. What changes take place in the vascular system of a child after birth?
6. What are the causes and evil effects of tardy and precipitate labors?
7. Give the pathology of phlegmasia dolens.
8. Give the differential diagnoses of ovarian tumor and tubal pregnancy.
9. Give the causes, symptoms, results, and treatment of pelvic cellulitis.
10. Give the symptoms and treatment of erosion of the cervix.

PRACTICE OF MEDICINE.

William Perry Watson, M.D., Examiner.

1. Locate the valves of the heart and the points at which their respective murmurs are heard with the greatest intensity.

2. Give a characteristic prodromal symptom (non-eruptive) of: *a*, mobilli; *b*, scarlatina; *c*, variola; *d*, varicella.
3. Coma.
4. Râles.
5. Renal casts.
6. Angina pectoris.
7. Spinal sclerosis.

Give varieties, causes, diagnoses, and prognosis of each.

8. Describe Bell's paralysis.
9. Describe Cheyne-Stokes respiration.
10. Give the differential diagnosis between acute, catarrhal and diphtheritic laryngitis.

SURGERY.

Aaron K. Baldwin, M.D., Examiner.

1. Give the treatment of a case of retention of urine.
2. Give the different varieties or hernia, and describe operation for strangulation of any one of these varieties.
3. How would you detect dislocation of the head of the femur into the thyroid foramen?
4. What are the symptoms of cerebral concussion? Of cerebral compression?
5. What is Pott's fracture? Describe treatment.
6. Describe varieties of luxation at elbow-joint.
7. Give varieties of luxation at shoulder-joint.
8. Describe the pathological condition of anthrax.
9. Give the various kinds of ulcers of the leg, and how would you treat one of them?
10. Give the cause, course, and termination of periostitis.

ANATOMY.

A. Uebelacker, M.D., Examiner.

1. Name the muscles of the forearm.
2. Describe the elbow-joint.
3. What muscles are in relation with the elbow-joint?
4. What arteries and nerves?
5. Describe the arachnoid membrane.
6. Describe the pancreas.
7. Describe the ophthalmic artery, and give names of its branches.
8. Describe the superior vena cava.
9. Give the origin and name the branches of the fifth nerve.
10. Give the average weight and principal divisions of the brain.

PHYSIOLOGY.

D. R. Atwell, M.D., Examiner.

1. What produces the first sound of the heart?
2. Describe the coagulation of blood.
3. Trace the fœtal circulation.
4. How is the heart's structure nourished?
5. What is a lymph node?
6. Where is the centre of taste?
7. What juices are concerned in the digestion of starch?
8. Give the normal temperature, pulse, and respiration of an adult.
9. Give location and function of the spleen.
10. What is *complemental air* as related to respiration?

CHEMISTRY.

Eugene Tiesler, M.D., Examiner.

1. Define the terms dialysis, distillation, sublimation, decantation, precipitation.
2. State what you know about soda bicarbons.
3. How is phosphoric acid prepared?
4. Define haloid salt. Give examples.
5. What is alum? How does it differ from alumen exsiccatum?
6. Give tests for albumin in animal fluids.
7. What is Hg? Name four officinal preparations thereof.
8. What is cupric arsenite? Give antidotes.
9. What is aqua regia? Why is it so called?
10. In what form is lime present in lime-water?

HISTOLOGY, PATHOLOGY, AND DISEASES OF EYE AND EAR.

H. G. Wagoner, M.D, Examiner.

1. Describe the nerve-cells.
2. Give the minute anatomy of the skin.
3. Give the minute anatomy of the arterial walls.
4. Describe the lesions of infantile paralysis.
5. What are the pathological processes in cirrhosis of the liver?
6. How many kinds of pleurisy are there, and what are the pathological changes in each?
7. What are the varieties of endocarditis, and what anatomical changes do we find in each?
8. What is myopia, presbyopia, and astigmatism, and treatment for each?
9. What is strabismus and its treatment?
10. What lesion of the ear may result from the use of the nasal douche?

HYGIENE AND MEDICAL JURISPRUDENCE.

A. H. Worthington, M.D., Examiner.

1. Give the best method of disinfecting a room after a contagious disease.
2. What is ozone?
3. Name two of the most valuable disinfectants.
4. What are ptomaines? Give types of different action and origin.
5. What is meant by "hardness" in water, and what are the causes and the different degrees of hardness?
6. State briefly the details to be noted in making a post-mortem examination for medico-legal purposes.
7. In a case of supposed drowning, how could you prove the body was alive or dead when submerged?
8. Name the different forms of insanity.
9. Describe the fœtus and its appendages at the beginning of the fourth month of intra-uterine life.
10. Give the symptoms of poisoning by opium and the treatment.

MATERIA MEDICA AND THERAPEUTICS.

Wm. L. Newell, M.D., Examiner.

1. What is dialyzed iron, and how is prepared?
2. What is cantharides? Its uses and doses when internally administered?
3. What is chloroform? Its specific gravity, uses, and doses?
4. Give the formula and mode of making camphorated tincture of opium.

5. Give the formula of the compound cathartic pill of the U. S. P.

6. Give average internal dose of each of: 1, atropia; 2, morphine; 3, strychnia, for a child four years of age.

7. How is antifebrin prepared? What are its physiological effects, uses, and doses?

8. Describe infusion, decoction, maceration, and digestion.

9. Give five irritant poisons and the antidotes of each.

10. Write a prescription containing nitro-glycerin, and give the symptoms to be relieved.

HOMŒOPATHIC MATERIA MEDICA AND THERAPEUTICS.

A. H. Worthington, M.D., Examiner.

1. Explain the difference that exists between the primary and secondary action of a medicine, and give an example.

2. Name the most important remedies, with their doses, for dysentery in an adult.

3. Differentiate the brain symptoms of cuprum aceticum and stramonium.

4. Give the thoracic symptoms of bryonia alba.

5. Give the enteric symptoms of colocynthis.

6. Describe the characteristic inflammation of belladonna.

7. Give the urinary symptoms of cannabis sativa.

8. Name the most valuable remedies in diphtheria—the simple and malignant forms.

9. Describe a disease in which hydrastis canadensis is the indicated remedy.

10. Give the skin symptoms of antimonium crudem.

The Medical and Surgical Reporter.—With the issue of *The Medical and Surgical Reporter* of April 25th, Dr. C. W. Dulles severed his connection as editor with that journal. During the three years Dr. Dulles has edited it he has not only proved himself to be possessed of a facile pen and editorial ability, but has doubtless given satisfaction to the subscribers of *The Reporter*. The next issue will appear under the editorial charge of Dr. E. T. Reichert, of the University of Pennsylvania, whose contributions to medical literature during the last few years have not only been interesting, but valuable. Dr. Reichert brings to *The Reporter* a mind well trained for the carrying out of his duties, and possesses the faculty, so necessary to the successful editor, of making friends through never-failing courtesy.

Jefferson Medical College.—At a meeting of the Board of Trustees of Jefferson Medical College held April 22d, Dr. H. A. Hare was elected Professor of Therapeutics and Materia Medica, to succeed Dr. Roberts Bartholow.

DR. J. M. BALDY, of Philadelphia, has been elected Professor of Gynecology in the Philadelphia Polyclinic and College for Graduates in Medicine.

A New Sanitary Journal.—The first number of a monthly periodical, devoted to sanitation, has been published at Dublin, Ireland. It has been named *The Health Record*, and will be edited by Edgar Flinn, M.R.C.S.I., of Kingstown.

Medicine has the Right-of-Way.—At Berlin, a corporation ordinance has been adopted which will give to the carriages of physicians the right-of-way through streets that are crowded. In order that these carriages may be at once distinguished from others like them, the coachmen who drive them will don a white hat. This new headgear has been proposed for the prevention of embarrassing delays of medical men in the principal thoroughfares, and will become a recognized demand for the right-of-way at all times.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 21 TO APRIL 27, 1891.

BUSHNELL, GEORGE E., *Captain and Assistant Surgeon* (Camp Pilot Butte, Wyoming).—Is granted leave of absence for twenty-one days, to take effect on or about May 1st next.—Par. 9, *S. O. 49, Department of the Platte, Omaha, Neb.*, April 20, 1891.

By direction of the Acting Secretary of War, ALFRED A. WOODHULL, *Major and Surgeon*, is detailed to represent the Medical Department of the Army at the International Congress of Hygiene and Demography at its meeting in London, England, from August 10 to 17, 1891. He will leave his present station not later than June 1, 1891, and will proceed to London. After the adjournment of the Congress, he will return to his proper station. While abroad under this order, and before returning to the United States, he will visit, on official business, such points in Great Britain as may be deemed necessary by the Surgeon-General of the Army.—Par. 17, *S. O. 91, A. G. O., Washington, D.C.*, April 22, 1891.

By direction of the Acting Secretary of War, WILLIAM L. KNEEDLER, *Captain and Assistant Surgeon*, is relieved from duty at Jackson Barracks, La., and will report in person to the commanding officer Fort Logan, Col., for duty at that post, reporting also by letter to the commanding general Department of the Missouri.—Par. 2, *S. O. 88, Headquarters of the Army, A. G. O., Washington*, April 18, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 25, 1891.

MCMURTRIE, D., *Medical Inspector.*—Detached from Navy Yard, New York, and ordered to the U. S. S. "Lancaster."

KERSHNER, EDWARD, *Medical Inspector.*—Detached from Marine Rendezvous, and ordered to Navy Yard, New York.

HERNDON, C. G., *Surgeon.*—Detached from Naval Hospital, New York, and ordered to Marine Rendezvous.

GARDNER, JAMES E., *Passed Assistant Surgeon.*—Ordered to Naval Hospital, New York.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

VOL. LVIII. SATURDAY, MAY 9, 1891. No. 19.

ORIGINAL ARTICLES.

A STATISTICAL HISTORY OF YELLOW FEVER IN PHILADELPHIA, WITH A REPORT OF TWO CASES RECENTLY TREATED AT THE EPISCOPAL HOSPITAL.[1]

BY ALBERT STAVELY, M.D.,
RESIDENT PHYSICIAN EPISCOPAL HOSPITAL.

WITH the exception of Asiatic cholera, perhaps, no epidemic disease of modern times elicits more widespread interest, or is attended with a greater fatality, than yellow fever.

To illustrate the frightful ravages this disease may occasion, I need only call to your mind the epidemic that visited London in 1660, in which 97,000 out of a population of half a million perished; that of St. Domingo in 1802, when 20,000 out of a population of 40,000 fell victims; or that of Constantinople in 1812, when the mortality was nearly 160,000.

Our city of Philadelphia had passed through only seventeen years of its existence when, in 1699, yellow fever, then an obscure disease, first terrorized its inhabitants. The records of this first epidemic are very meagre, being confined to a few letters written by unprofessional men. At that time there were less than 4000 inhabitants, and the mortality was 200.

For the next forty-two years there was complete exemption, and the memory of the first visitation had almost faded out, when a second occurred in 1741, and 240 died. On neither of these occasions was there a satisfactory cause for the disease obtainable.

There were some cases of the fever in 1747, but we know nothing of the number. This time the inception of the disease dates from and is attributed to the arrival of a vessel from the West Indies.

In 1760 there were a few cases.

In 1762 the disease originated in the sailors' quarters, and was apparently traced to a sick sailor recently arrived from Havana. We have no statistics of this attack, but it is supposed that several hundreds died. Then there was a lapse of thirty-one years without a case. In 1793, in the midst of seeming security, the city was visited by the most appalling epidemic ever known in its history. The population then numbered 50,000, and at least 4000 died.

When the people were fully convinced of the destructive nature of the disease, a panic occurred, and in a few weeks as many as 12,000 had sought refuge in the country.

Estimating the population then at 38,000, which is perfectly fair, the death-rate would be one to nine and one-half inhabitants, or about fifty-two deaths *per diem* during the yellow fever season, a period of about eleven weeks. At this time the fear of contagion was so great that people locked themselves up in their houses, both sexes smoked tobacco religiously, burned it in the houses and streets, used vinegar or camphor for inhalation, carried tarred rope around in their pockets, chewed garlic, walked in the middle of the street, tried to get to the windward side of any chance passer-by, and adopted other precautions quite as ridiculous. A West Indies vessel was assigned as the cause for this invasion.

In 1794, 1795 and 1796, there were a few cases.

1797 ushered in another epidemic, which occurred coincidently with the arrival of a vessel from the West Indies. About one-half the population sought safe quarters. Of those remaining about 1300 died.

In 1798, upon the arrival of the fever, two-thirds of the whole population, at least 40,000, fled, and of the remaining 20,000, 4868 were reported to the Board of Health as being affected, of which number 3600 died.

In 1799, again, there was a general exodus, and the city was left almost deserted. About 1000 died.

1800 and 1801 alike had about twenty deaths.

In 1802 the mortality was about 835; in 1803 about 190; in 1805 about 400; in 1806, 1807, 1808, 1809, and 1811 there were a few cases. In 1819 there were twenty-four cases, of which number twenty died.

In 1820, of 125 attacked, there were eighty-three deaths.

There were two cases in 1826, and after that, with the exception of one case, which slipped through quarantine in September, 1841, and was treated at the Pennsylvania Hospital, twenty-seven years passed without any yellow fever.

In 1853, upon the arrival of the Mandarin, a Cuban vessel, the disease broke out again. 170 cases were reported, and 128 died. Most of these cases were treated in the city hospitals, and without

[1] Service of Casper Morris, M.D., and Frederick A. Packard, M.D.

any communication of the disease. With the exception of Dr. La Roche's report of the fever in 1870, the records of cases from 1853 are almost entirely confined to a few hospital reports. A number of cases were treated at the Philadelphia Hospital, but the old records are not obtainable. The Pennsylvania Hospital admitted twenty-four cases in 1854, mortality fifteen; six in 1855, mortality six; four in 1856, mortality three; one in 1857, mortality one; one in 1858, mortality one; four in 1859, mortality three; one in 1868, mortality one; and one in 1870, mortality one. In 1858 a case was admitted to the Episcopal Hospital.

In 1860 a sporadic case occurred in the practice of Dr. Bournonville. The subject, a German, resided on Front Street and was employed in a board-yard at the foot of Green Street. Some time before he was stricken he was engaged in rafting lumber on the river, but in no way came in contact with any yellow fever. He became sick on September 1st.

On the last of September, the "Waterwitch," a vessel from Cienfuegos, Cuba, arrived at the Lazaretto, and landed five cases, of which one died.

On June 29, 1870, the brig "Thome" arrived at the Lazaretto, loaded with logwood, and in a filthy condition. The captain died of yellow fever on the way. Shortly after her arrival the fever broke out among the stevedores engaged in discharging the cargo, the bargemen, and the officers and employés of the Lazaretto. Altogether, twenty-nine were attacked, and eighteen died. On looking over the Municipal Hospital records, three cases were found to have been admitted there in 1870, one on August 10th and two on September 8th.

On August 25, 1878, an entire family named Bonelli, consisting of eight members, was taken to the Municipal Hospital from 804 South Eighth Street. They were refugees from Vicksburg, where the disease was then rife, and were all taken to the hospital on suspicion. Two of them had yellow fever of a mild type, and recovered in eighteen days. The rest were detained two weeks, and were discharged as having no disease. On September 21st of the same year a case was sent from 464 North Fourth Street. On August 21, 1879, a case was received from 509 South Front Street, which died at the end of six days.

The following note of the case is taken from the records: "Quite yellow; profuse black vomit; great irritability of stomach."

On the 6th of October, in the same year, a case was sent there from the Jefferson Hospital, and died in five hours. This memorandum was found: "Unconscious while here, unable to swallow, quite yellow, and after death became more so."

This is a summary, as near as can be obtained, of the cases of yellow fever that have occurred in Philadelphia since the first epidemic in 1699. There have been detained at the Lazaretto during eleven years, from 1873–1883, inclusive, twenty-five cases, and since the latter date not a case has been reported.

The following are histories of two cases of yellow fever, admitted to and treated at the Episcopal Hospital in Philadelphia, during the month of August, 1890.

On the morning of the 20th of August, 1890, the British steamship "Blakemore," from the port of San Diego, Cuba, arrived at Philadelphia with a clean bill of health, having on board, among others, two men, one the engineer, the other a deck-hand, both of whom afterward developed yellow fever. On questioning the patients about the existence of the fever at the ports they had visited, they replied that they had neither seen nor heard of any cases. Just before the vessel left San Diego there was a case of sickness on board, which was treated and cured by a physician of that place, but it in no respect resembled their disease.

CASE I.—Peter M., aged twenty-three years, was admitted on the afternoon of August 22. On Tuesday, August 19, after previous symptoms of anorexia, malaise and constipation, he had a marked chill, followed by fever and sweating, which recurred on the 20th, 21st and 22d. On admission his tongue was slightly coated, appetite wanting, bowels constipated. He had severe frontal headache, great tenderness in the epigastric, hypochondriac and lumbar regions, and general aching. There was vomiting of a brownish fluid. The skin was lemon-colored, the conjunctivæ were deeply jaundiced, and there was a slight injection of the conjunctival vessels. The patient was perfectly rational, but was very restless, and complained of sleeplessness.

A powder of calomel and bismuth subnitrate was ordered every three hours, and quinine sulphate gr. iv. every six hours. On the 23d he had a return of the chill, fever and sweat, and a continuance of the vomiting, the vomited matter assuming the appearance of coffee-grounds. In the afternoon the temperature was 103°, the pulse only 60, and the respiration 28. The pulse was regular, and of good volume.

The two following days were marked by no unusual symptoms. The vomiting persisted.

On the 25th he had a dark-colored movement.

August 26. At 5 A.M. he vomited a large quantity of fluid, which was described by the nurse as very dark in color, with streaks of light-red blood running through it. Whitish froth floated over the surface of the fluid, and in a few minutes an abundant black and tarry-looking sediment formed. He complains frequently of hoarseness and soreness of the throat. The fauces are considerably inflamed, and the gums very tender. He has been very much annoyed by hiccough, which was relieved

for a time, and re-excited by percussion over the liver. Musk finally controlled it. The pains in the back and knee-joints are very distressing. The pulse-rate is normal, but the heart is becoming very weak. The conjunctivæ are very much injected. The milk which he had been taking came up in tough curds, and rice-water was ordered instead, but, finally, nourishment by the mouth had to be discontinued entirely. In the morning he had two movements similar to the one of the preceding afternoon. Examination of the urine revealed the presence of a small amount of pus and a large quantity of albumin.

27th. Extreme restlessness has been a constant symptom. Vomiting continues, but is accompanied by no retching. Breathing is becoming difficult. The pulse is 80, and very feeble. The face is dusky. Toward the end the patient became stupid, then comatose, and about one-half hour before death he had a convulsion in which his limbs jerked violently. The head was turned to the right side, and there was violent twitching of the orbicularis palpebrarum muscles and general tremulousness. The tongue was firmly held between the teeth, a small quantity of blood escaped from the mouth (probably from the wound inflicted on the tongue), and at the same time he had an involuntary movement of about two drachms of blood. He had three convulsions, one following closely on the other, and the third closing the scene. During the whole course of the disease, with the exception of the few hours preceding his death, the patient was conscious, and unusually cognizant of everything that occurred.

On the second day, under the impression that the case was one of intermittent fever, the blood was examined microscopically for malarial bodies. None could be found; but in the field of the microscope several large bodies could be seen, somewhat larger than the normal white blood-corpuscles, containing finely granular pigmented matter, and possessing amœboid movement. The shape varied greatly, at one time being perfectly round, again oval, then elongated, dumbell-shaped, or crescentic.

Post-mortem examination: Well nourished. The skin retained the original deep-yellow tinge, save at the dependent portions, where it had assumed a dark-purple color.

The lungs were dark-red, very much congested, and were crepitant.

The heart was slightly dilated.

The liver weighed three and one-fourth pounds, was fatty degenerated, and was light-yellow.

The gall-bladder was full of dark-green bile.

The spleen was normal in size, somewhat elongated, very dark colored, soft, and very friable.

The kidneys were of natural size, rather pale, and colored yellow. Otherwise they seemed to be normal.

The stomach contained four or five ounces of coffee-grounds fluid, and its walls were covered with mucus. After washing out the organ, the mucous membrane appeared very much degenerated, dirty-white in color, with reddish foci of capillary congestion, and one or two ecchymotic patches.

The intestines were pale, and contained a thick, sticky, slate-colored fluid.

The mesenteric glands were dark in color, and slightly enlarged. A small hæmatoma was noticed in the mesentery. The tissues were uniformly yellow.

CASE II.—David M., aged forty-two years, was admitted on the morning of August 25, 1890. He had complained of anorexia and headache for a few days, and on Saturday evening, August 23d, he had a severe chill, followed by nausea and vomiting. He had only one chill, and since has complained of fever. On admission his temperature was $99\frac{4}{5}°$, pulse 68, respirations 22. His tongue was lightly coated in the middle with whitish fur. His skin was lemon-colored, and where it was exposed to the air it was bronzed. There was decided pitting on pressure. His face was somewhat flushed, but deep pressure revealed the yellow color beneath. His conjunctivæ were jaundiced, and the conjunctival vessels injected. Bowels were extremely constipated. He complained of intense pains in the epigastric and hypochondriac regions, dull and aching pains in the lumbar region and in some of the joints, especially the knees. Shortly after admission he began vomiting profusely a coffee-grounds fluid, first on one side of the bed, then on the other. The vomited matter gushed forth without any effort on the part of the patient, and hardly fifteen minutes elapsed between each act of vomiting. After midnight he vomited a quantity of blood, which was described as looking like tar. At 2 A.M. on the 26th the vomit was like blood much diluted with water—claret-colored. The milk which was given him came up in tough masses. Earlier in the evening his respirations, which had been normal in rate and easy, became very labored and 30 to 35 per minute.

On examining the chest the next morning (26th), there was marked dulness over the whole chest and feeble breathing; his pulse became very weak, but the rate was not much increased, being about 80. He was very restless, constantly tossing from side to side, and was unable to sleep. He became comatose, and died so about 1 P.M.

Post-mortem examination: A well-developed, muscular man.

The heart was normal in size, and quite firm.

The lungs were intensely congested throughout their entire extent, barely floating in water.

The spleen was normal in size, very black, and much degenerated.

The liver weighed three and one-half pounds; very light yellow in color.

The stomach: Mucous membrane degenerated. A few small ecchymoses were noticed—color dirty-white; contained about half a pint of coffee-grounds matter.

The intestines contained a thick, semi-liquid, slate-colored material.

Mesenteric glands were blackish.

Kidneys weighed eight ounces each; light yellow in color, capsule non-adherent.

NOTES ON THE RADICAL OPERATION FOR THE RELIEF OF HERNIA.[1]

BY H. W. BOONE, M.D.,
SURGEON TO ST. LUKE'S HOSPITAL, SHANGHAI, CHINA; PRESIDENT OF THE MEDICAL MISSIONARY ASSOCIATION OF CHINA, ETC.

IN this paper I hope to give a brief sketch of my experience among the Chinese in the treatment of hernia by the open method. Hernia appears to be common among the Chinese, but only a small proportion of those suffering from it ever apply to a foreigner for treatment. In examining people in the out-patient department one occasionally finds that they have a hernia, but the majority of these cases decline any treatment for their trouble. As they do not use any kind of truss, and as surgical relief is unknown to the native doctors, the number who die annually from strangulated hernia in this nation of three hundred millions of people must be very large indeed. From time to time we see the report of a case which has been operated upon by some foreign surgeon, but at best only a very few have been so treated. This whole subject of hernia amongst the Chinese, with the best way to obtain their confidence and to get them to apply for relief, and the methods of relief which will be best for them, is well worthy of our careful study and attention. I will relate a case that will serve to illustrate the method which I have commonly used when an operation was necessary, and then proceed to the general consideration of the subject:

W. A. F., male, aged forty-two, married, servant; has been in the chain-gang for some time; is poorly nourished; has led a dissipated life, and has smoked opium. He has a congenital inguinal hernia on the left side, which has given him trouble for the past two years; suffers from colicky pains and dragging sensations in his back and sides. The hernia is reducible. He desires to be operated upon for the relief of pain.

October 3d, assisted by Drs. Jamieson, Reid, Alsopp, and Whitney, under chloroform and with full antiseptic precautions, I cut down upon the sac, which was densely adherent to the surrounding parts. The cord was carefully separated, the sac freed, and, having ascertained that the bowel was returned to the abdominal cavity, the sac was twisted and transfixed at the highest point which could be reached, with a double chromic catgut ligature, the strands of which were interlocked, and then the neck of the sac tightly tied and cut across below the ligatures; the long ends of the ligatures which secured the sac were then made to pass through the pillars of the ring, were drawn tight and tied firmly. The remainder of the sac was left *in situ*, a drainage-tube was inserted, the wound sewed up, and a dressing of iodoform wool, absorbent cotton, and gauze bandages was applied, with an elastic bandage over all. The temperature on the sixth day was 101.9°, owing to a slight inflammation of the testicle, with a little fluid in the tunica vaginalis. On the eighth day the temperature was normal, and from that time there was no further trouble. On the twentieth day a small portion of the end of the sac was removed with scissors from the track of the drainage-tube, and on the twenty-eighth day the parts were firmly healed. The patient was kept in the hospital until the forty-fifth day, and was discharged cured, with no impulse on coughing and no sign whatever of the hernia.

The hospital record shows six cases operated upon and discharged as cured, and one death after operation. In this latter case I tied the sac with catgut, but omitted purposely to suture the pillars of the ring, relying on some statistics which went to show that this was not necessary for the success of the operation. The patient had a good deal of retching and vomiting after the chloroform, and the catgut slipped, with the result that the bowel was exposed in the neck of the sac. He died from peritonitis. I now use strong silk made perfectly aseptic, as it seems less liable to slip or to untie than the catgut ligature, and I prefer to stitch the pillars of the ring with strong sutures.

The above operation has often been called "the radical cure." This is evidently a misnomer, for the percentage of relapses, even in the hands of the most experienced operators, is large, some writers placing it as high as 31 per cent., though others claim better results. In the words of Mr. Mitchell Banks: "The operation is not, in the proper sense, a radical cure, since the inguinal ring is not closed." Mr. Banks's conclusions as to the nature and value of the operation are well worth quoting:

"1. The wearing of a well-fitting and well-acting truss is by no means so great a burden as is represented.

"2. The operation is very seldom indeed required in children. A well-fitting truss, worn for a sufficiently long period, will cure the vast majority of herniæ in children. In a few cases where the omentum is adherent, or where the hernia is very large, or where no proper precautions are observed with reference to the wearing of a truss, an operation may be performed.

"3. In small femoral ruptures with adherent omentum, the operation is especially to be advised. The same rule applies to inguinal ruptures with adherent omentum, and to such as are of very large size.

"4. No patient should be operated upon if the rupture can be well kept up by a truss."

These remarks apply quite as well to Chinese patients, and it seems to me that if we had a supply of suitable trusses, and took the utmost pains in fitting them accurately to our patients, at the same time using every means within our power to get them to return to us for observation, the number who would require a radical operation would not be very large. From time to time I have given trusses to patients, some of whom have returned, and they seemed to be kept in a comfortable condition by the

[1] Read at the monthly meeting of the Shanghai Medical Missionary Association, January 20, 1891.

use of the appliance. A greater number never returned to report, and I am unable to find out what benefit, if any, they derived from the appliance.

In the case of infants, I have used for some time the treatment advised by Mr. Coates. A folded skein of wool should have the end with the loop laid over the emptied inguinal canal, the other end being carried above the opposite pubes across the front of the adomen, round the back and over the hip of the affected side. The free end is then passed through the inguinal loop, carried round the inner side of the thigh, and over the buttock, to be firmly secured to that part of the skein which is already just above the great trochanter. This does not chafe nor hurt the child, is easily readjusted, and can be applied so as to exert accurate compression, and in due time cure the hernial protrusion.

In conclusion, I may say that my purpose has been to speak of my own experience, and not to weary the reader with the general statistics of the operation. It is the fashion at present to present long and elaborate tables of statistics, and these are very useful. As, however, we in Shanghai have the advantage of access to a fairly large number of medical periodicals, and to a reasonable number of the latest books on medical and surgical subjects, I shall suppose that we are well acquainted with the general trend of the professional mind on this question. When I was at home three years ago I had the privilege of seeing the various operations for the cure of hernia performed by some of the leading men in America, England, and France, and of learning their opinions upon the subject. Although the operation of Macewen has (in his hands) possibly achieved better results than any other operator can claim, the operation has not been so successful in the hands of other equally prominent men, and it is doubtful if any one method can claim great superiority over that of its competitors. While all have their drawbacks, the operator must select the operation best adapted to each individual case, and here he can show his skill and good judgment.

VON GIETH'S DRESSING FOR THE CHEST IN PNEUMONIA AND PLEURISY.

BY W. THORNTON PARKER, M.D. (MUNICH), M.M.S.S., OF SALEM, MASS.

IN THE MEDICAL NEWS of March 21, 1891, is reprinted an item from the *Annals of Gynecology*, of February 18th, concerning "A New Method of Dressing the Chest in Pneumonia and Pleurisy," and recommending successive layers of pure collodion and absorbent cotton. It is undoubtedly true that there are many objections to this method, and it will readily occur to anyone that such a procedure is not only expensive and inconvenient, but not always available.

Von Gieth, Professor of General Medicine in the University of Munich, has given the treatment of chest diseases considerable attention, and his very great experience in the wards of the General Hospital of Munich lends additional weight to his eminent ability as a practitioner. Von Gieth does not approve of the many applications so well known to the profession, and is especially averse to the heavy, wet, and uncomfortable poultices of Indian meal, flaxseed meal, etc., so often employed in this country. Any wet application must rapidly cool and then the poultice ceases to be of benefit, and can be of more or less injury.

The one application which Von Gieth recommends, and which has proved so valuable in many cases, is *pure* olive oil (oleum olivæ). In all diseases of the chest, whether in infancy or old age, olive oil stands first and foremost, not only as especially soothing and agreeable, but as being best suited to maintain equable temperature where warmth is most needed.

Since 1872 I have witnessed the value of this treatment in many cases, and nothing can supply the place of olive oil in my practice as a grateful and healing local application in diseases of the chest, either acute or chronic. The oil must be the pure olive oil, and not some one of the substitutes so frequently offered as "just as good." Vaseline, lard, "goose-grease," "camphorated oil," are all preparations greatly inferior to pure olive oil, and cannot act in the peculiarly healing and soothing manner which we are able to obtain when we employ the latter.

The method which has been found most convenient is to pour the quantity of olive oil required into a moderate-sized bowl, which has been previously warmed, which will take off the chill from the oil. A large strip of soft cotton cloth (an old pillow- or bolster-case will give just what is required) is then prepared, to completely encircle the patient's chest. The strip is then placed in the bowl of oil until it is completely saturated, or rather supersaturated, with the material. This is then applied to the patient's chest, and outside this strip a second one is placed of dry cloth, and when necessary a third strip may be used. Flannel and linen are not suitable in this treatment—old, soft, white bleached cotton is what is needed. The strips are secured and held firmly in place by safety-pins.

This treatment will be found most acceptable to patients and successful in results. At first the idea of the oil next to the skin may be repulsive, but very shortly patients learn to like it and recognize the comfort its application is almost certain to induce.

I have called attention to this practice in the medical journals from time to time, and my experi-

ence in practice has convinced me that there is nothing better for external application in these serious and so often fatal diseases. Prompt action with the olive oil, hot-water bags, hot beef-tea, and whiskey punch, with simple expectorants, like the lozenges of mist. glycerrhiz. comp. made by Wyeth & Co., has often held the threatened attack of pneumonia successfully at bay, and has been the means of saving many lives. *Nursing*, and *not dosing* is the common-sense treatment of pneumonia. We are constant witnesses of cases, especially in old and delicate people, where this course of treatment, if used promptly and thoroughly, would be sufficient to save life, and where the need of it has been followed by a fatal termination.

It is well worthy of careful attention by medical men, and I think, without doubt, the employment of olive oil in chest diseases is steadily increasing.

TOPICAL TREATMENT OF DIPHTHERIA AND CROUP.

BY B. M. BEHRENS, M.D.,
OF CHICAGO.

IN presenting this paper I wish it accepted as an argument in favor of an exclusively topical treatment possessing the aim of destroying the diphtheritic infiltration wherever it is found.

It will be agreed to by the medical fraternity that we have heard all we wish to hear about the general treatment of diphtheria and croup, and in spite of all assertions to the contrary, there is not one honest physician bold enough to proclaim this or that pet remedy as infallible. Whether it be given internally, or locally as gargle, vapor, or spray, it is sure to fail, except in cases of slight extent or infection, or in cases where Mother Nature herself succeeds in expelling the disease—but this is a complete failure so far as the efficacy of the remedy is concerned. There are, perhaps, physicians who still hold to the old creed, that diphtheria is a constitutional disease, with secondary local manifestations in the throat, and therefore they adhere to their pet remedy as being superior to all others; but in the minds of those who hold the other view, that diphtheria is primarily a local disease, and the constitutional symptoms secondary, it is evident that the present mode of treating it is inadequate. It is therefore, in my estimation—and my opinion is entertained by many—a Utopian dream to suppose that a remedy ever will be discovered whose specific action is of such a nature that it will check or counteract the production of toxic material or prevent its absorption. By this I mean a remedy of a chemical nature, and not one which may be discovered by bacteriology. Periodicals, and even the newspapers, are filled with "sure cures for diphtheria," that are tried to-day, to be laid aside to-morrow as sadly wanting. For, what can we expect but increased filth from remedies, taken internally or applied as gargles, sprays, and the like, the action of which on the diphtheritic plague can never be more than superficial? Whoever believes in any further effects is the victim of self-delusion, or of gross ignorance of the characteristics of the disease. And even if we must allow, to sprays at least, some mechanical effect—for instance, on the superficial layer of the diphtheritic infiltration—is it not more than likely that these will have no effect on infiltrations hid away in the deep pouches of the tonsils, or back of them? Besides, the danger lies not in the superficial layer of the infiltration, as we see it, as this contains only epithelium, pus cells and detritus, but in the deep layer of the mucous membrane, where absorption of the toxic products takes place, and the diphtheritic bacilli multiply. For this reason, and because as a usual thing the fauces are first attacked by the diphtheritic infection, what is demanded of us is the complete destruction of the infiltration, even if it must take place at the cost of some healthy tissue beside.

Some time ago I had the pleasure of presenting a paper on hypertrophic tonsils, in which I incidentally mentioned three cases of diphtheritic tonsillitis, with all the characteristic symptoms of the disease, which had come under my observation, and in which the disease was cut off, so to speak, by tonsillotomy. This result was, to my mind, satisfactory evidence that a removal, or, what is next best, a thorough destruction of the diphtheritic infiltration, is the sure cure, and that nothing else will answer. I regard it as an indorsement of the destructive procedure I have always followed in my practice, and from which I have never swerved, unless compelled by circumstances. I have never seen any reason to alter my views, or to abstain from this proceeding, unless the disease had assumed such proportions that it was beyond the reach of treatment of any sort. There are exceptions to every rule.

The shortcomings of my procedure are admitted in cases that come under observation late, and where the toxic symptoms pursue such a rapid course that we are only in time to witness the last struggles of the victim of the disease, although, even in the most desperate cases, agreeable surprises have taken place not infrequently. We give stimulants as long as there is a spark of life, and we are just as much justified in our efforts to destroy the infiltration as long as life exists. Unless the patient is moribund, and all hope of saving life is gone, I never hesitate in applying my method; and when I say that I have never regretted it, even in the most desperate cases,

this is the best recommendation I can give it. We must remember that even in such extreme cases as diphtheritic infiltration of the throat, nose, and larynx, the principal locality where the absorption goes on is in the throat; I mean in the tonsils and in their immediate surroundings, not only because this place is usually the first infected, but also because this part is most richly provided with glandular structure, which not only furthers the absorption of the diphtheritic poison, but also is the least likely to be interfered with by any remedy whose aim is only a superficial action, and not a total destruction of the infiltration itself. It is, therefore, in my estimation, no contra-indication that the diphtheritis extends above or below; on the contrary, by checking the main source of absorption, so much is done toward checking the spreading of the infiltration, that we can then regard infiltrations in other localities with a certain degree of ease. In short, I mean to say, that the disease is more than half conquered when we can succeed in destroying the infiltration *in* and *around* the tonsils. This may be deemed a bold assertion, but I can only say it is my conviction. But it will be willingly admitted, that with such complications as I have spoken of, the control of the disease is lost, more or less, so far as topical treatment is concerned. The difficulty increases in the same proportion that the infiltration extends, and the natural deduction from this is that the destroying process is best adapted, and most likely to give the best results at the onset of the disease. What is easy and feasible to-day, is perhaps out of the question to-morrow. If it were practicable, I should say, Never go to a case of diphtheria without the galvano-cautery; but I must limit my advice to nitrate of silver.

If this method be adopted, it will be a question for future solution as to what cautery is best adapted for the purpose of destroying the infiltration. I must hold to nitrate of silver, as being a remedy whose action is deep enough for the purpose, which does not extend further than we wish, and any superabundance of the agent can be immediately neutralized with a harmless stuff—common salt. My experience is limited to this, and because of its having served me so well in my practice it has become my pet remedy; but, of course, I am willing to give it up for another cauterizing agent, should one prove to be better. But the question here is only as to the merit of my proceeding.

To come, now, to the details of the application of my method, I will state that I never call on any case of throat disease without my head-reflector, tongue-depressor, cotton and cotton-holders, and the nitrate of silver. This I have mitigated with 10-per-cent. nitrate of potash, so that it will not so easily crumble or break. While it is melting I dip my probes in it, one with a blunt, another with a cone-shaped, sharp point; this last for the purpose of bringing the cautery deep into the follicles of the tonsils. The ends of the probes are roughened, so that the nitrate of silver will not fall off. The first thing I do is to place the light so that I can with ease throw it from the reflector into the throat. As objections in some form usually are met with in small children, I place them with the lower half of the body on somebody's lap, while I take the child's head between my knees—the position we employ in treating eye diseases in children. By pressing the tongue down and mopping off most of the detritus, I can at once get an idea of the extent of the infiltration. The first object of my attack is the locality in and around the tonsils, and I always satisfy myself that the work is done here thoroughly for the above-mentioned reason. Next comes, in the same sitting or later, the cauterization of other localities. A little while afterward I apply with the cotton-stick a solution of common salt.

As above said, we have, to some extent, lost control where diphtheria extends upward to the nose or downward to the larynx—at any rate, so far as topical treatment is concerned; so I shall only add a few words about this complication of the disease. The treatment here must be symptomatic, and according to the severity of the symptoms. If the nostrils are clogged with mucus and pus, I apply a nose-douche of some non-irritant disinfecting fluid in grown-up patients; in small children the air-bag alone will do in many cases, and *must* do, as injecting in a child's nostrils usually meets with a stubborn refusal. From the effects of nitrate of silver in other localities, we may infer that this agent would be likely to do much good here also, but it would not be advisable to employ it in sufficient strength to be of any use, because of its irritating effect on the non-affected parts, as it often causes quite severe pain. With our inability to treat this part properly, it is consoling to know that there is no immediate danger to the patient's life, or very little, compared with the danger involved in diphtheria of the larynx.

Diphtheritic and croupous infiltrations are clinically the same disease. The œdematous swelling of the laryngeal mucous membrane that accompanies the infiltration, together with the paralysis of the abductor muscles, are the main factors in bringing about the threatening suffocation. When I propose to apply here also the same agent, I am well aware of the difficulties and uncertainties of the procedure. Still it has been of so much service to me in my long practice that I feel compelled to recommend it. It is only fact, and not fiction, that cases that seemed to demand an immediate tracheotomy were benefited by the introduction of a 20-per-cent. solution of nitrate of silver repeated as often as the symptoms

required. For introducing this solution into the larynx I employ a bent cotton-holder having about the same angle as that which is used for introducing a tube into the larynx. After having soaked the cotton batting in the solution, I squeeze out most of it again, pull the patient's tongue out as far as it can be done without too much discomfort, and by a rapid movement introduce the instrument into the larynx. A choking spell, that soon passes away, indicates the success of the proceeding.

In many cases it is not practicable to pull the tongue out, but this same treatment can be made a success by simply pressing the tongue down with the tongue-depressor. As there is no harm in repeating it, if the first attempt fails, since the diphtheritic infiltrated fauces can easily stand a 20-per-cent. solution, it must not be given up until the choking announces its success. But, on the other hand, the more rapidly such manipulations are made the better for the patient and physician. How often these applications are to be made depends upon the severity and duration of the symptoms. To keep down the swelling in the larynx an external application of ice-bags, changed as often as required, will be found of very great utility, and children, after becoming used to them, will very often crave for them again, if they are taken away, although there is in any other way not much comfort connected with their use.

This is a general outline of my method of treating this disease. It would take me too long to detail it further, and I would probably trespass too much upon your indulgence if I further mentioned the advantages, and certainly, also, the shortcomings, of this proceeding, in dealing with a disease that just as often leads to good results under the most innocent and expectant treatment, as it baffles the skill of the most expert and conscientious physician. I have no statistics with which to support my statements. I can only say that for fifteen years I have treated no case of diphtheria in any other way. When one physician states that he lost some cases because his patients would not take the medicine, and another one that he never lost a case treated with this or that drug, then the value of statistics becomes very problematic. Only in hospitals for diphtheritic patients, where one or the other proceeding would be given a fair trial, would statistics be of any value. But, so long as no such opportunity exists, individual claims for this or that remedy or procedure must be considered of doubtful merit. I do not expect any unconditional acceptance of my views, but I do expect an unconditional surrender of the old ones. We owe thanks to the bacteriologists who have branded this disease as a filth disease, that is, one bred by filth and breeding filth, and one whose invasion usually starts in the throat. There is no loop-hole through which we can escape the urgent necessity of doing away with the filth. Nobody would think of soaking a diphtheritic ulcer externally with some indifferent drug, but he would cauterize it in one way or another to bring about healthy granulations, and thereby check the hideous disease. And why not, then, do the same thing in the throat? What excuse is there, other than customary laziness or hopeless fatalism, for not even taking the trouble to inspect the throat, and for prescribing some innocuous drug that can only increase the filth, at best, but that can never have the effect of checking the production of the toxic material, or of preventing its absorption? We scoff at Christian-science healers and faith-cures, but if this way of treating diphtheria is not faith-cure, then I do not know what it is.

Before finishing my paper, allow me to mention what I consider a real advance in the treatment of this disease—that is, the use of the spray. It does not meet all the requirements, but I cannot help regarding it as a step in the right direction. It has a sound basis, so far as it intends to remove the filth, and aid in its expulsion and in the sterilization of the infiltrated part. But I fail to see how we can expect from it any effect at all comparable to that which destruction of the infiltration yields. I am more inclined to believe that these two agents—cauterization and the spray—employed simultaneously, would give the best results, but I have not employed the spray so often that I am prepared to speak more definitely about it. But, then, the spray would have to be employed almost continuously, and not only once in a while and by inexpert hands. If such a proceeding can hardly obtain any footing, it must rather be ascribed to the difficulty of practising what we preach than to the failure of the method.

Another achievement that apparently indicates progress is the intubation of a diphtheritic larynx. The dexterity which this implies would find a better field if it were used for the purpose of effecting a change for the better in the diseased condition of the larynx. This it cannot do, and has, therefore, no more justification than that of being a bloodless relief from suffocation. The enthusiasts do not claim more for it either, so far as I know, unless it is to raise the percentage of successful results upon those intubated, after it becomes more commonly adopted and improved in its working details. This has not been effected up to this time. About 30 per cent. saved sounds better than 70 per cent. not saved. In this it stands equal with tracheotomy, but in the infliction of suffering upon humanity it stands far above the latter procedure. How far it will succeed in replacing tracheotomy is a question the future will solve; but even if it does do so, I cannot see any grand achievement in the method as

a way of dealing with a filth disease. By either of these two methods the disease is being complicated, certainly from necessity, as long as fatalistic prescribing reigns supreme. But when the view once shall be commonly accepted, that a diphtheritic infiltration in the throat ought to be as severely dealt with as a diphtheritic ulcer externally, then there will be less call for either of them. If we are to attain this end, then it is our duty to arm ourselves with the head-reflector, to see for ourselves, to make the diagnosis, and to carry out the treatment, and not merely prescribe something. This reached, something better is sure to follow.

DEATH FROM INHALATION OF GASES GENERATED BY A GASOLINE STOVE.

BY N. K. MCCORMICK, M.D.,
OF NORMAL, ILL.

MY attention was called to this subject by an accident, distressing in its results, which occurred in Normal, September 17, 1890.

At 8 o'clock in the morning of that day I was called hurriedly to the house of William Young. On my arrival I was first shown an infant aged four or five months, and was told that the child's parents were up-stairs and were thought to be dead. The child was almost lifeless, was barely breathing, and I could not detect any heart-beat. His hands and feet were cold. We applied heat and rubbed him with alcohol and hot water. This soon revived him, but we were obliged to continue the rubbing at intervals for an hour or more. As soon as I could leave the child, I went up-stairs and found the bodies of his parents in a small room, lying side by side on the floor, before a gasoline stove. The woman was lying on her right side, with her face away from the stove. The man was lying flat on his back, his shoulder and arm being thrown across her knees. It was evident from the position of the bodies that the woman had fallen first.

Before I arrived the neighbors had practised artificial respiration, but their efforts were of no avail. The room was small. The windows had been tightly closed. On a cupboard stood a lamp, which was still burning when the bodies were found. The stove was a "Globe, No. 5," manufactured by the Standard Lighting Company, of Cleveland, Ohio. The gasoline tank was entirely empty.

The developments at the inquest were substantially these: Mr. G. was a student of the Normal University. With his wife and baby he was keeping house in two small rooms. These rooms were not directly connected, but to go from one to the other it was necessary to pass through a narrow hallway. The front room they used for a sitting-room and bed-room and the back room for a kitchen. In the morning they were heard in the back room as early as 5 o'clock, and as late as 6 o'clock a young lady passing through the hall heard them talking with each other. At this hour there was no odor of gas in the hall, though the young lady noticed that light shone through the doorway. On examination we found that the door did not fit well, and that considerable force was required to completely close it.

About 7 o'clock Mrs. Young heard the baby crying for a long time, and going up-stairs found it lying in its crib in the front room. She wheeled the crib through the hall to the door of the back room and at once noticed the smell of some gas. Getting no response to her rapping, she threw open the door, and saw the bodies lying on the floor. She left the baby lying in its crib in the doorway, rushed down the stairs, and gave the alarm. Neighbors hurried in, took the baby down-stairs, and threw open the windows of the room. The man who was first in the room stated that he heard a noise as of gas escaping from the stove, and he at once closed the valves of the burners. He did not know whether there was any flame at the burners or not. A young lady who was next in the room stated that a lamp standing on the cupboard was burning, and that she turned down the flame.

The question was put to the man, "Did the gas smell like the vapor of gasoline?" His answer was "No; it was more like the smell you get from a hard-coal stove when you see a blue flame." The young lady did not hear him testify, but in reply to the same question, she said: "No; it was the same smell you notice when you first light a fire in a hard-coal base-burner stove."

From what I know of this case I am convinced that death was due to the accidental inhalation of some poisonous gas. It could not have been simply the vapor of gasoline, for the lighted lamp would surely have ignited that had it been present in any quantity.

Gasoline consists essentially of a mixture of three forms of hydrocarbon—pentane, hexane, and heptane. The normal product of combustion of gasoline is carbonic acid gas. To effect complete oxidation, an enormous quantity of oxygen is required, a hexane hydrocarbon requiring nine and one-half volumes of oxygen to one volume of gas.

There are three gases which might have been formed, any one of which could cause death if present in sufficient quantity. These three are acetylene, carbonic acid gas, and carbon-monoxide.

Acetylene exists in coal gas, and possesses a high illumininating power. It is formed by the imperfect combustion of organic gases or vapors, and gives the disagreeable odor detected in a room where a lamp has been burned "low" for some time. Liebreich, so long ago as 1868, pointed out that acetylene forms a combination with the hæmoglobin of the blood, and in quantity it must be considered a poison.

Carbonic acid gas (CO_2) is essentially the product of decomposition. Among its sources of production are respiration, fermentation, and oxidation of

vegetable and other organic bodies. It constitutes the choke-damp or after-damp of the miners, and is the principal cause of death in coal-mine explosions.

In cases of carbonic acid poisoning, if the gas be pure, it causes death instantaneously. It produces spasm of the glottis, and death is immediate from apnœa, none of the gas being able subsequently to enter the lungs. When this gas, somewhat diluted, is inhaled, there is immediate loss of muscular power. The patient drops without a struggle, unable even to call out. When the gas is still more diluted the patient complains of tightness in the throat, or heaviness and pain in the head, of drowsiness, of ringing in the ears, and there is a gradual loss of muscular power. There is lividity of the countenance, violent cardiac action, hurried respiration, and, in rare cases, convulsions and vomiting. These symptoms are followed by a state of complete coma. The amount of carbonic acid gas which must be present in a room must be viewed from two standpoints.

First: Where air is contaminated simply by the addition of the gas.

Second: Where, as in this case, the carbonic acid gas is produced in the apartment by combustion or respiration, or by both.

Here the normal oxygen of the air is consumed in the production of the carbonic acid gas, so that, while the amount of gas in the room is increasing, the amount of oxygen is decreasing, which makes the increase of the proportional amount of carbonic acid gas in the apartment very rapid.

Each adult requires for safe respiration 20 cubic feet of air each hour. An ordinary candle will vitiate the same amount of air in this time.

The room in which this accident occurred was closed tightly except a very small space about the doorway, which was noticed only from the fact that light shone through it. The room measured 10 by 13 feet on the floor, with the ceiling eight feet high, giving a total capacity of 1040 cubic feet.

Tending to vitiate this air we have:

First. The respiration of two adults.

Second. The burning lamp.

Third. Four burners of the gasoline stove.

Two adults would vitiate in one hour 40 cubic feet of air. The lamp would vitiate fully 60 cubic feet. A stove burner, in its consumption of gasoline, represents a power equal to thirty or forty candles, so that each burner will, in one hour, vitiate 600 cubic feet of air, and the four burners would vitiate 2400 cubic feet.

While we have a room containing only 1040 cubic feet of air, we have agents capable of vitiating more than twice that volume in one hour. The fact that the door was slightly ajar does not permit us to hold so precise an estimate as the above to be strictly accurate, but the opening was so slight, and the agents of vitiation so overwhelming in their force, that the conclusion reached must be the same.

The carbonic acid gas has a specific gravity of about 1.5, and would be more dense near the floor, so that a person stooping over would necessarily inhale more of the gas than when standing erect. While this alone could cause the accident under consideration, there is a third gas which must also be considered.

Carbon monoxide (CO) is a colorless gas, having a slight odor. It is breathed into the lungs freely, and is a very active narcotic poison. It is generally held that the poisonous action of carbon monoxide depends on the formation in the blood of a compound of the gas and hæmoglobin, giving the blood a bright-red arterial appearance. This compound is fixed and stable.

We are all familiar with cases, or accounts of cases, where poisoning has resulted from the inhalation of carbon monoxide thrown out from a hard-coal base-burner. Two such cases have already occurred in this county during the year.

In these cases the formation of the gas can be easily explained. Air enters at the bottom of the grate and carbonic acid gas is formed; this passes up through the grate, and taking up more carbon, becomes carbon monoxide.

It is my belief that in this case the deaths were due to the presence of both forms of carbon gas. Primarily, the carbonic acid gas was present as the product of combustion, but not in a quantity sufficient to cause death of itself, for in that case combustion would probably have ceased.

After the stove had been burning for some time, the supply of oxygen became limited, and the product of combustion was carbon monoxide rather than carbonic acid gas.

I believe that Mrs. G. noticed the odor of the carbon monoxide, and stooped down by the stove, possibly to adjust a burner, and while in this position inhaled enough of the gas to be overcome by it at once. Her husband stooped to aid her, when he was also overcome by the fatal gas and fell across her body. Death in each case was practically instantaneous.

It is a matter of great regret to me that I did not make a post-mortem examination of the bodies, at least to the extent of examining the condition of the blood. That alone could have decided positively the exact cause of death. Had the blood been wholly arterial we would know that death was caused by carbon monoxide gas, while if the blood was wholly venous, we would know that the carbonic acid gas was the cause of death.

Some weeks later I was called to another house about the same time in the morning.

Arriving there, I found a woman reclining on a bed. I was told that she had fallen over suddenly, but that she recovered consciousness soon after the messenger started for me. She stated that she was subject to such attacks and needed no treatment. Before leaving I noticed a gasoline stove, of the same make and pattern as that used by Mr. and Mrs. G. I examined the stove carefully; it was burning well, and no odor of gas of any kind was perceptible, even close to the burners.

I have since learned that soon after I left the house the woman again lost consciousness and that her son fell to the floor as in a faint.

Neighbors rushed in and at once pronounced it another case of gasoline poisoning. These neighbors stated that there was a strong smell of gasoline in the room. The patient, and the woman who was attending her, both state that at no time could they detect any unsual odor.

The doors stood wide open, and I do not understand how any such accident could have taken place in a room so well ventilated. I am positive that the patient's first attack was not due to any such cause. Her son was badly frightened when I was there, and I think it quite possible that he fainted on seeing his mother's condition.

I have been told of this case, which occurred in Bloomington:

A large, strong man was overcome by gas while bathing in a small bath-room. The water in the tub was heated over two large gasoline burners. This accident was undoubtedly due to the presence of one or both forms of carbon gas. The room was small and the oxygen present was quickly consumed by the large burners of the heater, leaving an atmosphere heavily charged with carbonic acid gas. Happily, he was heard to fall and was rescued at once. He was unconscious at the time, and had he not been promptly removed from such an atmosphere would surely have perished.

I cannot see that in the case of Mr. and Mrs. G. any blame can be attached to this special make of stove, for such an act can and will occur with any other make of stove under the same conditions. Neither do I think we should condemn the use of gasoline stoves in general.

The practice of heating water in bath-rooms with the gasoline heaters I believe should be condemned, for the reason that extra-large burners are used, consuming the oxygen very rapidly, while the rooms are almost invariably small and poorly ventilated. There is, also, the danger that the victim might fall face-down in the tub, in which position a few inches of water would suffice to drown him.

I cannot learn of any other accidents similar to that happening to Mr. and Mrs. G. This is probably due to the fact that these stoves are used almost exclusively during warm weather, when the doors and windows of houses are open, affording free ventilation. This calamity was essentially due, not to the use of the gasoline stove, but to the insufficient supply of oxygen. What I wish to urge is not the disuse of gasoline as a fuel, but the importance of an abundant supply of fresh air; for with proper ventilation such an accident cannot occur.

ORIGINAL LECTURES.

SOME OF THE PRINCIPAL VARIETIES OF DELUSIONS MET WITH AMONG INSANE PATIENTS.[1]

BY HENRY M. LYMAN, M.D.,
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN RUSH MEDICAL COLLEGE, CHICAGO, ILL.

I SHALL detain you but a short time in considering some of the principal varieties of delusion that are met with among insane patients. We find there are delusions among patients who are the victims of mania which have a characteristic form; there are delusions which are met with among cases of melancholia that have characteristic features; there are also delusions among the victims of general paresis which have marked and peculiar characteristics; and lastly, there are the delusions of paranoiacs that have decided family characteristics. The delusions of mania and melancholia are the most varied and have the least stability in their type. Patients who are maniacal present the delusion of exaltation as a general rule. They fancy they are gifted with great powers; that they have made great discoveries, or that they are endowed with remarkable qualities. But they have no very definite and sustained framework for this delusion. The delusion to-day is about one thing, to-morrow it is about another thing, and the next day still another object. I remember the case of a patient who was maniacal. It was what might be called a case of mania secondary to pneumonia. She labored under the delusion that she had been in heaven and was entrusted with a message to her husband, but though frequently alluding to this, she never could give any form to this narrative, and she did not describe the experience she had in heaven. The only thing she could say was that she had been in heaven and was entrusted with a message from God to her husband. She could not tell what the message was. After a few days the mania subsided and she recovered without any persistent form to the delusion.

Then again, in cases of melancholia the delusion is in like manner unstable. It is not definite and has no persistent framework. It is usually of a desponding character. The patient is overwhelmed with a sense of misfortune, of wrong-doing perhaps, and yet can give no definite shape to it. I have seen patients laboring under this form of delusion who would complain of

[1] Remarks made at a recent meeting of the Chicago Pathological Society.

having done something that was very wrong indeed. They felt bad, but could not tell exactly what they had done.

A gentleman came to see me (brought by his physician), a banker, a man of wealth and fortunately situated, who was suffering with the characteristic ill-health manifested by cases of melancholia. He was oppressed with this feeling of something wrong, a general discomfort which he could not name, describe, or give reason for. I asked him if his business troubled him. He said "No, it was not that;" and his physician assured me that it was not his family affairs, as they were pleasant and harmonious, yet he had a sense of oppression without giving a definite account of the fragmentary delusions under which he was laboring.

In general progressive paresis we find there is a marked state of delusion; it often assumes a more definite shape than do the delusions of true mania or melancholia.

I remember a patient suffering with mania when I first visited him, who said that he had discovered a method for squaring the circle, and he undertook to explain the matter to me, but as soon as he tried to do so he got confused and could not explain it. The next day he was forgetful entirely of his delusion of squaring the circle and imagined himself to be an electrical apparatus. He would place his knuckles near the face of the person near him and say "Don't you feel that shock?" The next day he would forget all these notions, and the delusions under which he labored would assume an entirely different shape. In general paresis patients labor under some distinct and definite delusion which assumes a shape that is oftentimes constant, but it does not usually persist for a long period of time and does not so thoroughly dominate the life of the patient as do the delusions of paranoia, yet these delusions often systematize themselves very considerably in general paresis. I once went to see a patient who was suffering in the early stages of general paresis. He was very considerably excited, and labored under the delusion that he had considerable property under his control, and this property was in his back-yard. He had established there an extensive tree plantation. He took me into his yard and showed me the trees he had there. There were trees from Sweden, Germany, and other valuable trees brought from different parts of England, Scotland, and the Eastern States. He then told me his plans. He was going to establish a saw-mill and cut a canal through to the Mississippi River. He showed me the canal he had started behind the back-fence in his yard. There was a little muddy canal and this was supposed to reach the Mississippi River, and barges and steamboats would come up to take away the property he was going to manufacture there, and he was going to amass an immense fortune in that business. This was a very systematic and constant delusion under which he was laboring, but it was a secondary consequence of a primary disease. Such delusions terminate in a comparatively short time with failure of the mental powers —in fact, the patient lapses into a condition of complete general paresis, the mental faculties disappear, and at last the patient forgets about his delusions, has no more of them, gradually sinks, and dies.

When you observe a paranoiac you soon discover that his delusions are of a more definite and constant character than those which I have mentioned. They frequently persist as long as the patient lives, and the patient's condition is not a consequence of some other form of brain disease, but it is the result of a faulty development of the brain structure itself. A large number of paranoiacs are born with such a defective condition. They have perhaps inherited their form of brain disease or defect; or they have acquired it through faulty habits of life, and the children that are born of such persons have a predisposition in certain morbid directions, which is the primary cause of their trouble. They are not physically diseased; that is, they have no morbid tendency to particular forms of inflammation, degeneration or other change in the brain structure, but their brain was constructed originally upon a faulty plan, and out of that defective formation has developed the peculiarity of the delusion to which the patient finally becomes subjected. The delusion that exists is a permanent thing, so to speak, continuing as long as the patient lives. Unless he contracts some intercurrent disease he may live in comparatively perfect health, and may attain to a reasonably old age. That is why the delusions are so persistent, and why they have the characteristic of being what is called systematized. We speak of the delusions that occur in mania, in melancholia, and the majority of those that occur in general paresis, as being unsystematized. They are dependent upon varying conditions in the brain. The brain disease is the cause of the delusions, and as the brain changes its condition through disease, excitement, or depression, the delusions will correspondingly vary, finally becoming extinct with the extinction of intellectual life. But in the case of the true paranoiac his bodily health is perfect, his brain is not the seat of inflammation or any particular degeneration, but he goes along leading this warped and twisted life, his perceptions giving rise to delusions which grow out of the defect in the action of the logical machinery of the mind in the brain. For instance, Dr. Clouston tells us of a man who insisted that two and two did not make four, but four and a quarter. He was an expert accountant and kept the books of the asylum with which he was connected, using the ordinary system of mathematics, but it was all wrong. He spent much of his time in working out problems in Euclid and in constructing logarithms according to the theory that two and two made four and a quarter. When he died he left immense manuscripts to the University of Oxford. Now, this man had a twist in the construction of his brain, and as a consequence of that defect the perceptions derived from the external world gave rise to delusions which were not to be considered as the products of disease, but rather as consequences of defective organization of the brain.

A CASE OF FRACTURE OF THE ORBITAL PLATE OF THE FRONTAL BONE, WITH RECOVERY WITHOUT AN OPERATION.

BY FRANK W. THOMAS, M.D.,
OF PHILADELPHIA.

THE following case which I report is of interest, not only because it is somewhat unique, but because of a certain medico-legal bearing which it may have, as illus-

trating the possibility of serious injury to the skull and its contents, without sufficient external lesions to even suggest the nature of the injury; and because its lesson is somewhat opposed to a rule laid down by Dr. Deaver in a paper read before the Philadelphia Neurological Society, on January 27, 1890, in which he makes the following remark: "I trephine when I suspect extra-dural hæmorrhage in fractures of the orbital plate of the frontal bone."

About eight o'clock in the morning of November 20, 1889, I was summoned to see W. L., a carpenter, who, while working in a house in the course of erection near the old "Indian Rock," Chestnut Hill, fell from a height of over thirty feet, striking his head upon a plank.

The lesions and symptoms presented were:

(*a*) Swelling and ecchymosis of the right peri-orbital region and cheek, and very slight excoriation above the brow.

(*b*) Impacted fracture at the right wrist-joint.

(*c*) Contusion of the arm, chest, and leg on the right side.

(*d*) Sensation was complete, and while the patient was somewhat "dazed," he was able to describe his position and fall, with sufficient accuracy to tally with the descriptions given by the companions who bore him home.

At this time there were absolutely no symptoms of compression.

The arm was dressed, the contusion about the orbit treated by warm stupes of the distilled extract of hamamelis, and the patient was given internally kali bromid., gr. xx., with morph. sulph., gr. $\frac{1}{16}$.

In the evening I found the patient quiet and sleeping, but easily aroused, and less capable of sustaining mental effort than in the morning. For some fever and rapid pulse I gave drop doses of tr. aconit. rad. and tr. belladon. every two hours.

By the morning of the next day (28th) the somnolence had developed almost into coma, nourishment being swallowed but automatically.

The decubitus was lateral (principally on the right side), the arms were drawn up and flexed over the chest, and the limbs drawn close to the body; the tongue dry. The patient remained in about the same condition for forty-eight hours, and then somnolence began to be less profound.

By this time the swelling had so far subsided as to admit of the outlines of the orbit being examined; and I was surprised to find, at the point of the supra-orbital notch, a depression into which the little finger could be placed, and a bulging was felt within the roof of the orbit pressing upon the eyeball. The right eye was pushed down and was lower than the left; but at that time, owing to the swelling which still existed, I regarded the deformity as apparent rather than real.

December 1 and 2. The patient had lost somnolence, and had become actively delirious, tossing from side to side, constantly talking, with hallucinations, and all the symptoms of cerebral irritation.

7th. The patient much improved. Intellect clearing, but concentration of thought and ideas of time completely absent. He remained quiet, but was easily aroused and quickly "dozed off" again; recognized those about him, but astonished them by the most irrelevant questions. Dr. A. F. Muller was called in consultation, and together we carefully examined the skull, and found, in addition to the injury described, that the whole right frontal bone seemed to be depressed, and the line of the medio-frontal suture appeared as an elevated ridge.

The question of trephining was considered; but as nothing was to be gained, we determined to await results, which have since proved in every degree satisfactory.

The patient slowly, but steadily, improved, the mind daily growing more clear, and muscular contraction, which had been lost to a certain extent, became more and more perfect.

Double vision remained, and I had my friend, Dr. C. S. Turnbull, examine the patient's eyes, the report of which I append:

"Eye (R.) mechanically displaced downward and slightly outward, and muscular action limited on account of pressure of the roof of orbit. Homonymous images (double), and R. displaced more or less below L. and normal position. Refraction Hy. As. Ophthalmoscopic examination negative."

The points of special interest in this case are:

First. The possibility of a blow upon the sharp supra-orbital ridge, sufficient to cause fracture and downward displacement of orbital plate, without cutting the skin, particularly as the character of the fracture would lead to the belief that the patient in falling struck the edge of the plank.

Second. The presumable extra-dural hæmorrhage, as evinced by a succession of symptoms:

(*a*) Momentary stunning at time of fall.

(*b*) Immediate regaining of consciousness.

(*c*) Gradual supervention of coma.

(*d*) Succeeded by slow awakening of intellect.

Third. The question of appropriate treatment. Had the trephine been used and recovery taken place, to surgical interference would have been given the glory. Had operative interference been called for by the urgency of the symptoms, I think that the operation suggested by Dr. A. F. Muller, of introducing an inflexible, flat elevator above the ball of the eye and moulding the depressed fragments back into place, would have held out the greatest probability of a successful result.

At the present writing, six months since the accident, the patient seems intellectually completely recovered. He has been steadily working at his usual occupation since last May, but a certain amount of deformity remains. His double vision, under the influence of an appropriate pair of glasses, gave him no trouble whatever; and now, even without glasses, the eyes have completely gained binocular vision and normal sight.

6 MOUNT AIRY AVENUE.

MEDICAL PROGRESS.

Angina Pectoris.—Dr. R. DOUGLAS POWELL, in *The Practitioner* for April, reaches the following conclusions in regard to this dangerous and painful affection:

Angina pectoris is an innervation of the heart or vessels, associated with more or less intense cardiac distress and pain, and a general prostration of the forces, always producing anxiety, and often amounting to a sense of impending death.

1. In its purer forms we observe disturbed innervation of the systemic or pulmonary vessels, causing their spasmodic contraction, and consequently a sudden extra demand upon the propelling power of the heart, violent palpitation, or more or less cramp and paralysis ensuing according to the reserve power and integrity of the organ—angina pectoris vasomotoria.

2. In other cases we have essentially the same mechanism, but with the extra demand made upon a diseased heart—angina pectoris gravior.

3. The trouble may commence at the heart through irritation or excitation of the cardiac nerves, or from sudden accession of anæmia of cardiac muscle from coronary disease—primary cardiac angina.

4. In certain conditions of blood or under certain reflex excitations of the inhibitory nerves, always, however, with a degenerate feeble heart in the background, we may observe intermittence in its action prolonged to syncope—syncopal angina.

Ligation of the Common Carotid Artery in Tonsillar Hæmorrhage; Recovery.—T. D. DUNN reports a case of a boy, three and a half years old, of a rather lymphatic temperament, with no history of hæmophilia in his family, who was attacked by abscess of the right tonsil which opened spontaneously, discharging a considerable amount of pus and blood. Twenty-four hours after the first discharge he vomited several large clots after having been asleep for some hours, and fainted from loss of blood. The hæmorrhage at this time was controlled by the application of Monsell's solution. Forty-eight hours later a similar hæmorrhage occurred, the bleeding being checked by powdered alum. Great exhaustion and fainting were present. Within the next three days several equally severe hæmorrhages occurred, and the child's condition became exceedingly critical and finally so serious that it was considered necessary to ligate the common carotid artery in order to prevent further hæmorrhage. Rapid recovery took place, the wound uniting without suppuration and the stitches were removed on the eighth day. The rapidity with which the child made blood was remarkable, as was also the absence of any cerebral symptoms.

Methyl-blue as an Anæsthetic.—PIETROWSKI has verified the statement of Ehrlich that methyl-blue is possessed of anæsthetic power to a remarkable extent. He has administered it both by way of hypodermic injections and by the mouth, to ten cases, including patients suffering from acute rheumatism and neuralgia of the intercostal, supra-orbital and sciatic nerves, as well as from lumbago. In all of these cases the urine became first green and then blue. After these injections there was some redness and tumefaction and perhaps some pain. In every case the pain was diminished.—*Revue Internationale de Bibliographie.*

Treatment of Acute Coryza.—In individuals who are subject to repeated attacks of coryza it will very frequently be found that the trouble depends upon a disorder of the general nutrition, which must be improved before a complete cure can be obtained. In addition to this it is absolutely necessary that a thorough examination of the nasal chambers shall be made in order that local applications may be applied. Generally inhalations of a mixture of carbolic acid or ammonia are useful, and the following may be employed:

℞.—Pure carbolic acid	. . .	80 grains.
Aqua ammonia	. . . .	1 drachm.
Water	. . . . .	4 drachms.
Alcohol	. . . . .	4 "

Several drops of this may be placed upon bibulous paper in the form of a cone and the vapor inhaled for a few seconds. Sometimes the disease may be aborted by the employment of atropine, and antipyrine may be used for the relief of the headache. As the disease progresses the following powder may be used as a snuff:

℞.—Subnitrate of bismuth	. .	1½ drachms.
Powdered benzoin	. . .	1½ "
Boracic acid	. . . .	1 drachm.
Menthol	. . . . .	3 grains.

Five or six times a day a pinch of this powder may be snuffed up into the nostrils, or in other instances a powder composed of small amounts of morphine and calomel is useful.

For the relief of the excoriation about the nostrils an ointment composed of equal parts of subnitrate of bismuth and vaseline may be employed.—*Journ. de Méd. de Paris.*

Ointment for Eczema.—

℞.—Thymol	. . . . .	30 grains.
Oxide of zinc, Starch	of each . .	6 drachms.
Lard	. . . . .	1½ ounces.

Apply twice a day to the affected part.—*Journ. de Méd. de Paris.*

Ichthyol in the Treatment of Dyspepsia.—STOCQUART is quoted by the *Revue Internationale de Bibliographie* as having recorded seven clinical observations regarding the use of ichthyol, for the purpose of relieving vertigo and other cerebral disturbances arising from simple dyspepsia or indigestion in the gastro-intestinal canal. He found that when ichthyol was administered with the bromide of potash, the latter drug was very well borne by the stomach, and that the appetite was improved simultaneously with the increase of digestive power.

The Treatment of Hiccough.—The *Gazette Hebdomadaire* gives the following treatment for hiccough. The local treatment is to compress the phrenic nerve and the pneumogastric in the neck by pressure with the index finger, which will often cause immediate cessation of the spasms. The medicinal treatment consists in the administration of a coffee-spoonful of vinegar mixed with a little powdered sugar, or the following formula may be used:

℞.—Subnitrate of bismuth	. .	45 grains.
Oxide of zinc, Valerianate of zinc, Powdered calumba	of each .	1 drachm.
Powdered opium	. . .	½ grain.
Essence of anise, a sufficient quantity.		

Mix thoroughly, and give half a teaspoonful of this powder in a wineglassful of sweetened water.

Current Literature.

SATURDAY, MAY 9, 1891.

PARTIAL EPILEPSY OF SUB-CORTICAL ORIGIN.

Duflocq, in a contribution to the study of cerebral localizations, reports an interesting case of partial epilepsy in which the cause of the paroxysms —an old and well-encapsulated blood-cyst—was without any point of contact with the cortical layer of the brain, but was completely separated from the gray substance by an absolutely healthy layer of white matter. The patient was a hatter, forty years of age, who gave a history of a fall from a step-ladder twenty years before, striking upon his head. There was no loss of consciousness and no subsequent pains in the head. He had had no syphilis, nor had he ever handled the acid nitrate of mercury. Three days before his admission into the hospital he was suddenly taken with a form of aura, consisting of a constriction which began at the epigastrium and in a few moments mounted to the throat, thence radiating toward the left side of the jaw. The patient heard a loud noise, which seemed to resound in the left half of the head and the left side of the chest at the level of the semi-lunar space. Severe pains in the head were felt, which persisted throughout the attack. The attack commenced at the moment the painful constriction reached the throat. The first phenomenon was a drawing of the tongue backward, so that respiration was impeded; then the head was turned slightly toward the left and inclined upon the left shoulder. The left corner of the mouth was drawn toward the ear; the mouth was slightly opened and held so. The eye did not participate in the convulsions. The movement extended to the shoulder, but the muscles of the arm and forearm remained relaxed. The head was strongly held by muscular contraction to the left shoulder during the paroxysm. The end of the crisis was marked by a pretty abundant salivation, which commenced a little previous to the end. The tongue was hard and could not be drawn out. The patient could emit only unintelligible and hoarse sounds, but memory and consciousness were well preserved. The pulse was regular and the respiration preserved its normal rhythm. After the attack there existed a facial paresis. There was no febrile elevation. Successive attacks were followed by loss of consciousness, increasing stupor, and death five days after admission. Trepanation was performed on the morning of the last day, with very marked amelioration of the symptoms. The patient spoke, drank, and watched a game of dominoes, but death occurred suddenly in the evening.

The autopsy revealed no deformity of the cranial walls. The brain and dura and pia mater were intact. The left hemisphere was normal. Examination of the surface of the right Rolandic region showed nothing abnormal. The fissures were clearly marked and the gray matter presented its usual coloration. An antero-posterior section, made just above the plane of the corpus callosum, revealed a brownish-red mass in the middle of the white substance corresponding to the lower extremity of the ascending frontal convolution. This mass was rounded in form and the size of a billiard-ball. It was surrounded by two concentric zones—the inner one clear yellow and of a slightly softened consistency; the outer one was of the consistency and ordinary appearance of the white substance. Finally, toward the surface of the convolution was a perfectly intact band of gray matter. A vertical and transverse section at the level of the foot of the ascending frontal (the frontal section of Pitres) showed the approaches to this rounded mass to be reddish in color. The mass was found to be composed almost entirely of the white substance of the lower frontal fasciculus (the foot of the ascending frontal), and the region of the island was intact. The external capsule was far distant from the diseased focus. There was no atheroma of the arteries of the base of the brain. The brownish mass was firm and was composed of a central portion of a mahogany-colored detritus, slightly foliated and manifestly consisting of blood. Around this was a shell, firm but thin.

It is quite exceptional to see a tumor situated in the white substance give rise to a partial epilepsy. Duflocq has searched medical literature and has succeeded in finding only three cases which are analogous to the one above reported—those of Osler (*American Journal of the Medical Sciences*, January, 1885), Taddeo de Hyeronomus (*Riform. Med.*, 1887), and Bouveret (*Lyon Méd.*, September 28, 1884). The clinical study of the patient above recorded reveals a certain number of functional troubles which appeared at the same moment as the epileptic crisis and which constituted it. These are the traction of the tongue backward, the retraction of the labial commissure, the opening and contraction of the mouth, the constriction of the pharynx, and the alteration of the voice. To each of these troubles a cortical centre corresponds, which numerous experiments and a few rare clinical observations have located in the lower third of the ascending frontal convolution. But it was in the white substance immediately adjacent to this limited region that the autopsy of this patient showed the existence of a hard, small, and perfectly circumscribed focus, of very old date, and one which could not have determined any lesion in the vicinity. All the centres involved indicated in a very positive manner that the seat of the lesion was the foot of the ascending frontal convolution; and if it is established that partial epilepsy may be of subcortical origin, the operator should feel authorized to search, in analogous cases, even in the white substance subjacent to the cortical centres for the original cause of the epileptiform accidents noticed in the patient.—*Revue Médicale*, Feb. 10, 1891.

PURULENT OPHTHALMIA OF THE NEWBORN.

Professor de Lapersonne (of Lille), in a report presented to the *Société Médicale du Nord*, gives the

following instructions upon the subject of purulent ophthalmia in the newborn:

"Purulent ophthalmia of the newborn is a very grave disease which every year renders blind a large number of children. Official statistics prove that one out of every three cases of blindness in children is due to this disease. This blindness might have been avoided by care, intelligently and promptly bestowed. The ophthalmia commences ordinarily on the day after birth; but it may begin toward the eighth or tenth day. It manifests itself by a swelling and redness of the lids, which prevents the eye from opening. There flows from the eyes a fluid at first clear lemon-yellow, then thick and creamy, then greenish. If the affection is not energetically treated, the eye, becoming involved by the fourteenth or fifteenth day, will be perforated, its humors escaping. Complete and incurable blindness will be the consequence of this accident.

"The secretion which flows from the eyes is virulent and contagious; it transmits the disease to the other eye, if only one eye has been at first affected; it produces ophthalmia in other children, if the necessary precautions are not exercised; transported by insufficiently washed hands, it may become the cause of that terrible accident, peritonitis, in the newly-delivered. To escape these grave dangers it becomes necessary to take the following precautions:

"1. Antiseptic vaginal injections should be made before delivering the woman, whenever the abundant leucorrhœal discharge gives rise to fears of contagion for the child.

"2. In *all* children, immediately after birth, *before the bath*, the lids should be washed with an antiseptic solution, by means of a fine linen cloth, which is very suitable, or better still, by means of a small tampon of antiseptic wadding. For this purpose either a solution of phenic acid, 1 to 100, or equal parts of boiling water and Van Swieten's fluid, or a solution with the following formula will suffice:

No. 1.

℞.—Sublimate	. . .	1½ grains.
Tartaric acid	. . .	3 grains.
Distilled water	. . .	3 oz. 2 drachms.

"Immediately after this the lids should be opened and a drop of the following collyrium should be allowed to fall into each eye from a dropper, a glass rod, or simply a roll of paper:

No. 2 (in colored bottle).

℞.—Silver nitrate	. . . .	2 grains.
Distilled water	. . .	2½ drachms.

"These formulæ may be handed to the midwives; all that will be necessary will be to give the direction 'For the eyes.' These bottles should always be carried by midwives in addition to other articles indispensable for accouchement.

"3. If, in spite of these precautions, the first signs of swelling and secretion present themselves, the physician should be immediately summoned, and he alone should make the necessary cauterizations.

"4. Whenever it becomes necessary to treat a purulent ophthalmia, all the articles which are to serve for the dressings should be carefully placed on one side. After each washing of the eye the linen cloths or the wadding which have been used should be burned. The hands should be properly washed with soap and soaked in a solution ready prepared for this purpose, consisting of phenic acid, 1 to 40, or the undiluted Van Swieten's fluid."

According to Professor de Lapersonne, it is because of these rigorous precautions that the midwives now escape these accidents, unfortunately too frequent.—*La Médecine Moderne*, March 5, 1891.

PUTREFIED MILK IN THE BREAST.

Jorissenne reports a rare and curious case which occurred in his practice during the year 1874, and which, for want of an explanation or any comparison with a case more or less analogous, he had refrained from publishing hitherto. The facts of the case are as follows:

Mrs. P. V. was delivered with the aid of forceps on the 5th of October, 1874. The sequelæ were normal and she had regularly nursed her child. Of a rather delicate constitution, small, pale, with flushed cheeks, of a lymphatic temperament, possibly not without tuberculous taint (although still living and with less pathological appearances than formerly), she was a good specimen of a blonde. Her child was well developed, but in 1875 it suffered with the milk-crust. On the 7th of December she took a short trip and remained away about seven hours and a half. On her return she hastened to give it its nourishment, and it suckled eagerly. A fœtid odor, however, disseminated itself with the milk. The husband and the other members of the family left the room, compelled to hold the nose. It was, they said, intolerable; a sulphurous and extremely offensive odor, resembling putrid eggs, with a mixture of sour acidity. The mother herself became ill from breathing these disgusting emanations, and the child vomited some time later. Jorissenne did not see the patient until the next day, at which time none of the sheets soiled by the vomited food retained the foul odor. The patient did not at that time seem to be suffering any ill effects from the trouble of the previous day. The breasts did not present any fissure nor any trace of engorgement; the milk was no longer odorous. On questioning, it was learned that the milk had remained three times as long as ordinarily in the glands, without occasioning any difficulty, even moderate in amount. The two breasts, nevertheless, had contained vitiated milk. The woman also confessed that several times her milk had begun to become offensive, but to a less degree, when the interval between the nursings had been too considerable. It is necessary to add that her trip had been rapid and fatiguing. An hour of carriage-riding and five hours and a half of rapid walking had been broken by only an hour's rest at the table. This, however, will not explain the peculiar odor of this putrefaction. Whence came the germ of decomposition? At the time none of the milk was

preserved to ascertain if, upon becoming putrid, it would give rise to phenomena analogous to those of the first occasion.

The conduct of the child is no less of interest than were the heteroclite alterations in the mother. It sucked the infected milk with the same avidity it evinced when swallowing the nutriment in its normal condition. There was no evidence of repugnance on its part, no hesitation, no unusual interruptions. Neither the taste nor the odor caused it to reject the food. The odor of the milk was beyond doubt, since all who were in the room were compelled to beat a hasty retreat. The child, however, was unaffected. It is fair to conclude that the sense of smell in an infant is but slightly, if at all, developed. It can hardly be believed that milk possessed of such an odor should be sweet and agreeable to the taste. It is probable that the savor was associated with some alteration in the taste, the sour acidity which was noticed probably indicating such a change. Various experiments have shown that the sense of taste perfects or develops itself with age. It is, therefore, probable that the ability to discriminate between the taste of pure and tainted milk was but poorly developed in this child, probably to no further extent than was the sense of smell. The perception of exceptional odors in the alimentation of early age is certainly obscure, indistinct, or even *nil.* The iodide of sodium or of potassium has been frequently administered to the newborn without concealing the bitter, salty taste, by the use of some agreeable syrup, and without any show of repugnance on the part of the child. Frequently will one see a child of five or six months suck toys which are covered with paints disagreeable to the taste. This is proof incontestable that there is not that acuteness of the sense of taste in these children that there is in older individuals. It is well known that olfactory sensations exert an influence upon the gustatory sensations. The absence in the power of smelling in this instance may have had a favorable influence upon the sense of taste.—*Archiv de Tocol. et de Gynécol.*, February, 1891.

CASE OF A FORM OF NYSTAGMUS HITHERTO UNDESCRIBED.

DR. C. S. FREUND reports a case of nystagmus occurring in a locksmith, nineteen years old. It developed shortly after Whitsuntide, 1889, following a severe day's field-duty in the army. The man awoke in the morning with flickering before both eyes, considerable weakness of vision, with pain "behind" both eyes, and with great oscillation of both eyeballs. This oscillation is said by the patient not to have changed in character since its first occurrence. It consisted of a permanent, extremely rapid, to-and-fro vibration of the eye-ball; it was constantly attended by a feeling of flickering of objects before the eyes; and surrounding objects, corresponding to the oscillation, appeared to move with extreme rapidity; they seemed to whiz to and fro. The patient discovered at the beginning of the disease that the oscillation diminished in intensity if he fixed an object sharply, and that, moreover, it ceased entirely if he closed one eye, no matter which; it was reproduced immediately if he opened both eyes. Not only the nystagmus ceased upon monocular vision, but also the seeming movements of surrounding objects and the pain behind the eyes. The patient was admitted to the hospital June 27, 1889. The pain behind the eyes lasted about fourteen days after that, and then gradually grew less within six weeks under daily use of mustard paste to the nape of the neck. No change occurred in the other symptoms, though the nystagmus varied in intensity from time to time.

As to vision, the patient from childhood had seen better from the left than the right eye. Three months from the occurrence of the other symptoms, especially since the middle of March, 1889, he had noticed that vision of the right eye was gradually getting worse. The weakness of vision seemed to the patient to be independent of the flickering, as it persisted upon monocular vision. It seems to have persisted without getting better or worse since June 12, 1889. There was never double vision.

At the request of Professor Magnus, Freund examined the nystagmus from a neurological point of view. Both eyeballs were found to move in a horizontal direction, to and fro; they vibrated frequently, and in such small arcs that the rate of vibration could not be counted; it appeared like trembling of the eyes. There was no hippus. Both eyes "trembled" equally. There was intermittent clonic blepharospasm. The vision was: Right eye, hypermetropia 2.5 D.; S. $\frac{20}{CC}$. Left, hypermetropia 3 D.; S. $\frac{20.}{XX}$

Freund reviews the forms of nervous disease in which nystagmus has been found, and concludes that the present case does not belong to any of them.

The galvanic current effected the most striking improvement. The anode was placed on the brow in the eye region, the cathode behind upon the neck, and a current of four milliampères was allowed to pass for five minutes. Improvement was perceptible at once. Gradually the strength of the current was increased to six milliampères, and the time lengthened to eight minutes. After seven days' treatment not the slightest indication of the former nystagmus could be discovered. The result remained permanent, with the exception of an insignificant relapse. The subjective disturbances—flickering before the eyes and seeming movements of objects—ceased simultaneously. The trembling of the upper eyelid persisted longest, but disappeared after three weeks of electrical treatment.

There were general clinical symptoms of diagnostic importance. The pulse was arhythmic, dropped a beat, and was accelerated to 100–110 per minute. The first sound over the mitral area was impure. The thyroid gland was enlarged. It was learned that the patient had had a peculiar, profuse, watery diarrhœa, without colic, and that he suffered with increased perspiration, which appeared especially upon the brow and shoulder-blades. This had been noted since 1888.

Freund, therefore, comes to the conclusion that

the nystagmus in the present case was a symptom of Graves's disease. The difficulty in reaching this diagnosis was increased by the fact that Magnus found in the right eye a striking central defect for red, while the left eye had normal color vision, and by the fact that nystagmus, as a symptom of Graves's disease, had been rarely observed before. Bramwell reports a case of nystagmus in which symptoms of Graves's disease occurred. Bramwell suspected disease of the cervical sympathetic.

Nystagmus resembles most the trembling of the limbs, the so called Marie's symptom, which occurs in Graves's disease. As regards the localization of the disease, Freund follows Uhthoff. Clinical experiences and *post-mortem* findings of Nothnagel, Friedreich, Roehlmann, Prévost, and others, show that the region of the brain the lesion of which may cause nystagmus is extensive. The most likely regions are the mid-brain, the corpora quadrigemina, and the medulla oblongata. It is significant that in these regions are found the nuclei of the cranial nerves, and that in Freund's case three or four cerebral nerves were involved.—*Deutsche med. Wochenschrift*, February 19, 1891.

SOCIETY PROCEEDINGS.

[*By Telegraph.*]

THE AMERICAN MEDICAL ASSOCIATION.

Forty-second Annual Meeting, held at Washington, D. C., May 5, 6, 7, 8, 1891.

THE opening session of the American Medical Association was held in Albaugh's Opera House, on Tuesday morning, May 5th, at 10 o'clock. The Hon. John W. Ross, one of the Commissioners of the District of Columbia, extended to the delegates a hearty welcome to the city.

The Annual Address to the Association was delivered by the President, DR. WM. T. BRIGGS, of Nashville, Tenn.

THE PRESIDENT, after speaking of the high mission of the physician as a scientist and philanthropist, referred to the scientific and practical progress of the day. The science of medicine, he said, had been almost completely revolutionized in our day. In every part of the habitable world blessed with civilization, members of the medical profession were enthusiastically engaged in the work of mitigating disease and prolonging life. Through the brilliant genius of one known as the Father of the Association, this Association had been formed and had grown to its present proportions. He referred to the venerable members of the body, associates of its founder, who, from the first had made annual pilgrimages to this Mecca. Chief among these he mentioned Dr. Nathan Smith Davis—a reference which elicited applause.

Dr. Briggs, continuing, reviewed in general terms the work of the Association, and the great benefits it had conferred on the medical profession. Referring to the code adopted and recognized by the Association, Dr. Briggs said that it would seem that every honorable member of the profession would be willing to abide by this code, but there were some men, men of a high order of talent, and who are justly distinguished, who have a repugnance to a part of the code and hold themselves aloof from the Association. They undoubtedly had as much pride in the profession as did members of the Association. Could they, however, say that their action was not inspired by some selfish motive?

He referred to the gradual elevation of the standard of education through the influence of the Association. He was ready to maintain that the advantages and facilities for medical and surgical instruction in our institutions were fully equal to those in any other country. These institutions had graduated men who were the peers of any the world had produced. In all the practical branches of medicine, he held, America was in advance. He believed that a majority of the American medical colleges were ready to accede to the demand of the Association for higher education. The success of the Association in these and other directions had been very great. The Association now, he said, occupied an advanced position in the great deliberative bodies of the world. It was full time, he said, that it should take the position of legislating for the whole profession in America. Speaking of those who had alienated themselves from the Association, he said that they should put aside petty differences and show how good it was to dwell together in perfect unity. It was proper, he thought, to pass a resolution, now that so many medical colleges had adopted the advanced course recommended, that no medical man not a graduate from a college that had adopted the approved course, and no professor attached to a college that had not adopted such a course, be admitted as a member or delegate of the Association.

Dr. Briggs suggested various changes in the routine programme of the Association, and urged that the prize essays contemplated in the formation of the Association would tend to excite interest and encourage study. He believed that medical science would be advanced by the establishment of schools of original research. He thought it might be well to add to the Association a section of original research to encourage members to make or repeat original research. He urged that every effort be made to advance the *Journal* of the Association to the highest point. Next to providing for an ample income, he said, it was important to select an able editor with ample powers. The salary of such an editor, he said, should be $10,000 or $15,000, enough to make him pecuniarily independent. In closing, Dr. Briggs expressed the hope that the deliberations of this meeting would carry the profession still further onward in the great road of progress.

DR. CULBERTSON, of Ohio, offered a vote of thanks for the able address, and moved that a committee be appointed by the presiding officer to develop the suggestions made by him. Drs. Hooper, Culbertson, Moyer, Marcy, and Conner were appointed such a committee.

The Trustees of the *Journal* made a preliminary report upon the question of the establishment of a permanent home for the *Journal*. The question having arisen of changing the place of publication to the National Capital, it was resolved to submit the matter to the members of the Association through the columns of the *Journal*. The result of this has been the undoubted choice of Chicago as the place of publication. The con-

troversy has strengthened the *Journal* by increasing its subscriptions and arousing the interest of other subscribers hitherto lukewarm.

DR. ALBERT L. GIHON, Medical Director of the U. S. Navy, presented the following amendment to the Constitution: "That the first day of the general session of this Association shall be the first Wednesday of May or June, the Tuesday preceding being devoted to the registration of members and delegates, the meeting of the standing committees, and the organization of the several Sections." The object of this amendment is to facilitate the work of the Association, to enable all the members to be present on the opening day of the session, that they may be prepared to take part in the business of the meetings, and to give an opportunity to the other National organizations, the organization of the Medical Examining Boards, of the Railroad Surgeons, the American Medical Temperance Association, founded on a line similar to the British Medical Temperance Association, the Association of Medical Editors, the Association of Superintendents of Insane Asylums, etc., to unite with the Association in its labors.

The motion was laid upon the table until the next day.

The Treasurer reported the balance in the treasury, $9427.21. The statement of accounts will be published in the *Transactions* of the Association.

DR. COMEGYS, of Ohio, offered the following resolution: "That a committee be appointed to consider the question of petitioning Congress to create a Cabinet officer to be known as the Secretary of Public Health, the committee to report on Thursday morning." The motion was carried, and Drs. Comegys, N. S. Davis, and Richardson, of Louisiana, were appointed as the committee.

DR. C. A. L. REED, of Ohio, offered the following:

"*Resolved*, That the American Medical Association hereby extends a cordial invitation to the medical profession of the Western Hemisphere to assemble in the United States in a Continental American Medical Congress.

"*Resolved*, That the Committee on Nominations be expressly instructed to nominate one member for each State and Territory, and one each from the Army, Navy, and Marine-Hospital Service, who shall constitute a committee which is hereby instructed to effect a permanent organization of the proposed Continental American Medical Congress, and determine the time and place at which the same shall be held.

"*Resolved*, That the Committee on Nominations be and is hereby further instructed to report the nominations pursuant to the foregoing resolutions at the general session on Thursday morning."

Carried. Adjourned.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

DR. CHARLES A. L. REED, of Cincinnati, delivered the annual address. He limited himself to a few words upon the progress which the department of obstetrics and gynecology had made during the recent past, noting especially the *evidences* of this progress. As one of these, he regarded the admission of women to the session of the American Medical Association, and another was the growing tendency to specialism. He would suggest that early steps be taken to procure a division of the section into its two distinct portions, gynecology and obstetrics. The two are not necessarily interdependent, and facts go to show that they are growing more and more apart. He felt that such a division would be conducive of benefit to each section.

The subject of abortion and premature delivery was treated of first by DR. H. D. FRY, of Washington, who spoke on the "Prevention of Puerperal Convulsions by the Induction of Premature Delivery." Albumin in the urine disappears under treatment, as a rule, or remains small in amount, except in a few instances. These exceptions formed the subject of Dr. Fry's paper. The amount of albumin in the urine does not alone indicate the gravity of the case. Severe toxic symptoms may manifest themselves with only a trace of albumin present. Examination of the urine should be made every few weeks. In doing this, the specimen tested should be taken from the whole amount passed in twenty-four hours. The specific gravity should also be taken. When serious symptoms are present, and the treatment is not successful, the induction of labor must be thought of, especially if the child be viable. If the symptoms, however, are very serious, the child must not be taken into consideration. Out of over 800 premature infants, with an average weight of four and a half pounds, 600 and over lived. Viability exists at the sixth month. Dr. Fry reported a case of a primipara of thirty years. While nursing an invalid sister she had taken cold, and when he saw her she was suffering from headache, insomnia, and nausea. She was seven months pregnant. On the second day 21 per cent. of albumin was found in the urine, and hyaline casts were present in large quantity. Hot baths were given the patient, and she was kept in a warm temperature. Her bowels were kept open and diaphoresis was produced. The specific gravity varied from 1026 to 1010, and the albumin from 18 to 31 per cent. by volume. As her condition did not improve, and the urine continued small in amount, induction of labor was suggested. The patient was placed in Sims's position. After cleansing the vagina and cervix with carbolized solution, labor was induced by means of a bougie. The internal os gradually dilated; forceps were applied to hasten the dilatation under the influence of chloroform. The right blade was inserted first, intermittent traction was made until the os dilated, and the child was then delivered. A laceration of the cervix was sustained, which was at once repaired. The child weighed five and a half pounds, and was asphyxiated at first, but recovered under proper treatment. The quantity of urine now increased in amount, and the albumin disappeared. The infant was raised in an incubator until sufficiently strong to be treated in the usual manner. Dr. Fry induced labor at the thirty-fourth week in another case with evidences of toxæmia and with albumin in the urine. The child was healthy; convalescence was rapid. In this case organic disease of the kidney was compatible with health except during gestation. In four other cases reported by him the result justified operative interference. In all, eclampsia was threatened. The insertion of a bougie between the membranes and the intra-uterine wall is the safest way of inducing labor. The bougie should be soaked twenty-four hours in bichloride 1 to 1000, and then washed in warm water before using. The end of the

bougie should be bent at an obtuse angle and then inserted. If this fails, the instrument can be removed and a fresh one inserted. Another method of inducing labor is by the application of alternate hot and cold fomentations to the abdomen.

DR. BEDFORD BROWN, of Alexandria, Virginia, read a paper on "The Practical Treatment of Accidental Abortion," as deduced from 200 or more cases occurring during his practice of forty years. He first gives a hypodermic of one-quarter of a grain of morphine and one-sixtieth of a grain of atropine, and if there is much depression, one-sixtieth of a grain of strychnine and twenty minims of ergot to produce contraction of the arterial system and stimulate the heart. Antiseptic vaginal douches are given, and then one pint of hot water containing alum, to reduce the hæmorrhage. If these measures fail to arrest the progress of the abortion, the patient is placed in the lithotomy position across the bed, a speculum is inserted and iodoform gauze pressed around the cervix, and over this absorbent cotton. A catheter is placed in the cervix. This usually results in the expulsion of the fœtus. Should it fail, a conical tampon, covered with cosmoline, is inserted into the os, and allowed to remain there. An enema is also given to induce contractions. Dr. Brown has little or no faith in the use of ergot to arrest the hæmorrhage or to expel the placenta. A tampon is necessary for the bleeding. In delivering the placenta he relies on his finger alone. The patient being in the lithotomy position, an assistant forces the uterus down, while the finger is inserted and removes the placenta. If all cannot be removed the patient is chloroformed and the whole hand inserted. Safety, speediness, and completeness are the essential factors in the treatment of these cases. The use of the tampon in retained placenta is neither wise, safe, nor scientific. In collapse following hæmorrhage one-eighth of a grain of morphine, one-hundredth of a grain of strychnine and atropine each, and hypodermics of hot water, 110° F., containing small amounts of chloride and bicarbonate of sodium, are given.

Dr. Stanton, of Cincinnati, thought that the cases where induction of labor is necessary are very rare. The condition of the patient and the time of convulsion will indicate the need of action. If labor has already commenced it is wise to hasten the process, if not it is better to wait as long as possible. The fact that albumin is present in the urine is not sufficient reason to justify the induction of labor. Other measures will usually suffice.

Dr. Potter, of Buffalo, emphasized the importance of the early induction of labor in *threatened* eclampsia. It is not always necessary to wait until there is absolute convulsion. If a uræmic condition is present induction is necessary.

Dr. King, of Washington, urged that induction of labor should not be performed until everything else had failed. He suggested the value of postural treatment, changing the woman from the genupectoral to Sims's position and back again. Good results have followed this method.

DR. W. W. POTTER, of Buffalo, read a paper on "Joint Reflexes Consecutive to Pelvic Inflammation." He called attention to the multifarious reflexes following pelvic disease, and mentioned specially those which occur about the larger joints of the leg. He said that an intimate relationship existed between the pelvic organs and the hip-joint, a relationship which is conveyed from the spinal cord through the sacro-sciatic foramen into the joint itself. He illustrated his paper by the case of a woman, twenty-two years of age, who, when six months pregnant, was attacked by what was diagnosed as general peritonitis, from which she recovered. She was delivered at full term with forceps and made a rapid recovery. Some weeks after she suffered with pain in the right hip-joint, which was so severe that she called in a physican. Hip-joint disease was diagnosed and the leg put in a splint and kept there for several months. There was no immobility of the joint nor any shortening of the limb. As a result of this mistaken diagnosis the case was taken to law. The points suggested were the necessity for examining into the condition of the pelvic organs in cases of joint symptoms, and the importance of an early diagnosis, since the treatment depends upon the accuracy of the diagnosis.

DR. LLEWELLYN ELIOT, of Washington, read a paper on "Spasmodic Stricture of the Urethra Following Labor." He regards this as one of the rare accidents complicating labor. It may be extremely painful or painless. It may be entirely spasmodic or symptomatic. The former may be found in connection with injuries of the vagina and rectum and in hysteria. Symptomatic stricture is more frequent, and may occur in any portion of the urethra. In the treatment of this condition iron is needed for anæmia, the bromides for the nervous condition, the iodide of potassium and colchicum for the rheumatic cases. Locally, astringents and caustics are needed, as solution of silver nitrate. If these fail, cystotomy must be performed.

DR. I. S. STONE, of Washington, read a paper on the query, "Can the Gynecologist Aid the Alienist in Institutions for the Insane?" He is strongly of the opinion that the question should be answered in the affirmative. The paper was mainly a compilation of cases which had been reported in the various journals of cures of insanity following operations upon the internal genital organs. Stone believes that many women are now living, confined in asylums, who could be cured by proper surgical procedures. He urged the importance of increasing the staff of medical attendants in the institutions for the insane.

Dr. Eastman, of Indianapolis, reported a case of a woman who suffered from violent neuralgic attacks in the head and who eventually went insane, but who was cured by the removal of a diseased Fallopian tube, followed by a year's careful treatment. The woman is now the head of a public school and in excellent health, both physical and mental.

Dr. Walker, of Indiana, regards many of these cases as true neuroses in which rest alone, without operative treatment, will result in a cure.

Dr. Reed, of Cincinnati, enlarged upon the necessity of increasing the staff of physicians in connection with insane asylums, and suggested the appointment of specialists to visit these institutions and investigate the condition of the pelvic viscera.

Reports of laparotomies were made by Dr. J. H. Branham, of Baltimore, and Dr. J. H. McIntyre, of St. Louis.

SECTION OF DISEASES OF CHILDREN.

The Section of Diseases of Children met for the first time on Tuesday, May 5th, at 3 P.M., the President, DR. W. PERRY WATSON, of Jersey City, in the chair. The afternoon was devoted to a discussion upon the composition and clinical value of Sterilized Milk.

DR. HENRY KOPLIK, of New York, treated of the bacteriological aspect of the question, and exhibited specimens of cultures made from different preparations of sterilized milk. After reviewing the literature upon the subject, the processes described and practised by Pasteur and Hueppe were narrated. It had been repeatedly shown by different observers that the lactic acid bacterium gains access to milk from without, that it is destroyed by heat, but that a high degree of heat is needed to kill the spores of the bacteria, which multiply after several days and produce a second or alkaline fermentation. Pasteur's method of sterilizing consists in heating milk to 75° Celsius in bulk for half an hour; it is then cooled by passing over ice. Such milk keeps for twenty-four hours, but the process is impracticable. Soxhlet's method, most in use, requires the milk to be boiled in a water bath. The best of all methods is that of Hueppe, by which steam is the active agent. In an ordinary covered tin vessel, twenty minutes is sufficient to sterilize milk by steam; forty-five minutes is ample time for permanent sterilization. Milk will decompose, however, several days after being well steamed, by the action of rod bacilli isolated by Löffler and Koplik. In this process small flocculent clots are formed with characteristic odor, leucin and tyrosin resulting. Milk may be colored by litmus and then subjected to bacterial change when discoloration is observed. The pus coccus turns milk acid, and seems to peptonize it; other poisonous bacilli grow well in milk. After exhibiting and describing cultures of the forms of bacilli which may develop in milk after sterilization, Dr. Koplik formulated the following practical conclusions: That prolonged sterilization by steam is necessary, and that sterilized milk should not be kept for several days, but should be used promptly. The particular form of apparatus or cork is not important. Absorbent cotton is a bad cork, as it mats and leaks; cotton-wool which has been baked is better. He obtained the best results by using digestive ferments (pancreatin, etc.) after sterilizing, not before. He does not feed by weight or age, but in quantities proportionate to the size and vigor of the child. Efforts at securing good milk will be most successful when milk is sterilized at dairies.

Next in order, a summary of a paper by PROF. ALBERT R. LEEDS, of Hoboken, and DR. EDWARD P. DAVIS, of Philadelphia, entitled "The Chemistry and Clinical Value of Sterilized Milk," was read by Dr. Davis.

From a chemical examination of different samples of sterilized milk, Prof. Leeds concludes that sterilization destroys a starch-liquefying ferment normally present in milk. Lactalbumin is partly coagulated, and casein is made less readily digestible by rennet, pepsin, and pancreatin. Butter fat sometimes forms, and the albuminoids in their changed condition hinder the assimilation of fat. Milk sugar is destroyed by long heating.

The process most likely to give good results is to render milk feebly alkaline with lime-water, then treat with pancreatin at 155° F. for six minutes; if not used at once, raise the milk to boiling for a moment. Dr. Davis's experience in the Philadelphia Hospital and Polyclinic had indicated that while infants fed on sterilized milk and treated by modern methods of intestinal antisepsis were relieved of acute gastro-enteritis or "cholera infantum," yet they were not nourished by sterilized milk; they frequently suffered from obstinate constipation, and their bodies presented after death appearances characteristic of atrophy of the digestive tract. Sterilized milk *as nourishment* was not successful in his hands.

Dr. J. Lewis Smith, of New York, discussed the papers, emphasizing the many sources of contamination to which milk is open. He narrated Klein's experiment, in which cows inoculated on the shoulder with bacteria, excreted germs in their milk. Milk strained through wine-strainers, exposed to the air of infected rooms, and handled by infected hands, is dangerous. Before the use of sterilized milk among asylum children in New York, 100 per cent. under eight months perished; one child lived two months. A considerable improvement followed the introduction of sterilized milk. He favored sterilization prolonged for two hours.

The subject was viewed from quite a different standpoint by Dr. E. N. Brush, of Mt. Vernon, who has given much attention to securing proper production of milk. He considered the lactic fermentation normal, and advised "souring" the milk and breaking up the curd. The process secondary to lactic fermentation in which ptomaines are formed is the injurious one. He practises spaying cows to be used for milk; they are kept clean, carefully groomed, and the udders cleansed before milking. Milk is received in a small basin, which overflows into a linen cloth which strains it. Dr. Brush objected to any process which devitalized milk, arguing that young animals need vitalized food. He instanced calves, which have, while fed on mother's milk, large, soft livers, suited for human food; when fed on artificial food, the liver becomes small and hard. Especial importance is laid upon removing sexual excitement and functions from cows giving milk, and numerous examples of abortion and the bad effects of rut were given. Cows excrete through the teats, and milk is unfit for use after the cow has fed on poisonous substances. Cholera infantum increases as grass fails and cows eat noxious herbs. Good milk costs twelve cents to produce. Poor milk, costing five cents, is frequently peptonized at a cost of twenty-five cents per pint!

Dr. Adams, of Washington, had obtained very happy results from the use of sterilized milk with barley or oatmeal added. Examples of parental prejudice against sterilized milk were given. In transportation, the use of ice was deprecated.

The frequency of fermentation in children's stomachs was explained by Dr. Simon Baruch, of New York, by the absence of hydrochloric acid, which is a valuable antiseptic. He sterilized forty-five minutes, at 212° F. He had been interested in a recent visit to Escherich's establishment in Germany, where sterilizing in quantity is done.

Interesting corroborative remarks were made by Dr. Latimer, of Baltimore, and Dr. Bright, of Toronto.

In the treatment of cholera infantum, Dr. Smith found especial value in withholding milk, sometimes for a week,

and feeding white-of-egg and water, with barley flour which has been subjected to prolonged boiling.

SECTION OF MEDICAL JURISPRUDENCE AND NEUROLOGY.

The subject of the address by the chairman of the Section, DR. T. D. CROTHERS, of Hartford, Conn., was "The Early Psychical Symptoms of Traumatic Brain Injuries." The speaker spoke of the great field open to the investigation of the neurologist, and how, instead of being a specialty in itself, it had reached that point where it must be divided into many special studies. He thinks that much can be expected from the investigations now going on in the almost unknown field of brain physiology. The speaker then spoke of the confusion existing between law and medicine as regard many nervous diseases. Many of the ideas, according to the speaker, embodied in our laws are based upon superstition and error. He considers that medical jurisprudence must depend upon scientific understanding. He then spoke of the difficulty of an early diagnosis in many of the diseases of the nervous system. As an instance, he spoke of the uncertainty of a diagnosis in general paralysis of the insane, even after many of the symptoms were quite marked. The friends and family of a patient suffering with this disease first notice that there is an alteration in his character, but pay no special attention to it until there is a sudden development of some marked peculiarity or reckless conduct, when the family physician is called in, who in many cases explains the change of character on some moral basis. Many serious blunders in diagnosis are made during this period. If the condition is diagnosed early, great subsequent trouble may be avoided.

The speaker then spoke of the alcohol, opium, and other habits. He said that they were usually considered as due to the habit into which the patient had fallen. He divided these conditions into two classes; first, those with a history of traumatism, such as sunstroke, blows on the head, etc. These cases, after recovery, often take to the use of alcohol, or opium, and go downward into the worst inebriety, and later insanity, while others are carried off before they become insane by some intercurrent disease, like pneumonia. The second class of cases he refers to "psychical traumatism." The patient is suddenly overwhelmed by great grief, business reverses, etc., after which his entire character is changed, and the drink habit is developed. Alcohol is first taken as a medicine, followed later by confirmed alcoholism. In these cases the patient is treated as a common drunkard, is despised by his associates, and is an outcast in society.

The drink habit is in many cases the symptom of grave cerebral trouble, and should receive prompt attention. Often the drunkard is confined in jail, and during his confinement acute mania or melancholia develops. In many of these cases the alcoholic habit is the symptom of the approaching disease.

The neurologist must point out the road for the family physician, who must be able to study his cases closely, as it is during this stage of the disease while the patient is under the care of the family physician that benefit from treatment can be expected. The heredity of the patient, his early life and surroundings, must be closely studied. Dr. Crothers believes the time will come when the inebriate will be protected and cared for as thoroughly as the subject of insanity.

The subject of the next paper on the programme was "Status Epilepticus," by GROSVENOR R. TROWBRIDGE and CHARLES B. MAYBERRY, of Danville, Pa. The writers of this paper gave a very interesting description of this disease. They described twenty cases which had come under their observation, from which they draw the following conclusions: First, there is no demonstrable cause for this disease; second, the convulsion is always followed by coma; third, there is no post-mortem lesion that is characteristic of this disease; fourth, the unfavorable prognosis of these cases, and lastly, it must be treated symptomatically. The treatment must meet two indications, first, the attack itself; second, the exhaustion following the attack during the stupor.

The use of chloroform and ether to control the attack is temporary; they only stop the convulsion while the patient is completely under their influence. Ether is the preferable drug, as it does not depress the heart or respiration.

They have administered chloral by enema in thirty-grain doses, often repeated in some cases, without effect. They think it might be used with advantage hypodermically, but have never administered it in that way. Bromide of potassium is useless in these cases on account of its slow action. Nitrite of amyl is also of little value to control the convulsions. Hypodermic injections of morphine have succeeded in some cases, while in several others it has been found valueless. Atropine is useful in so far as it stimulates the heart and respiration. The use of hyoscine promises good results, as it has acted well in a number of their cases. It does not end the attack, but induces sleep, during which the patient is free from the convulsion. Salicylate of physostigmine has been tried, but has been found valueless.

Coniin has given the best results of any drug that they have employed. The effects of one-hundredth of a grain are as follows: Decrease of the convulsion, commencing first in the lower extremities and gradually extending upward, followed by ptosis and slowing of the heart and respiration, and later sleep, which lasts several hours. As soon as the patient awakens the convulsion returns. It usually acts best in combination with morphine. In four of these cases this treatment was of no benefit, but in several other cases it was used very successfully.

It is usually useless to attempt medication by the mouth. If drugs or food are given, they should be introduced through a stomach-tube. Whiskey, atropine, milk, nourishing broths, etc., should be given to stimulate and sustain the strength of the patient.

In discussion, Dr. Hughes, of St. Louis, spoke of the use of chloral during the attack, and disagreed with Dr. Trowbridge in regard to its value. He says the reason why it does not succeed in many cases is because it is used too timidly. A profound impression must be made upon the vasomotor system. His rule is to give eighty grains of chloral hydrate by the rectum at one dose, and in the majority of cases this treatment is successful.

Dr. I. N. Quinby, of Jersey City, N. J., administers large doses of calomel and swift purgatives, with the view

of removing the serous effusion in the brain, after which anodynes are given.

The next paper was by DR. IRVING C. ROSS, of Washington, D. C., entitled "The Neuroses from a Demographic Point of View." The observations of Dr. Ross in many countries showed that certain races were peculiarly subject to certain neuroses, while other races were almost free from a given nervous affection.

In discussion, Dr. Osler, of Baltimore, spoke of the freedom of the negro race from chorea and locomotor ataxia. He has found that hysteria is not an infrequent disease among this race.

Dr. Ross, in reply, said that the observation of Dr. Osler as regards locomotor ataxia had not been borne out in his experience, as he had seen two typical cases of locomotor ataxia occurring in negroes within the last year.

Dr. Hughes, of St. Louis, spoke of the increase in insanity in the negro race since the war.

This discussion was followed by a paper on "The Functional Degeneracy of the Brain," by DR. J. T. SEARCY, of Tuscaloosa, Ala. He claims that the brain-power of an individual depends upon heredity and the constant exercise of the cerebral function. Idleness of the brain is followed by degeneration, just as muscular degeneration follows inactivity of the muscles. The two extremes in the social scale, the wealthy man and the very poor, are most subject to degeneration of the brain, while the middle classes furnish examples of the highest cerebral development. Next to idleness he places alcoholism as the most potent agent in the causation of cerebral degeneration. Long use of alcohol begets such impairment of the brain function that complete recovery rarely ever follows. The brain of the inebriate is usually weak to start with, and quickly degenerates after the use of alcohol is commenced.

The next paper was entitled, "A Description of the Newly-discovered Virile (Penile) Reflex," by DR. C. H. HUGHES, of St. Louis. The discovery of this new reflex has been made by Dr. Hughes within the last year. The description of this reflex is as follows: A healthy individual whose genito-spinal centre is entirely normal is placed in the supine position, and the sheath of the penis made tense by clasping the foreskin with the left index finger and thumb and pulling it firmly toward the umbilicus, placing the finger low down upon the dorsum of the penis for perceptive purposes. On then sharply percussing the dorsum of the penis, near the perineal extremity, a retraction of the bulbo-cavernous portion will be felt. The full value of this reflex is yet to be determined.

DR. JOHN MORRIS, of Baltimore, Md., gave an extract from his paper entitled, "What Can be Done for Overtaxed Brain-workers to Prevent Inebriety?"

DR. I. N. QUINBY, of Jersey City, also gave an extract of his paper on "The Therapeutic Action of Alcohol."

SECTION OF SURGERY AND ANATOMY.

The Section was opened by the address of the chairman, THEODORE A. MCGRAW, M.D., of Detroit, upon "The Use of the Elastic Ligature in the Surgery of the Intestines."

After paying a glowing tribute to the impetus given to abdominal surgery by Senn, and particularly to the ingenuity and skill of this eminent surgeon in devising a new method of intestinal anastomosis, McGraw briefly indicated the now well-known conditions requiring the performance of this operation. Rapidity is here, as in all cases of abdominal work, of cardinal importance. The old method of suture requires half an hour, Senn's method consumes from fifteen to twenty minutes, but a still further saving of time is desirable. One of the greatest dangers of any method requiring incision into the bowel is the escape of fæces into the abdominal cavity; hæmorrhage, too, is always a possible grave complication in all cutting operations.

With the idea of devising a method which should consume the minimum of time and which should be free from the risks necessarily dependent upon incision, McGraw first experimented with metal plates so designed that they should clamp together two bowel segments and subsequently form an opening between them by pressure necrosis. This method was, however, abandoned in favor of the elastic ligature.

The rubber ligature was previously used in Von Bergmann's clinic. Here the method consisted in constricting the approximated portions of two bowel segments by means of several rubber ligatures arranged in successive loops. The author was not aware of this work before his own investigations were inaugurated. By repeated trial he found that thin rubber cord, 2 mm. in diameter, was the best material to use. It is smooth, elastic and tenacious. By shaving one end thin it can be threaded upon an ordinary worsted needle. By stretching the rubber cord as the needle draws it through the walls o the bowel a small opening is made which is completely filled and even slightly stretched by the increased thickness of the rubber incident to the release from tension. The loops of intestine between which an anastomosis is to be made are stretched together in a straight line by means of the ordinary Lembert suture; close beside this row of sutures the rubber ligature is carried in the long axis of the bowel, including from an inch to an inch and a half of its walls; the needle is then carried through the coats of the other segment for the same distance in its long axis and out again, leaving two free ends, which are then drawn taut and firmly secured by means of a fine silk ligature. Thus the walls of the two bowel segments are puckered in the elastic ligature and firmly apposed to each other. Another row of Lembert sutures is now so placed that the ends of the ligature and the seat of approximation are completely enclosed in the peripheral lines of sewing.

In experimental work obstruction occurred at times from a too acute bending of the bowel. The puckerings, however, occasioned no inconvenience, nor did the strangulation incident to the ligature produce pain, either in animals or in the human subject.

In all animals with antiseptic wounds recovery was prompt. In not a single instance did the ligature allow of fæcal extravasation.

After twenty-four hours there was adhesion of the adjacent surfaces and partial obliteration of the folds, occasioned by tightening the ligature. After forty-eight hours the folds were entirely obliterated and the rubber was observed to be cutting through. In seventy-two hours there was a small space on either side of the liga-

ture through which water readily passed from one bowel segment to the other. At the end of the fourth day the ligature had disappeared and the anastomosis was complete, leaving free, smooth edges, with just enough plastic lymph to glue together the apposed surfaces. In all, thirty-nine dogs were employed, and in addition the method was proven to be practically valuable as applied to man in one case.

In this case the man had been a sufferer from cancer of the pylorus for three years. For three months he could retain practically no food. The temperature ranged about 100° F. On examination a fixed tumor was found. The stomach was washed out for several days with a soda-boric-acid solution. An incision was made over the stomach, beginning in the middle line and running transversely to the left. A cancer of the pylorus was found so firmly fixed that removal was out of the question. As the duodenum or jejunum could not readily be found the highest coil of small intestine was stitched to the stomach wall by a line of Lembert sutures, and the rubber ligature was made to include one and two-fifths inches of both the intestinal and stomach wall. A final row of Lembert sutures was then applied, and the external wound was closed. After exposure of the stomach the operation consumed just eleven minutes; the greater part of this time was wasted in endeavoring to pass a needle through the ends of the rubber ligature to secure them from slipping. Since ligation has been proven safely to accomplish this purpose a subsequent operation would require even less time. In dogs the whole operation can be done in three minutes.

The patient vomited once on the third day. On the fourth day the food that was taken was not regurgitated, hence it is probable that the passage from the stomach to the bowel was open at that time.

The patient suffered for two weeks from constant diarrhœa, and died at the end of that time from exhaustion.

A post-mortem examination showed that the case had run a typical aseptic course. A loop of the small intestine three feet from the ileo-cæcal valve was found firmly adherent to the stomach wall. The elastic ligature had disappeared, and there was an opening from the stomach to the gut slightly obstructed by a bridge of mucous membrane, which was caused by passing the needle too obliquely through the thick gastric wall, which had not been included in the constricting band. The application of this operation is necessarily limited by the fact that the continuity of the intestinal tract is not immediately restored. Thus, in internal strangulation, volvulus, or intussusception another method will be needed. Here Senn's plates will be found useful. In partial stenosis, however, as in cases of pyloric cancer or stricture, anastomosis by the elastic ligature is safer, quicker, and more efficient than any other measure yet proposed.

In ileo-colostomy, particularly, this latest method of anastomosis promises well, since here the danger incident to tearing out of sutures and consequent fæcal extravasation is especially great.

In gangrenous hernia the formation of an artificial anus may be anticipated by the application of the elastic ligature. Helfrich has already, in two such cases, made a lateral anastomosis by incision and stitching, with success in one instance. Here, on the ninth day after the anastomosis was formed, the gangrenous gut was excised and the healthy ends were turned in and stitched. The method by elastic ligature would, in these cases, be far more safe than is that of incision and suture.

Existing fæcal fistula or false anus is also amenable to the application of the elastic ligature; it may be employed to divide the projecting skin, or if this is not practicable, a formal operation may be undertaken, and by its aid the continuity of the intestinal canal may be restored. By this method McGraw endeavored to establish an opening between the gall-bladder and the intestine, but in this he was not successful, his results according with those of other experimenters. There was a tendency for the bile to escape beside the ligature into the peritoneal cavity. Of nine dogs experimented upon, six died. In two of the three survivors the ligature had disappeared, and the orifice was completely closed; in the third the ligature was still in place. There was still an opening between the gut and the gall-bladder, but it was very much smaller than the original amount of included tissue.

Following Dr. McGraw, Dr. T. G. MORTON, of Philadelphia, read a paper upon "Appendicitis and Pericæcal Inflammations, with Notes of Cases Illustrating Special Difficulty in Diagnosis." In this long paper nothing new was advanced. The author strongly urged early operation, operation in the intervals of recurrent attacks, and, in acute cases, excision of the appendix, followed by invagination and suture.

DR. HENRY O. MARCY, of Boston, followed with a classical paper upon "The Scientific Rationale of Modern Wound Treatment." In his remarks he quoted largely from the "Discussion upon Antisepsis," between Tait and J. William White, declaring in strong terms against the illogical and irrational arguments of the great English opponent of Listerism in its modern developments.

DR. CHRISTIAN FENGER, of Chicago, followed by a paper and illustrations of "A New Operation for Harelip." He strongly advised close suture of the mucous surfaces first; next, the placing of a certain number of tension sutures; finally, the insertion of the coaptation threads. His incision is so planned that no tissue is sacrificed.

The meeting was closed by a discussion of "Some Points in the Surgical Treatment for the Radical Cure of Hernia," by Dr. AUGUSTUS P. CLARKE, of Cambridge, Mass. The author strongly insists upon antisepsis, incision of the sac and ligature at the internal ring, the restoration of the obliquity of the inguinal canal, and, finally, closure of the wound without drainage.

SECTION OF PRACTICE OF MEDICINE AND PHYSIOLOGY.

The proceedings of the Section were opened by the address of the chairman, DR. V. C. VAUGHAN, of Michigan, on the subject of "The Growing Importance of Chemical Studies in Medical Education and in Medical Research."

The speaker began by an exhaustive description of our present knowledge of the physiological and patho-

logical chemistry of cells, and then went on to a consideration of the chemical changes of many substances in the body in health and disease. A succinct, but thorough, account of recent researches in uræmia was then given, indicating the desirability of investigations in the synthesis of urea and the relations of creatine, creatinine, and the poisonous methyl-guanidin. Among the writer's conclusions having direct practical bearings are the following: That the substances which produce uræmia are not present in normal urine; that the poisonous effects of vitiated air are not due to substances existing in the air, but formed from the altered chemistry of the body; that albumins are often absorbed without being changed into peptones. As might have been expected, the paper gave a full account of our present knowledge of the subject, and suggested many lines on which future investigations may be made with distinct advantage to practical medicine and therapeutics.

DR. J. P. CONNELLY, of Williamsport, Pa., read an interesting account of a case of "Fatty Urine Accompanying an Abscess in the Right Iliac Fossa, with Recovery." The fat appeared in the urine before general or local symptoms of the abscess were present. After fat passing for eight days, a large amount of pus was suddenly discharged, when the fat suddenly and entirely disappeared. While the fat was passing the urine was clear, without sediment; color, amber; reaction, acid; specific gravity, 1020; no albumin; no sugar. In the warm urine the fat floated on the surface, resembling castor or olive oil. It rapidly solidified on cooling, to the consistency of beef tallow, and was of a yellowish-white color. The amount of urine passed in twenty-four hours was twenty-four fluidounces. In this the fat, when collected, measured four and a half fluidounces, and weighed three and a half ounces avoirdupois. No cod-liver or other oil had been taken; there was no suspicion of deception. The blood was frequently examined for filaria, with negative results.

Dr. Connelly looked on the passage of the fat as a pressure symptom.

DR. J. W. CARHART, of Texas, read a paper on the "Use of Digitalis in the First and Second Stages of Pneumonia," strongly deprecating such use, and recommending rather veratrum viride, morphine, and atropine, or venesection.

DR. S. K. JACKSON, of Norfolk, Va., read a paper on "Tuberculin: Its Value as a Discovery, Apart from Its Therapeutic Importance, together with a Consideration of the Most Rational Mode of Employing the Principle Involved in It."

DR. H. D. GEDDINGS, of the Marine-Hospital Service, read part of a very exhaustive report on the "Use of Tuberculin in Twelve Cases of Tuberculosis and One of Lupus." The writer's conclusions were very conservative, showing the remedy to be of value only in a small proportion of cases.

DR. GEO. E. FELL, of Buffalo, read a report on "Two Additional Instructive Cases of Forced Respiration," and gave a demonstration of his apparatus, which elicited some discussion.

DR. ASA F. PATTEN, of Boston, read an exhaustive paper on the "Pathology and Treatment of Phthisis," eschewing the idea of its microbic origin, and giving various methods, hygienic and medicinal, for combating it.

SECOND DAY—GENERAL SESSION.

The general meeting of the Association was held in the Opera House, at 10.30 A.M., DR. WILLIAM T. BRIGGS, the President, in the chair.

The address on General Medicine was by DR. E. L. SHURLY, of Detroit, Mich.: "The Relations of Microorganisms and Toxæmia to the So-called Zymotic Diseases." He confined himself to a generalization of the pathologica and chemical features of the subject. He laid stress at the outset of the address upon the importance of bearing in mind the fact that the organized human body is under the influences of the forces of nature—ether, energy, and matter—with the addition of the vital force, and that the only difference between life and death consisted in a different arrangement of the molecular elements. The changes which are continually going on in the human body give rise to a vast array of physiological and pathological products, some of the latter being so noxious as to rapidly destroy life. Proteids, peptones, and ptomaines are all formed in this manner, and over forty of the latter, all more or less noxious, have been discovered. These, once formed, are received into the system and produce a general toxæmia which is characteristic of the disease which they represent. These diseases, therefore, are in reality blood diseases, due to an altered pathological condition of the blood. Many of these poisonous substances, however, are rapidly destroyed in the blood before they are able to produce any depression of the system. Others maintain their noxious property. Absorption of ptomaines from the intestinal canal may account for many of the so-called malarial diseases, the proof of which may be found in the rapid relief following the administration of brisk cathartics. Chemists and pathologists have discovered that diphtheria, tubercle, and other diseases, including gonorrhœa and syphilis, give rise to the formation of a ptomaine, which is itself the cause of the diseased condition, or toxæmia, rather than the original trouble itself. In addition, the development of the microscope has revealed the presence of immense numbers of bacilli and micrococci in the atmosphere, which play an interesting part in the production of disease. Most of the species of these bacilli are destroyed by the tissues of the body; others are destroyed by healthy tissues, but find a favorable nidus or soil in unhealthy tissues. It is probable that pathogenic bacilli never develop except when some previous disease has brought the body into the proper condition necessary for such development. This development then occurs by catalytic action.

After merely touching upon the subject of immunity and susceptibility, Dr. Shurly turned to the practical consideration of the therapeutic action which appears to be indicated by the facts obtained. He said that the main therapeutic indication is: antagonism of the action of the ptomaines and microbes within the body. Such drugs must be administered as have been found in the laboratory to be detrimental or destructive to the existence of these poisons. Thus, chlorine, iodine, the chloride of gold combined with glycerin and sodium chloride, have been found by Drs. Gibbes and Shurly to antagonize successfully the action of tubercle bacilli within the body. Hypodermic medication seems to be better adapted to the

successful treatment of these various conditions, as it appears to act more directly upon the diseased cells. Thus, Lauder Brunton recommends injections of balsam of Peru in phthisis; the bromide of gold, one-quarter to one-half of a grain, hypodermically, is lauded in the treatment of epilepsy as more valuable than the employment of the bromides in the usual manner. Dr. Shurly believes that animal poisons can be neutralized in the blood, and that this assumption will be shortly demonstrated. A sort of isomerism or antagonism exists between animal and chemical poisons, as proven in the laboratory, and this fact may be productive of tremendous progress in the therapeutic management of these cases.

Dr. A. L. Gihon's proposed amendment to the Constitution became the matter of business at 11.30. His object in presenting the amendment was to dispose of all preliminary work before the meeting of the general session. Dr. X. C. Scott, of Ohio, regarded the resolution as one which would make the American Medical Association the tail-end of all other societies, and, therefore, moved that the matter be laid on the table. Dr. N. S. Davis, of Illinois, said that the so-called Constitutional amendment was in reality not such, but merely an amendment of the By-laws. Dr. Scott's motion was then carried.

Dr. Scott's amendment to abolish the Committee on State Medicine, on the ground that the Section on State Medicine covered the work, was carried.

The motion of Dr. E. A. Wood, of Pennsylvania, that the word "Physiology" be stricken from Section I., and a new section entitled the "Section on Dietetics and Physiology" be formed, was carried.

Dr. J. C. Culbertson, of Ohio, moved that the State and geographical district societies in affiliation at this time with this Association, having a membership of one hundred or more, shall be recognized as branches of the American Medical Association. Dr. Davis moved that the proposed amendment be referred to a committee of five to be appointed by the President, and that the said committee shall confer with the State and other societies upon the desirability of such a change, and to report at the next annual meeting of the Association. Carried.

Dr. William H. Daly, of Pennsylvania, moved that in the future the permanent members have all the rights of delegates. On motion of Dr. Davis, the motion was laid on the table.

A communication was received from the State Medical Association of West Virginia, protesting against the infringement of the rights of practitioners by the laws governing the railroad surgeons. The matter was referred to a committee to consist of one from each State medical society.

SECTION OF PRACTICE OF MEDICINE AND PHYSIOLOGY.

DR. J. W. SMALL, of New York, read a paper on "The Treatment of the First Stage of Pneumonia." The treatment recommended was based on the idea of local congestion and inflammation. The author stated that in several hundred cases, in which the method was used before the second stage, the disease was arrested within twenty-four or forty-eight hours. The treatment consists in the application of external heat and friction to the extremities, hot poultices to the chest, Dover's powder and nitrate of potassium. Sometimes a single dose of 15 grains of antipyrine was given.

Dr. Goodall, of Vermont, said he had used veratrum for many years, and considered it preferable to the newer remedies. His method was to give three drops of a reliable fluid extract every three hours. This sometimes produces nausea, and at times copious bilious vomiting, but usually reduces the pulse to normal within twenty-four hours.

DR. J. W. SMALL, of New York, read a paper on the "Therapeutic Action of Tonica Water, an Alkaline Chalybeate Water from a Spring at Highland Park, Conn."

Under the title of "Some of the Remote Effects of Injury to the Brain in Delivery," DR. F. W. GOODALL, of Vermont, attempted to prove the cause of right-handedness to be some injury to the motor centres of the brain on the right side, owing to the peculiarities of the majority of presentations. Exceptional cases of right-handedness with other presentations the author referred to heredity.

The writer's conclusions were criticised from various standpoints by Drs. Eccles, Putnam, Aulde, and Cronyn.

DR. J. LEWIS SMITH, of New York, gave extracts from a paper on "Recent Contributions to the Knowledge of Diphtheria."

After a review of the wide distribution of the disease, and its high death-rate, the author considered the question of etiology, which he considered settled, the cause being the bacillus of Klebs and Löffler.

The appearance and characteristics of this organism and of the ptomaine produced by it were described, and the part played by each in the causation of the anatomical changes and symptoms detailed. Dr. Smith then considered the so-called pseudo-diphtheria, which he held to be caused by other organisms than the Klebs-Löffler bacillus, and which, though the membrane and many symptoms were similar, differed from true diphtheria in certain important particulars. The diphtheria complicating scarlet fever was one of the pseudo variety.

The writer then took up the question of the mode of contagion, giving instances proving the great vitality of the pathogenic germs.

With regard to diagnosis, Dr. Smith holds that an exact diagnosis can be made, provided the Klebs-Löffler bacillus can be demonstrated.

Dr. Eccles, of Brooklyn, thought that the writer had gone too far in claiming so much for the Klebs-Löffler bacillus, and referred to the work of Dr. Vaughn, which indicated the possibility of a number of organisms being able to produce similar effects.

Dr. Osler agreed with the writer, and said he had recently had two cases in his wards in which Dr. Welch had demonstrated the presence of the bacilli. He thought the vexed question of the relation of croup and diphtheria would be settled by such investigations as soon as typical cases of croup presented themselves.

The Chairman briefly reported his experience in three epidemics of diphtheria. In the first and second he had no difficulty in demonstrating the Klebs-Löffler bacillus. In the third, with a death-rate of 50 per cent., with no paralysis, most of the deaths being from suppression of urine, the bacilli were absent. He held, therefore, that we must be careful in the use of the term pseudo-diph-

theria, so as not to give the impression that it is a non-dangerous and non-contagious disease.

Dr. Early, of Pennsylvania, attributed the origin of diphtheria to dampness and mould.

Dr. Smith, in conclusion, remarked that the difficulty in the diagnosis was similar to that in many others, and that of the pseudo-diphtheria probably various forms would be determined. He thought the general practitioner should be able to examine for the bacillus.

DR. JAMES J. PUTNAM, of Boston, read a paper on "The Character of the Evidence respecting Arsenic as a Domestic Poisoning," giving the results of his extensive investigations.

Dr. Wolf, of Philadelphia, confirmed the statements made as to the frequency of occurrence of arsenic in the urine, but did not look on the arsenic in such cases as being a source of danger to the individual.

Dr. Osler thought there must be some difference in the conditions of various observers. He had never seen the cases of neuritis as described by the writer. He had given arsenic many times in large doses, but never with bad results.

DR. L. WOLF read a paper on "The Use of Naphthalin in Typhoid Fever," based on one hundred cases, which was discussed in connection with a paper by DR. B. M. GRIFFITH, of Springfield, Ill., on "Antiseptic Treatment and Liquid Diet in Typhoid Fever."

Dr. Osler said he had found that naphthalin did no harm and was valuable for that reason. It certainly controls diarrhœa, not only in typhoid fever, but in other diseases. It must be given in large doses. He recalled the treatment of Nathan Smith, which was purely symptomatic, making free use of fresh ale, diet, cold water, and not too much medicine.

Dr. Levick, of Philadelphia, thought much medication a mistake. His advice was to wait. He especially opposed the use of digitalis in fevers.

Dr. Kramer, of Cincinnati, questioned the rationale of using antiseptics in such cases.

Dr. Cronyn, of Buffalo, recalled the theory of King-Chambers that the condition of the blood in typhoid fever is one of super-alkalinity. He had acted on that theory for many years, using hydrochloric acid, and with great advantage.

Dr. Wolf closed the discussion. He said he could not reply to the theoretical objections to the use of antiseptics; the results could not be questioned. He described the great improvement in the treatment of typhoid fever by the German method of cold baths.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

The Section of Obstetrics and Diseases of Women met for the second time on the afternoon of May 6th. Two subjects of very general interest had been chosen, "The Forceps," and "The Causes and Treatment of Uterine Displacements." New forceps were shown by Drs. L. E. Neale, of Baltimore, and McGillicuddy, of New York. Dr. Neale's instrument is an axis-traction forceps with metal traction bar, possessing very considerable compressing power; its cost is almost that of Tarnier's. Dr. McGillicuddy had modelled a forceps much resembling that invented by Hubert, with the difference that in the former the traction handles are detachable from the outer end of the handles, while in the old forceps there was no such separation, but axis-traction was effected by a sharp angle in the handles. The blades were those of Simpson in the cephalic portion and lock. He also showed an anti-craniotomy forceps which lessens the size of the fœtal head by compressing the upper, non-vital segment of the cranium, thus avoiding the medulla. A class of cases in which the forceps is positively indicated was described by Dr. A. P. Clarke, of Cambridge. Such are cases where the head is engaged at the brim, but uterine action fails; also occipito-posterior position under similar circumstances. When the head is movable above the brim it must be pressed down and steadied by an assistant until the forceps can be applied. Resistance of the soft parts contra-indicates forceps and calls for narcotics or anodynes followed by oxytoxics. In oblique situations of the head the forceps guides rather than forcibly rotates the head. The long forceps, of greater than usual length, is required, and is preferred by Dr. Clarke to version.

The discussion of these papers elicited the comparative cost of the various instruments, Dr. McGillicuddy's being made for five dollars, while Dr. Neale's costs eighteen dollars.

Axis-traction by tapes was commended, and forcible rotation and compression of the head were deprecated.

A very interesting and well-illustrated paper was that of DR. J. W. KELLOGG, of Battle Creek, Mich., which embodied the results of the examination of large numbers of healthy and ailing women to determine the relation between dislocation of the abdominal viscera and pelvic disease. It was observed that the so-called feminine type of respiration depended entirely on the presence of the corset and tight clothing, there being no difference between the breathing of normal men and women. The modern woman is deformed, however, by a vicious dress and lack of exercise, which result in morbid conditions of the abdominal viscera and pelvic disease. In the modern woman the relation of the waist measurement to the height is but 33 to 100, while in the Greek statue 43 to 47 to 100 is found. The abdominal viscera are readily displaced, the uterus yielding far less easily to pressure.

Headaches and neuralgias were observed to be reflexes from disordered abdominal surfaces, whose perverted function result in toxæmia. The prophylactic treatment advised was a reform in dress and calisthenic and gymnastic training. In regard to the treatment of uterine displacements when they become pathological, Dr. W. J. Asdale, of Pittsburg, described four interesting cases, two of prolapse and two of retroflexion, which he successfully treated by ventro-fixation (laparo-hysterorrhaphy). In two cases the appendages were removed. The patient had been under observation for two years after operation, and cure seemed to have resulted. In no case had pregnancy supervened.

An additional case of ventro-fixation by a single suture passing through the anterior uterine wall was reported by Dr. W. P. Chunn, of Baltimore. The appendages were removed, and, as the patient collapsed, time was taken to pass but one suture through the uterus; a cure of the displacement followed.

Dr. Asdale had employed two or more sutures in his cases. An illustration of the failure of classic symptoms in a case of displacement was narrated by a woman physician, Dr. Carpenter, of Cincinnati. Extreme ante-

flexion with small os and long cervix existed in the patient without symptoms, save neuralgia in one lower extremity. Pregnancy ending in a tedious instrumental labor cured the neuralgia and corrected the uterine condition. The vexed question of the value of pessaries in treating displacements was warmly argued. The majority favored the carefully-fitted hard pessary used for a short time as a palliative splint, or the tampon of antisepticized wool. Pessaries, however, were of very limited value and rarely effected a cure.

The question of pregnancy with ventro-fixation was raised, and recently reported cases showed that a considerable proportion went to term, while some aborted, and in one case difficult labor from atrophy of the anterior uterine wall resulted.

Dr. Howard A. Kelly, of Baltimore, stated that in his investigations he used small, carefully fitted pessaries to relieve pain caused by adhesions. He rarely continued such use for more than a short time. Ventro-fixation was a resort only when other means failed. He performed it by attaching the utero-sacral ligaments to the abdominal wall, thus not interfering with the body of the uterus.

Dr. Kellogg had succeeded in many cases by shortening the round ligaments.

The following officers were elected by the Section for the ensuing year:

President, Dr. E. E. Montgomery, of Philadelphia, Pa.
Vice-President, Dr. Bedford Brown, of Virginia.
Secretary, Dr. F. H. Martin, of Illinois.

SECTION OF NEUROLOGY AND MEDICAL JURISPRUDENCE.

The first thing on the programme was the election of officers for the ensuing year, which resulted as follows:

President, Dr. Harold N. Moyer, of Chicago.
Secretary, Dr. Grosvenor R. Trowbridge, of Danville, Pa.
Assistant Chairman, Dr. J. E. Emerson, of Detroit.

The first paper was read by Dr. B. A. WATSON, of Jersey City, N. J., on "The Diagnosis of Traumatic Lesions in the Cerebro-spinal Axis and the Detection of Malingering Referred to this Centre." This was a very interesting paper, as the speaker had conducted a series of experiments upon dogs to ascertain the lesions and pathological changes produced by concussion of the spine. In concussion he has found that the vibratory force is not only expended upon the spinal cord itself, but also upon the surrounding soft parts and adjoining organs. All tissues do not transmit the vibratory force equally well. In some tissues there can be little or no vibratory force produced, while a comparatively slight blow produces considerable vibratory force on other tissues.

He gave as an example the transmission of force applied to the nates, caused by a blow or fall, up the spinal cord to the brain. The smaller the area to which the traumatism is applied the greater the concussion. The same force distributed over a wider area produces much less concussion. He claims that concussion of the spinal cord cannot be produced by blows on the anterior part of the body, as a force sufficient to do this will cause instant death, because of the injury to the intervening viscera. According to his researches, the force of an electric shock produces the same lesion as any other traumatism. Concussion, according to the speaker, is a condition of nervous and circulatory excitation.

Rapidly-repeated slight blows produce concussion in the same manner as a heavy blow applied at one time. This has been demonstrated upon animals. The same laws hold good in cerebral concussion as in spinal concussion. The difference in symptoms is simply due to the difference in the function of these two organs. He spoke of how many writers considered hæmaturia as a symptom of spinal concussion, but, according to his observation, this was not nearly always true; it is rather due to concussion of the kidney than the spinal cord.

Concussion always produces either functional excitation or depression. In some cases the depression is due to organic lesions. The sudden development of symptoms after the reception of an injury always point to a grave lesion. The symptoms of disease of the cord come on slowly, while the symptoms of concussion are always sudden in their onset. There are always symptoms of paralysis in concussion, often both motor and sensory, but especially the former. The speaker then described a series of experiments which he had performed on dogs. In all of his experiments paraplegia occurred; it followed immediately after the traumatism. In those dogs in which there was complete paraplegia, there was never any improvement in the paralyzed parts. In some of the cases where there was incomplete paraplegia, there was slight improvement after a few days.

The speaker said that it was unfortunate for science that such a large class of conditions are classed under the head of concussion. Many of these conditions have wholly different causes and symptoms, and should be placed in separate classifications. He said that so long as the present classification was retained error must result. He spoke of how the term railroad spine was used to cover many different conditions. He classified the results of concussion under three heads: first, injury to soft parts surrounding the spinal column; second, injuries directly to the spinal column; and, thirdly, injuries to the cord and its membranes. In his experiments upon animals, the speaker has invariably found post-mortem lesions.

Out of fifty dogs experimented upon, thirty-three showed distinct symptoms of concussion during life, while seventeen did not show these symptoms, but in all of the cases post-mortem lesions were demonstrable. In no case was there a failure to find distinct evidences of concussion after the death of the animal. He believes that the vasomotor system plays an important part in concussion. According to the speaker, in the majority of instances a diagnosis is not difficult to make. In the differential diagnosis between the symptoms assumed by the malingerer and the true cases of concussion a careful history of the case should be obtained. In all cases a systematic methodical examination must be made.

In conclusion, he said that no physician should go upon a witness-stand and swear that there had been concussion of the spinal cord unless the symptoms of this condition appeared soon after the receipt of the injury. In all cases a very careful examination must be made.

DR. THOMAS H. MANLEY, of New York, next read a

paper on "The Consideration of Traumatic Lesions of the Spine Resulting from Railroad and Other Injuries; Their Immediate and Remote Results, Etiology, Pathology, and Diagnosis." He made two classifications of "railroad spine:" first, those cases showing distinct lesions; and, second, those cases showing functional disturbance, but with no demonstrable lesion.

The time allotted to the speaker was almost consumed in a description of the cord and its surroundings, and he was compelled to give an extract of the last part of his paper. In conclusion, he claimed that concussive force must always produce a lesion to cause paralysis, and that there are no distinctive characteristics of railway spine.

DR. JUDD, of Galesburg, Ill., next described an interesting case of supposed railway spine. The patient, a cattle dealer, had received a slight injury to his thumb while on his road to Chicago with a load of stock. The injured thumb was dressed and the man continued his journey, and after selling his stock returned home. He carried his arm in a sling and used it very little. A railroad attorney and a local doctor talked to him and convinced the man that he had the so-called railroad spine, and should enter suit against the company. As he was very ignorant, he accepted their suggestion and asked damages from the railroad. Dr. Judd saw the patient six months after the injury; he still carried his arm in a sling and claimed to have no use whatever of it. The shoulder was somewhat shrunken. He would not consent to the administration of an anæsthetic, and only after considerable persuasion consented to the application of electricity. The arm was apparently paralyzed, but on his taking hold of the two handles of a battery there were marked contractions of the supposed paralyzed arm. The patient was very much surprised, and expressed great joy at finding that there was no paralysis of his arm, and at once commenced to use his arm again. The atrophy that was noted by the doctor was simply due to inactivity of the part. Dr. Judd believes that the patient was not a malingerer, but was the subject of suggestions from his doctor and lawyer. He terms this condition "litigation disease," and thinks it a species of neurosis the same as hysteria.

In discussion, Dr. Frank Lydston, of Chicago, cited cases to prove that the symptoms of concussion need not necessarily come on immediately after the receipt of an injury, but six months might intervene before symptoms appear. He not only took issue with Dr. Watson upon this point, but also claimed that there are cases of concussion in which there are no demonstrable lesions.

Dr. Clevenger, of Chicago, believes that there are always symptoms in cases of true railway spine that cannot be mistaken. He also said that one point that all the speakers had overlooked was the part played by the sympathetic system in these cases. According to this speaker, Dr. Watson's conclusions from his experiments are not to be relied upon, as the arrangement of the spinal cord of the dog and man are different because of their different positions, the former being horizontal during locomotion while the latter is perpendicular.

Dr. Kiernan, of Chicago, also held the same view.

Dr. Harvey Reed, of Mansfield, does not believe that concussion always produces a demonstrable lesion, but that there is simply a disturbance of the molecular relation of the cord. He believes that permanent lesions of the cord are not due to concussion and that the effects of concussion are but temporary.

Dr. Moyer, of Chicago, thinks that there is a source of fallacy in Dr. Watson's experiments, and considers his results almost without value.

Dr. King, of Tennessee, believes that there is no such condition as concussion without a demonstrable lesion. He has never seen the analogue of "railway spine" in private practice, but has seen at least a hundred cases of this condition while in the service of different railroads. He claims that, without exception, these cases are malingerers and only assume this condition for the purpose of pecuniary gain.

Dr. Hughes, of St. Louis, spoke in favor of Dr. Watson's paper, and thought that he had tangible ground upon which to work. He also believes that the condition known as railway spine is often the expression of a latent neurotic condition, which becomes manifest because of the shock of the injury.

Dr. Diller, of Pittsburg, believes that railway spine is often the result of suggestion of the patient's doctor or lawyer. A nervous woman receives a slight injury and her lawyer suggests this condition to her, as the result of which a psychical impression is made, followed by the symptoms of this affection.

The discussion upon the subject of railway spine was quite animated, and each speaker had a theory of his own in regard to this disease.

DR. SILAS B. PRESBERY, of Taunton, Mass., next read a paper on "The Medico-legal Investigation of Deaths by Violence in the State of Massachusetts." In that State each county is divided into districts, usually four, and a medical examiner is appointed to investigate all deaths by violence. This examiner is appointed by the Governor, and holds his office for seven years. Any responsible citizen may notify this examiner of a death supposed to be due to violence, and he must at once institute an examination unless he deems it unnecessary. After being notified, the examiner takes charge of the body and a careful examination is made for marks of violence. The surroundings are accurately recorded, and if he finds no cause for suspicion, the body is delivered to the friends. If he deem an autopsy necessary, he so reports to the district attorney, or if in the city, to the mayor, who gives him authority to conduct the post-mortem. Two assistants are appointed, who assist the examiner. He may also call in the service of a chemist, if necessary. The result of the inquest is carefully recorded, one copy being filed with the attorney of the district and another with the justice.

The medical examiner does not hold the inquest, and only acts in the capacity of a medical man, the legal matters being in other hands. The fee for an inspection of a body, without an autopsy, is five dollars; with an autopsy, it is thirty dollars. A mileage fee is also allowed.

The advantages of this system over the investigation of deaths by a coroner is the lessening of expenses, promptness and accuracy of the examination, the careful recording of the investigation, and the fact that the examiner only deals with the medical aspect of the case.

DR. DILLER, of Pittsburg, next reported a case of "Idiopathic Spinal Hæmorrhage."

SECTION OF SURGERY AND ANATOMY.

The Section was called to order by the chairman, THEODORE A. MCGRAW, M.D.

The first paper read was by J. McF. GASTON, M.D., of Atlanta, Georgia, the subject being "Traumatism of the Chest." The author considered all trauma of the chest, including penetrating and gunshot wounds.

He called attention to the well-known fact that serious injury to the chest contents might result without any external evidence of violence.

Dr. Gaston was especially emphatic in that portion of his paper devoted to the treatment of penetrating wounds. He said that while all writers advised closing the external wound, if it was small, the opinions were divided as to the proper treatment of large penetrating wounds. The author advises hermetical closure of the external wound in every case. He believes that in those cases in which there is a large amount of effusion or hæmorrhage, it will be gradually absorbed, while if the wound is not closed, pyothorax is much more apt to occur. Should the wound be closed, and pus form, the surgeon may open the chest at a favorable location.

In the *Medical and Surgical History of the War*, 1 per cent. of the recorded non-penetrating wounds proved fatal and over 65 per cent. of the penetrating.

In the discussion, Dr. Mynter, of Buffalo, quoted from an article in a recent foreign journal, in which the author advised, in cases of pneumothorax from injury, the conversion of the pneumothorax into a hydrothorax. For this purpose two canulæ are inserted into the chest, one at a higher plane than the other. Through the lower of these, sterilized boric acid solution is injected until the chest cavity is filled, the air escaping through the upper canula. The canulæ are then withdrawn and the wounds closed. The liquid may then be drawn from the chest by aspiration when thought best.

The next paper was on "The Surgical Uses of Aristol," by W. C. WILE, of Danbury, Connecticut. He considered the drug entirely from a clinical standpoint. Before the attention of the profession was called to this drug he had used iodoform very extensively and with great satisfaction.

In every extensive trial of aristol he has found it to answer every purpose for which he had formerly thought iodoform indicated. He uses it freely in all forms of recent wounds, dusted on the part. In burns an ointment is prescribed. Several cases were mentioned from his practice with very pleasing results. He considered aristol superior to iodoform, because of its absence from odor and freedom from toxic properties, and is equal to the latter in therapeutic value.

In the discussion following, Dr. Newman, of New York, stated that he has examined the urine many times of patients upon whom aristol was being employed, and always without finding any evidence of its elimination by the kidneys, proving to him the harmless nature of the drug. In some of these same cases, iodine applied to the wounds was promptly detected in the urine.

Dr. M. PRICE, of Philadelphia, then read a paper on "Peritonitis from a Surgical Standpoint." He began by stating that all cases of peritonitis were the result of a surgical cause. Idiopathic peritonitis he characterized as a delusion and a myth. The prominent symptoms of the disease, he said, were vomiting and tympanitic pain, which, while generally present and pronounced, might be but slight. The temperature usually runs high at first. The pulse may be weak from the first, and becomes thready. The expression is peculiar and characteristic; the face is anxious, pinched, and the person seems to have aged several years. Constipation is a constant symptom. Tympanites may or may not be present, and, when marked, it adds to the gravity of the cases. Dr. Price considers the opium treatment the worst that could be adopted, while poultices, turpentines, etc., add to the liability of pus-formation. In an acute case, he gives saline purges, and if in three days the patient is not relieved, or if the temperature does not fall below the pus standard, he opens the abdominal cavity and drains.

By far the most prolific cause of peritonitis is disease of the uterine appendages; next in frequency comes appendicitis, and along with this, meddlesome gynecology. In five hundred cases in which Dr. Price operated or assisted, not one was idiopathic. Many of the chronic cases die of tuberculosis, which is another plea for early operation.

Dr. W. E. B. Davis, in the discussion, spoke particularly of peritonitis after perforation of the intestine or rupture of an abscess, advising immediate operation. If operation is postponed more than twenty-four hours, the case will almost surely result fatally.

The next paper was by DR. B. A. WATSON, of Jersey City, N. J., on the "Relation of Concussion of the Brain and Spinal Cord to Inflammatory and Other Morbid Changes in These Organs." The author said that, inasmuch as concussion of the brain had been pretty thoroughly investigated, he would confine himself particularly to the spinal cord. He considers the spinal cord the best-protetced organ of the body, and that concussion of this organ is much less frequent than is usually supposed. By experiment it has been found that it takes a severe trauma to affect the cord, and this in certain limited areas of the body. He does not credit rupture of the membranes or gross hæmorrhage, without fracture or luxation of the vertebræ. Partial luxation, he believes, may occur, injuring the cord, and reduction follow from the resiliency of the parts.

In concussion the force is so dissipated that the effect is diffused. In cases such as gunshot wounds, however, the force is concentrated, and a gross lesion of the cord might result. Concussion itself, he thinks, does not give rise to inflammatory action.

The last paper was that of DR. MYNTER, entitled: "Is Early Excision or Conservative Treatment in Coxitis Indicated?" The pathology was very carefully discussed, and the tubercular origin insisted upon. He considered that most cases began as an ostitis, later involving the joint. He cited several cases from his own practice, and concluded that the most useful limb and the most satisfactory results followed early excision. He showed specimens of two cases in which this plan had been followed with happy results.

Drs. Townsend, Sayre, and Ridley, of New York, were unanimous in advising conservative treatment.

THIRD DAY—GENERAL SESSION.

The general session convened in the Opera House at 10.15 A. M., the President in the chair.

DR. JOSEPH M. MATTHEWS, of Louisville, Ky., delivered the address on General Surgery. Since a review of the whole field would require too much time, Dr. Matthews limited himself to a special subject, the discussion of which does not appear in the Sectional meetings, namely, "Stricture of the Rectum: Its Etiology, Pathology, Symptomatology, Diagnosis, and Treatment." The position taken by him in the paper he confessed was for the most part contrary to the opinions of the day. Following Kelsey's classification of the causation of stricture into the congenital and acquired forms, he considered the subdivisions in turn. He denied the existence of spasm of the rectum as a variety of stricture, and even doubted its existence at all. Although dysentery is stated by many authors to be a common cause of stricture, he has never seen a case of such an origin. If such a condition existed it would be very common among the veterans of the late war, but the Pension Department has no such cases on record. He doubts the tubercular origin of stricture. He regards the prime cause of stricture to be inflammatory action, either of syphilitic, cancerous, or traumatic origin.

Secondary syphilis is the usual and only form of venereal disease giving rise to stricture of the rectum. He has never seen a case resulting from a soft sore. Considering the subject of colotomy, as advised by Bryant, of England, he concludes that it is but rarely indicated, and bases his belief upon the pathology of the disease. Incipient cancer is not an indication for the operation, nor is pain relieved by it, since the latter results from the action of the morbid process upon the nerves of the diseased portion. The passage of fæces over the cancerous portion is not productive of pain, or if it is, to but a slight degree. Dilation will relieve the trouble. Syphilis he regards as the cause of more than one-half of the cases of stricture; but he believes that colotomy is not indicated by the existence of this disease.

As regards the statistics of the operation of colotomy, it has been shown that thirty-eight out of every hundred cases of lumbar colotomy, and forty-five in every hundred of iliac colotomy, perish within twenty-four hours. The early symptoms of stricture are marked or entirely *nil*. The inflammatory process is very slow in the rectum.

So-called constipation is often the first symptom, and this is followed, as the disease progresses to ulceration, by a discharge of bloody or muco-pus, with alternating diarrhœa, flatulency, and constipation. Irritation of the kidneys and bladder is frequently present. Pain is not a prominent symptom and is often entirely absent. Acute obstruction, as a primary symptom, he has never seen. The diagnosis is easily made by the finger when the stricture is within four inches of the anus, as happens in the majority of the cases. Malignant and syphilitic srricture are similar in regard to their mode of invasion, both beginning as a deposit, which is followed in time by ulceration. Benign cases, including the traumatic forms, begin with abscesses in ulcerations which are followed by plastic deposits.

Dr. Matthews objects to the employment of rectal bougies of any form for the purpose of diagnosis, as they are apt to do more harm than good. The usual seat of the stricture is low in the rectum, and if above this, what is the advantage secured by employing a dangerous instrument which can do no possible good? In considering the treatment he strongly opposed gradual dilatation as being apt to cause the throwing out of more plasma and the increase in size of the stricture. Forcible divulsion is much preferable. He prefers the method of incision, especially multiple internal incision, followed by the introduction of a drainage-tube, around which antiseptic dressings are to be packed. The objection to the external form of incision is that in division of the sphincter sometimes incontinence of fæces results. Electrolysis is too slow a process to be of any value, excision, or better, extirpation, is much to be preferred to colotomy, since the disease is removed by the former and only palliated by the latter. The entire length of the rectum may be removed without interfering with the action of the sphincter. Colotomy, he claims, is rarely justified, if at all. Whenever the stricture, other than the malignant form, is located in the movable gut, then exo-femoral colotomy should be performed, provided that the bowel below the seat of operation be closed to prevent the passage of fæces beyond the opening in the bowels.

The report of the Board of Trustees for the year ending March 31, 1891, was submitted. The circulation of the *Journal* is 5450 copies. The cost of publication and editing, $23,373.97.

The receipts for the year have been $14,465.59. From the general funds $8909.38 were drawn, leaving a balance of $762.40. The amount in the hands of the Trustees is $4503.39.

An editor has not yet been selected, the matter being in the hands of the Trustees. It was recommended that a suitable building be erected for the publication office. The report was signed by P. O. Hooper, President; John B. Hamilton, Secretary.

The Committee on Nominations made the following report of officers selected for the ensuing year:

President.—H. V. Marcy, M.D., of Boston, Mass.

Vice-Presidents.—Willis P. King, M.D., of Missouri; Henry Palmer, M.D., of Wisconsin; W. E. B. Davis, M.D., of Alabama; W. E. Taylor, M.D., of California.

Treasurer.—Richard J. Dunglison, M.D., of Pennsylvania.

Secretary.—William B. Atkinson, M.D., of Pennsylvania.

Librarian.—George W. Webster, M.D., of Illinois.

Trustees of Journal.—W. W. Dawson, M.D., of Ohio; W. W. Potter, M.D., of New York; J. H. Rauch, M.D., of Illinois.

Judicial Council to fill Vacancies.—H. O. Walker, M.D., of Michigan; W. L. Hubbard, M.D., of Indiana; Hunter McGuire, M.D., of Virginia; G. L. Porter, M.D., of Connecticut; C. H. Hughes, M.D., of Missouri; A. M. Owen, M.D., of Indiana; D. R. Didamos, M.D., of New York.

Place of meeting in 1892, Hot Springs, Arkansas.

Time of meeting, first Tuesday in May.

Special committees were named for State Medicine, International Medical Congress, and Necrology.

It was moved by Dr. Walker, of Michigan, to strike out "Hot Springs" and insert "Detroit." Carried.

The report of the Nominating Committee was then passed as amended.

Dr. Scott, of Ohio, nominated Dr. H. O. Walker as

Chairman of the Committee of Arrangements for the meeting in Detroit.

Dr. N. S. Davis moved as an amendment to the report that the time of meeting be changed to the first Monday in June. Carried.

The report of the Committee on the new Medical Cabinet Officer was received, recommending the petitioning of the next Congress to appoint such an officer, to be known as the Secretary of Public Health. Adopted as read.

NEWS ITEMS.

University of Pennsylvania.—The Medical Department of the University of Pennsylvania held its 117th annual commencement on Friday, May 1st, at 12 o'clock. The degree of M.D. was conferred on 133 candidates. THE MEDICAL NEWS prize of $100 was awarded to Dr. Joseph B. Sailer for an experimental essay. The Alumni prize for the highest average during the three years' course was awarded to Edward C. Ellett, of Memphis, Tenn.

Dr. James Tyson pronounced the valedictory address, in the course of which he alluded with much feeling to the death of Dr. Joseph Leidy, which occurred the day before commencement.

PROF. ROSWELL PARK will deliver the remaining four lectures of the Mütter Course on Surgical Pathology in the hall of the College of Physicians of Philadelphia, on May 12th, 13th, 14th, and 15th, at 8.15 P.M. Subject: "Surgical Bacteriology." Lecture VII. Actinomycosis; malignant œdema; rauschbrand; anthrax; glanders. Lecture VIII. Tuberculosis; introduction to a study of mixed and secondary infections. Lectures IX. and X. Mixed and secondary infections—sequelæ of pneumonia, typhoid, exanthemata, cholera, dysentery, erysipelas, gonorrhœa, syphilis, tuberculosis, etc. The medical profession are cordially invited to attend.

A Singular Accident.—On April 18th Rev. Dr. Bothwell, of Brooklyn, while withdrawing the cork from a medicine bottle was suddenly seized with a fit of laughing during which, in an effort at inspiration, the cork was drawn into the trachea. The presence of the foreign body immediately caused a severe attack of coughing accompanied by marked and very painful dyspnœa. Several attempts were made to dislodge the cork without success, and on the day following the accident the patient was removed to the Brooklyn Hospital, where tracheotomy was performed with the intention of removing the cork through the wound. It was found, however, that it had been drawn down deeply into the bronchus, and all efforts to remove it were futile. A delicately-made probang-like instrument, concealing within it a small corkscrew, was inserted into the bronchus, and an attempt to dislodge the cork in this manner also proved of no avail. It was suggested that if the ribs over the site of the cork were removed the bronchus might be opened. The condition of the patient, however, would not admit of this operation, and he died on May 3d of exhaustion.

Foreign substances in the upper part of the trachea are not uncommon accidents, but there are not many cases on record where so large a body as a cork has been drawn down so deeply into the bronchus as in this case.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 28 TO MAY 4, 1891.

By direction of the Secretary of War, JAMES C. MCKEE, *Lieutenant-Colonel and Surgeon*, having been found incapacitated for active service by an Army Retiring Board, is relieved from further duty as Attending Surgeon and Examiner of Recruits at Philadelphia, Pa., and will proceed to his home, and report by letter to the Adjutant-General of the Army.—Par. 3, *S. O. 96, A. G. O., Washington*, April 28, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 2, 1891.

LUNG, GEORGE A., *Assistant Surgeon.*—Granted two months' leave of absence.

HOEHLING, A. A., *Medical Inspector.*—Detached from Navy Yard, League Island, and waiting orders.

JONES, W. H., *Surgeon.*—Ordered to Navy Yard, League Island.

NORTON, O. D., *Passed Assistant Surgeon.*—Detached from Naval Hospital, Chelsea, Mass., and waiting orders.

CORDEIRO, F. J. B., *Passed Assistant Surgeon.*—Ordered to Naval Hospital, Chelsea, Mass.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MAY 2, 1891.

BROWN, B. W., *Assistant Surgeon*—Detailed as Medical Officer Revenue Steamer "Rush," during summer cruise, April 14, 1891.

AUSTIN, H. W., *Surgeon.*—Detailed as member of Board of Examiners Marine-Hospital Service, April 21, 1891. Detailed as Chairman of Board for Physical Examination of Officers and Candidates Revenue-Marine Service, April 29, 1891.

GODFREY, JOHN, *Surgeon.*—Detail as member of Board of Examiners revoked, April 21, 1891.

IRWIN, FAIRFAX, *Surgeon.*—Detailed as Recorder of Board for Physical Examination of Officers and Candidates Revenue-Marine Service, April 29, 1891.

CARRINGTON, P. P., *Passed Assistant Surgeon.*—To proceed to Fernandina and Jacksonville, Fla., as Inspector, May 1, 1891.

STIMPSON, W. G., *Assistant Surgeon.*—When relieved, to proceed to Savannah, Ga., for temporary duty, May 2, 1891.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: H. A. HARE, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

ORIGINAL ARTICLES.

MINOR UTERINE SURGERY.

BY J. M. BALDY, M.D.,

PROFESSOR OF GYNECOLOGY IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

IN these days of uterine and pelvic surgery the minor operations on the uterus, of which we used to hear so much, have been in great measure lost sight of by students of the diseases of women. In consequence of this very fact of being overshadowed by newer and more alluring procedures, fortunately many of the abuses of the old days have disappeared from the practice of those working in gynecology in our large medical centres. Unfortunately, this is not equally true of the vast majority of practitioners, either in the cities or in the rural districts; the old teachings and the old books still manifest too much influence. The time has come when we should carefully look back over our work of the past few years and see what lessons it has taught us.

The one great fact which stands staring us in the face in this connection is, that most of the troubles which we have been in the habit of considering as situated in the uterus are not in that organ at all. Thus, at one sweep we are able to dispose of a large proportion of the so-called uterine diseases. It is then manifestly improper and dangerous to direct treatment to the uterus when that organ is perfectly healthy, and the trouble is situated in the neighboring tissues—most probably of an inflammatory nature. In a large proportion of the remaining so-called uterine diseases the womb itself is undoubtedly affected, but the lesion in the uterus is only secondary to a lesion in the uterine appendages, or, if it was the seat of the primary disease, its continuance is surely due to the inflammatory condition of the contiguous organs. Here, again, a treatment directed against the uterus itself is both irrational and dangerous. This leaves us but a comparatively small number of cases of pure uterine disease. Such is the true situation. Uterine disease such as metritis, endometritis, pathological displacements, etc., uncomplicated by other and more serious troubles, is the exception rather than the rule, and in a large dispensary practice during the past few years the small number of such cases which have come under observation has been a matter of surprise to me.

It would seem, then, that the old methods proposed for the treatment of uterine diseases were not in themselves necessarily faulty, although most of them have undoubtedly been carried to excess, but that the trouble lay in faulty diagnosis, and consequent application of methods of treatment unsuitable for the true disease. If the true lesion be overlooked, and many of the minor operations be performed, the result is sure to be disastrous in a certain proportion of cases. How often an acute pelvic inflammation will be lit up will depend in great part on how carefully the given manipulation is carried out.

All this being true, there still remain a certain proportion of diseases which are uterine, pure and simple. The fact that in the past so many mistakes in diagnosis have been made, and that disastrous results have followed the application of certain treatments, should not blind us to the value of these same methods in cases in which they are properly applicable; and yet at the same time a proper limit should be put to their use.

The Uterine Sound.—On the whole, it had been better for womankind had this instrument never been invented. For the application of the electric current it has its uses, and in an occasional case where one is uncertain as to the connection of the uterus with a given tumor it may possibly give some definite information. For the purpose of measuring the depth of the uterine cavity, or for locating the position of the fundus, as it is generally used, it is absolutely superfluous. Anyone who is forced to use it for these purposes, unless it be in rarely exceptional cases, must confess to himself his lack of even an ordinary amount of manual dexterity. For replacing a displaced womb it is a dangerous instrument, and its use is very painful. A movable uterus can be invariably replaced by bimanual manipulation, with the patient on the back, or in the knee-chest position, with the aid of a tenaculum and a repositor. If the organ is adherent it no longer comes under the head of simple uterine disease, and should then be dealt with by other and safer procedures. The uterine sound may be used with perfect safety in careful hands; but, as ordinarily employed, it is capable of causing considerable traumatism, and of carrying septic material into the uterine cavity.

Dilatation.—This operation is one which has been much abused. It is capable of much good or much harm, depending upon whether it is used carefully

and in suitable cases or not. Personally, I have never had any permanent bad results follow its use. On the contrary, I have seen severe dysmenorrhœa relieved and even permanently cured: in not a small proportion of cases have I observed pregnancy follow dilatation. Patients have come to me suffering from a pelvic inflammation following a dilatation performed by others, but everything pointed to the fact that the pelvic disease had existed first and that the operation had been performed probably under a mistaken diagnosis for the relief of symptoms produced by the diseased appendages. In but one case have I had an inflammatory attack follow this operation when there was no complicating disease. In that case I made an incomplete dilatation without ether upon the dispensary table, in a young woman, married for five years and sterile. The inflammatory attack cleared up within a week, she soon conceived, and a month ago I delivered her safely of a large, healthy baby. She made a perfect and uncomplicated recovery. I should be exceedingly loath to discard the dilators from my armamentariun, and can only attribute serious accidents following their use to a wrong diagnosis or a faulty use of the instrument.

Intra-uterine Medication.—There is undoubtedly a limited field for the application of drugs to the uterine cavity. It should not be forgotten, however, that it is often only supplementary to other treatment. It is just as rational to expect results from local applications to the uterine mucous membrane, as from applications to the mucous membrane of the nose and throat. The fault here is much the same as in other minor operations—either a wrong diagnosis is made, and local applications are used to the exclusion of other and probably better methods of treatment, or they have been injudiciously and rudely applied. Certainly in chronic endometritis we may expect some good from them, especially after the application of the curette.

The Curette.—This instrument, in properly selected cases, is invaluable. In my own hands the dull curette has proven worthless, and I much prefer a sharp one. Of course the instrument is capable of harm, but so is every other that is used in surgery. If even ordinary precautions are taken in selecting cases and manipulating the curette, no damage will follow its application. For affections of the endometrium following labor, or of a fungoid character, it is exceedingly useful; I know of nothing which will take its place. In removal of retained clots, etc., in the puerperium, the finger will be found to be more certain.

Operations on the Cervix.—The splitting up of the cervix for dysmenorrhœa and sterility has fallen into deserved disuse; all that can be accomplished in that direction can be done with the dilators.

Emmet's operation for the closure of lacerated cervix should meet much the same fate, at least in the vast majority of cases. The only excuse for the number of such operations which are being continually performed is a fear of subsequent cancer. A simple, uncomplicated cervical tear causes no more trouble or inconvenience to the patient than does a woman's ear which has been torn through by her earring. The ear would be repaired for cosmetic effects; the cervix is hidden from view, and that factor would not come into consideration. Most women have lacerations of the cervix of more or less degree. If the lips are thickened, everted, and eroded, they will need treatment. Oftentimes simple scarification, followed by the application of iodine and glycerin tampons, will reduce this condition and leave a clean, healthy tear—one which will remain so until the end of time. If the lips cannot be brought into a healthy condition, or if the uterus is subinvoluted and the endometrium diseased, the case may resolve itself into an operative one; but even here a trial with electricity will often disappoint the surgeon. In my practice it is rare to see a lacerated cervix which calls for surgical repair. Cases which come to me from other men, who have advised an operation, get well without it. Oftentimes the symptoms for which the operation was proposed were found to be due, not to the torn cervix at all, but to other troubles, principally constitutional.

It is the easiest thing in the world to re-light a pelvic inflammation whilst repairing a cervix, and I have seen this result follow such practice only too often.

Taking it all in all, I decidedly approve of minor uterine surgery in the field to which it is applicable, but it must be borne in mind that this field is a limited one, and one which becomes more and more narrow as our diagnostic resources increase.

CERVICAL ADENITIS.

BY BENJAMIN T. SHIMWELL, M.D.,
DEMONSTRATOR OF SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA, PA.

THE occurrence of this condition in children, with its consequent results, is of such frequency that it is necessarily a matter of no little import.

The consideration of this subject will be confined principally to the treatment of the disease, especially the surgical means to be employed. The endeavor will be made to prove the advantage obtained from the radical treatment. This is based on an experience of many cases, which have proven the value of positive work, aided by definite aseptic rules. Close adherence to antiseptic principles has enabled us to place this treatment on a secure footing.

The annoyance and anxiety caused by a suppurating cervical gland have given way to a certainty of results, with less labor and loss of vitality. The suppurating scrofulous neck has been converted into a simple abscess which is easy of treatment.

It is not in the province of this paper to discuss the germ development as a factor in this condition, but it accepts the fact that it is proven; neither is it requisite to discuss the question whether the cocci have been excreted from the blood, or whether they have spread from the mouth along the salivary ducts.

There is a class of cases that have been placed in the category of scrofulosis, though I am not prepared to accept as positive evidence the wholesale classification under this head. While I must admit it in part, I argue from the basis, so claimed by its advocates, that this condition does arise in those of low vitality.

Let us examine into the physical state of children of tender age. How many are there who are up to the standard? Lack of care or proper feeding and attention at an age when this is most required has a positive tendency to produce this condition independent of any family history.

Lymphatic stasis, at this age, is the rule, not the exception. The examination of the neck in children, especially between the ages of two and ten years, shows marked glandular engorgement.

This form of adenitis is a local manifestation of a constitutional vice. It is more apt to be chronic in character, yet at times it takes on acute action which results in destruction, not only of the glandular, but also of the cellular structure. There may be only enlargement of the gland with suppuration of surrounding cellular tissue.

The peculiarity of scrofulous adenitis is its tendency to caseation; but in the neck it is more apt to result in softening, forming a whitish, whey-like fluid, holding a curd-like detritus. Yet it is not scientific to place in this list every case of caseation, for it is beyond doubt that this condition does occur in poorly-nourished children who show no history of scrofula.

Enlargement of the cervical glands frequently takes place in comparatively healthy children, in whom there is no cachexia. This is always charged to exposure in change of temperature, producing suppression of cutaneous perspiration, with glandular engorgement as a sequel. This is not a scientific explanation of the cause, yet in the absence of any known factor it is generally accepted.

Septic adenitis is due to absorption of septic products from the fauces, as they occur in scarlet fever, diphtheria, tonsillitis, and aphthous affections. We find at times that the tumefaction of the glandular structure may extend beyond the simple inflammatory into the suppurative stage, yet it is surprising to what an extent suppuration may take place in the surrounding cellular tissue without any breaking down of the gland structure proper.

The amount and location of the deposit generally governs the glandular involvement. When pillars and fauces are involved, then marked engorgement is apt to be present. It is less likely to occur when the tonsils alone are involved. Yet we see many cases of extensive faucial complication with little gland trouble.

The importance of early operation is not appreciated, especially in the acute or septic abscess, until the anatomical arrangement of the deep cervical fascia is understood.

While the arrangement of this fascia limits the direction of the abscess, it is not to be supposed that every case of suppuration follows its course, for it is evident to us all at times that the inflammatory action may be such that the continuity of these spaces is limited and the abscess circumscribed. Still again, how often have we seen a violence of action so great that there seemed to be no limit to its course?

The superficial fascia has no import in this disease.

The deep fascia is a dense membrane arising from the seventh cervical vertebra and the ligamentum nuchæ, and passes forward across the neck until it reaches the posterior border of the sterno-cleido-mastoid muscle; it there divides into an anterior and posterior leaflet. The anterior leaflet passes over the anterior part of the muscle to unite with the opposite side, and then passes upward, covering the masseter muscle and parotid gland, making the masseteric and parotid fascias, and thence passes down to the clavicle and sternum. This superficial layer is strong enough generally to prevent the progress of abscesses to the surface and would compel or encourage them to take deeper positions. The posterior leaflet passes behind the sterno-mastoid to unite with the anterior leaflet at the anterior border of the muscle. It then gives off a process which passes behind the hyoid depressors, invests the thyroid body and front of the trachea, and passes down in front of that tube and the large vessels to the fibrous layer of the pericardium. It also gives off a layer—the pre-vertebral layer—which passes behind the pharnyx and gullet and descends into the thorax behind the œsophagus. The sheath of the carotid artery, jugular vein and pneumogastric nerve is made by processes from the posterior leaflet and the pre-vertebral layer.

Henke, by injecting gelatin into the interspaces of the cervical region demonstrated their relations, as follows:

"*1. The capsule of the submaxillary gland.* It forms a completely closed envelope to the gland, from which continuations extend to the deep and superficial fascias.

"*2. Peri-visceral interspace.* The connective-tissue planes or interspaces situated between the pharyngeal group of laryngeal muscles (hyo-thyroid, sterno-hyoid, and sterno-thyroid) anteriorly, and the larynx, thyroid gland, and trachea posteriorly. It communicates with the anterior mediastinum. Perforation of a suppurating thyroid gland leads to invasion of this space, with subsequent compression of the trachea.

"*3. Retro-visceral interspace.* The interspace between the larynx and œsophagus in front and the vertebral column behind. It communicates with the posterior mediastinum.

"*4. Peri-vascular interspace.* This interspace contains the carotid artery and jugular vein. It communicates with the anterior mediastinum along the course of the large vessels, and is important on account of the frequent suppuration of the group of lymphatic glands situated in front of, and external to, the jugular vein. Abscesses of this space displace the sterno-mastoid muscle outwardly; they extend along the vessels downward, and, if left to themselves, either perforate the deep and superficial fascias and the skin near the clavicle, between the lower end of the sterno-mastoid muscle and the trachea, or make their way along the vessels into the anterior mediastinum.

"*5. Intermuscular space.* An interspace situated at their crossing between the lower third of the sterno-mastoid and omo-hyoid muscles. This space owes its origin to the sliding of the contiguous muscles upon each other, and is limited posteriorly by the scaleni. It contains a group of lymphatic glands situated near the posterior edge of the lower third of the sterno-mastoid muscle (supra-clavicular glands), and communicates inward with the retro-visceral space, and along the subclavicular vessels with the axillary cavity. Supra-clavicular abscesses usually extend into the armpit."

These experiments show the course that abscesses are liable to take. The difficulty in treating is to secure proper drainage.

Simple glandular inflammation does not require any special discussion. Special septic or non-septic inflammations must by their gravity call for knowledge of cause and effect.

External manifestation is no evidence of trouble more deeply seated. An engorgement of the cervical region, with all the evidence of superficial inflammation, will often, on incision and exploration, show that the location of the pus sac is deep in the tissues of the neck, extending in some cases to the retro-visceral space. These are the cases where injudicious applications would give serious results. It can readily be seen how destruction would take place in this location before softening and sloughing of tissue would go on sufficiently to give external manifestation.

The treatment is modified by the cause. It is promotive and radical.

In those cases that come under the head of scrofulosis, the preventive treatment is not one of easy management. The outline of treatment for this affection is too well known to need discussion. It should be obligatory upon us to so look over the children of our *clientèle* as to place them in such a condition that will, if it does not entirely avert, at least modify any outburst.

Too little attention is given to the growing child unless it is positively ill. Its food, hygiene, exercise, schooling, should all be the physician's care. The pinched face, thin neck full of enlarged glands, skinny legs, and tumid belly should be changed. By doing this in time of seeming health many after-ills might be prevented.

In the septic form the preventive treatment is more positive. To prevent the absorption of septic material from the throat is the object. This is met by means that will get rid of the deposit and prevent its absorption. There is one thing to be avoided, and that is anything that will tend to lower the patient's vitality. Stimulate for effect. Give food in sufficient quantities. Keep the emunctories free. If these fail, septic infection takes place. This brings us to the surgical consideration of the disease.

It is at this place I wish to enter my protest against the use of poultices. I have been forced to this conclusion, not only by scientific considerations, but by actual experience. I am emphatic when I say that the day of poultices has gone by. I wish to lay stress on this, for, the moment glandular enlargement appears, the patient is swathed in hot flaxseed, repeated *ad infinitum*. I must admit it is true that heat favors relaxation in the beginning congestive stage. I deny its efficacy when it gets beyond that point.

The scientific interest in the disease lies in the question, Which has the more vitality, the cocci or the phagocyte? After the inflammatory stage has set in, heat and moisture only tend to soften and lower the vitality of the tissue and increase the vitality of the cocci, thereby increasing their development with conseqent destruction.

It has been my experience that after glandular inflammation has been fully reached, all things being equal, suppuration is always present. Still, inflammation may be present and the general condition be well maintained or improved; then, possibly, suppuration does not occur. When we see the engorgement persisting or increasing, and the general condition not maintained or decreasing, then pus is of necessity present. If the latter, and the pus be not interfered with, your patient dies as much from septicæmia as from the primary disease.

What, then, is the treatment? A clean pair of hands and a clean knife.

In the beginning of septic infection warm applications may (?) favor relaxation. Massage of the parts and absorbents in lanolin give, at times, good results. Keep up the systemic treatment;

stimulate for effect; the nearer the patient gets to the normal condition the less the chance for infection. If this treatment does not abate the condition, then radical measures must be taken.

The first step in the operation is the preparation of the patient, for to be successful thorough antiseptic precautions must be taken. The neck is to be well scrubbed, then washed with ether or alcohol, and afterward with bichloride solution, 1 to 1000. Every particle of dirt must be removed. If time allows, the neck should be wrapped in bichloride towels. The child is etherized and placed on the table in a good light, the head being so arranged that the suppurating side is made as prominent as possible.

The anatomical relation of parts must be carefully noted and the location of the adenitis outlined. The direction of the line of incision is made to take advantage of the platysma myoides muscle; by this we secure perfect dilation of the superficial wound.

I have always followed the method suggested by Hilton in opening abscesses in important regions. The skin and superficial fascia are incised; the knife is then laid aside and the grooved director used; the deeper layers are then torn asunder until the pus sac is found. The director is thrust through it, which is known by escape of pus. Having done this, a pair of strong narrow-blade dressing or bone-forceps is inserted through the opening; having entered the sac this is then opened and drawn out with the blades apart; this tears the sac and superimposed tissues, allowing free exit to the pus. The well-asepticized finger is then introduced to find the extent and character of the cavity. All loculi are broken down to make the cavity one. This done, the sac is well irrigated, and this is carried on until every particle is washed out. If the irrigant has returned clear and then shows even the slightest amount of pus, the finger must be re-introduced to discover the source of its exit. This is important, for it is a sign that complete evacuation has not taken place. It is a reason why recovery is at times slow; the condition has not been entirely removed.

The drainage is governed by the location, size, and character of the cavity. Make a counter-opening, if necessary. Use rubber drains if the sac is situated deeply and is of considerable size; catgut if more superficial and smaller. Iodoform is used, bearing in mind the idiosyncrasy to it in children. Bichloride gauze in large, well-crumpled masses is applied; no compresses are to be used; all the dressing is to be held in place by bandage. This is the method in simple phlegmon.

When gland destruction is present it requires more care; the same method of incision is used; the broken-down gland is removed by the finger, knife, or curette, and its removal must be thorough. The finger is a very useful and safe instrument. Careful exploration with the finger is to be instituted. Here the rubber drain *must* be used. If the cavity remaining be superficial, careful packing with iodoform gauze is advisable, being sure to get the gauze in contact with every part of the wound.

The changing of the first dressing is to be governed by the discharge. The rubber drain is removed as soon as possible and catgut substituted if necessary. A cervical phlegmon, with non-removal of glands, should get well under three dressings.

Bichloride solutions should never be used, unless they be well washed out with some other antiseptic.

I have found silico-fluoride of soda, half a grain to the ounce, an excellent non-toxic antiseptic. Thursch's boro-salicylic acid solution has also given me good results.

Under this method we find that pain and fever abate at once, with lessening of all other symptoms.

In conclusion, there is one thing to which I would call attention in operations in this region, and that is shock. This is entirely out of all proportion to the amount of interference. Therefore, it is necessary that you should be sure of the ability of your ether-giver.

MALIGNANT DISEASES OF THE DEEP LYMPHATICS OF THE NECK.

BY OTTO JUETTNER, A.M., S.M., M.D.,
OF CINCINNATI, OHIO.

THE neck is a region of the greatest anatomical and surgical interest, because of the intricate and intimate aggregation of the vital structures which it contains. The following history is given on account of the many interesting features which the case presented from the time it came under observation until the patient was discharged.

In the beginning of this year, Christian H., aged fifty-six years, was referred to me by one of my professional friends on account of very distressing dyspnœa. The patient was robust in appearance, and, according to his own statement, had always been in perfect health. His family had shown, for several generations, a strong tendency to malignant disease. Six or seven months before consulting me the patient began to complain of soreness in the right side of his neck. Pressure over the line of the carotid artery produced sharp pain. In a short time a well-marked indurated growth appeared in this region. The tumor gradually became more and more pronounced, and within six months after the first appearance of local symptoms grew into a hard, immovable, uniform mass, extending in the line of the cardia from the lower jaw to the clavicle. The growth was about the size of a moderately large cocoanut, and was unyielding, and could neither be lifted from its bed nor be shifted from side to side. Dysphagia finally became so great that swallowing even liquid food was performed with some

difficulty. As the result of pressure by the tumor upon important nerve-trunks incipient motor paralysis and paræsthesia of the right arm appeared, and there was very distressing dyspnœa. In the face of all these symptoms, and the gradual reduction of the patient's strength and weight, the malignancy of the growth seemed evident, and this diagnosis was subsequently confirmed by a microscopic examination of the tumor.

The question of giving the man relief by operative procedure resolved itself into the choice between removal of the tumor or tracheotomy. Extirpation of the growth, although a much more difficult and dangerous operation, offered not only relief of the dyspnœa, but also a chance of recovery, while tracheotomy could only give temporary relief. When the nature of the two operations was explained to the patient he immediately decided in favor of the radical operation.

The operation for the removal of the growth was performed at the Good Samaritan Hospital, January 23, in the presence of Drs. Orr, Juettner, Sr., Beckler, and Walker. An incision extending down to the tumor was made from a point midway between the angle of the lower jaw and the mastoid process to a point about one inch above the junction of the outer and middle thirds of the clavicle. The superficial cervical fascia, the platysma, the deep fascia and part of the sterno-mastoid and trapezius muscles were divided. A dense network of fibrous bands surrounded the tumor, and bound it firmly to the contiguous structures, particularly to the inferior maxillary bone. By means of the handle of the scalpel and my index finger the growth was slowly isolated. Its deep attachments were intimately blended with the carotid sheath and the chain of lymphatics accompanying the carotid artery. Upon lifting the tumor from its socket the interior of the cavity presented an anatomical and pathological condition of unusual interest. The common carotid, exposed for a distance of at least a half-inch, could be seen pulsating violently. Five or six enlarged glands, about the size of hazel-nuts, lay in contact with the arterial sheath, arranged like peas in a pod. A meshwork of nerves, arteries, and veins covered the greater portion of the interior of the cavity. The muscles of the affected region had slowly yielded to the pressure exerted by the neoplasm and had become atrophied. The omo-hyoid, for instance, could be traced as a delicate fibrous band, emerging from the submaxillary triangle, and lay loosely among the other abnormally located and altered structures.

After the removal of the enlarged glands the cavity was carefully cleansed and packed with sublimated gauze, and the patient was returned to his room. In connection with the after-treatment I cannot extol too highly the excellence of peroxide of hydrogen as an antiseptic agent. The patient reacted satisfactorily, and left the Good Samaritan Hospital eight days after the operation, with a healthy and rapidly granulating wound.

The intricate and close arrangements of important bloodvessels, with the corresponding danger of hæmorrhage, during and after-operation, makes the neck a kind of surgical *noli me tangere*. But the amount of blood lost is not always in proportion to the extent of operation. It is this feature which makes the foregoing case worthy of notice. In spite of the fact that the operation was a veritable dissection of the right side of the neck, the quantity of blood lost did not amount to one ounce. The extent of hæmorrhage accompanying or following operations on the neck depends in no small degree upon the care taken in examining parts before dividing them. In all operations in the cervical region the rule should be *festina lente*.

Malignant disease of the deep lymphatics of the neck is always serious. The clinical history of most cases is one of intense pain. In its incipiency the symptoms of malignant disease of the deep lymphatics are obscure, or they may be absent. When the case has progressed to a point when the diagnosis can be made, the prognosis is hopeless. Aside from the fatal termination of these cases *per se*, there is danger of serious hæmorrhage caused by ulceration of bloodvessels contiguous to the tumor. In the non-ulcerative malignant tumors of the neck, the only mode of treatment worthy of mention is complete extirpation of the growth, which, however, is by no means a trifling operation, and must be carefully weighed in the mind of the surgeon before being decided upon. Postponement of the inevitable end by means of an operation is justifiable in certain cases. If the patient survives the operation he may enjoy a short period of freedom from pain. Within a few weeks or months the disease will return, however, with renewed malignancy. This is the uniform history of these cases. In the foregoing case there is as yet, five weeks after the operation, no signs of recurrence. The patient has unobstructed respiration, and his weight has not decreased since the operation. The questions of vital interest are, How long will this so-called recovery last, and, Is the operation justifiable in the face of certain recurrence? The change in the condition of my patient, from one of indescribable agony to one of ease and comfort, speaks volumes in favor of the operation.

EXCISION OF SPINA BIFIDA.

BY IRA K. GARDNER, M.D.,
OF NEW HAMPTON, IOWA.

SPINA BIFIDA is one of the most serious malformations which we are called upon to treat in infantile life.

I desire to make this article brief, and consequently will not discuss the pathology, diagnosis, or prognosis of spina bifida, but will describe its treatment at once, as illustrated by a case which

came under my care. The treatment of this congenital malformation is divided into two classes—palliative and curative.

The protection of the tumor with a soft, hollow truss, and the application of a simple cerate or collodion to the skin, if it is thin or seems likely to ulcerate, are sufficient to fulfil the first indication.

The curative plan of treatment is usually by puncture, injection, ligation, or excision. I treated my case by puncture and excision.

On May 24, 1886, my partner, Dr. H. M. Mixer, and I, were requested to examine a female child, two months of age, with a congenital tumor about the size of a hen's egg, situated on its back in the lumbar region. Upon examination it was promptly diagnosed as spina bifida. The skin was normal in appearance over the surface of the tumor, except near the apex, where it was thin and of a dusky color. The tumor was sessile. The child was well nourished. There was neither hydrocephalus, paraplegia, nor paralysis of sphincter muscles, and there had never been any convulsions. There was a simple talipes equinus. Dr. Mixer and I punctured the tumor with a medium-sized aspirating needle, and a few drachms of a light-colored fluid of a slightly alkaline reaction were withdrawn. No symptoms of collapse or convulsions followed. After four days the parents returned with the child. The tumor had again filled with the fluid. It was evacuated of its fluid at this time, and again on May 30th, June 8th and 18th, but refilled after each operation. The child continued to thrive and there was no decrease in the size of the tumor. The patient was not seen again until January 15, 1887, when nearly two ounces of fluid were withdrawn.

Nothing more was seen of the case until April 12th of this year. The child was now fourteen months old. Its general health was good. The tumor had increased considerably in size and measured nine and a half inches in circumference and was still sessile.

The operation of excision was now considered. The many failures and few successes attending this operation were stated to the parents. After thinking the matter over they decided to have the operation performed, which was somewhat reluctantly consented to on our part. The operation for its removal was performed April 15th. An anæsthetic was administered and a curved incision extending through the skin and sac was made on one side of the tumor near its base.

Dr. Mixer and I decided before beginning the operation to abandon it if the spinal cord occupied any part of the sac or if it contained any large nerves. On inspecting the interior of the tumor through the opening in the sac, it was found to be free from these important structures. The cleft in the vertebræ was quite small. A band of connective tissue passed from the apex of the tumor to its base. The operation was completed by making an incision similar to the first on the other side of the tumor. The elliptical opening in the skin was closed by interrupted silk sutures. The incision was so made that the edges of the wound were in exact coaptation, and would, after removal of the tumor, probably have remained so without the use of sutures. The sac was adherent to the skin and cellular tissue. A few adhesive straps were applied to prevent tension upon the sutures, and the dressing was completed by the application of a large compress of carbolized absorbent cotton, secured in position by a broad bandage around the body. A mixture of bromide of potassium and chloral was given to guard against a possible attack of convulsions. Twenty-four hours after the operation the child looked as well as it ever did. Every function seemed to be performed perfectly and continued so for forty-eight hours. Seventy-two hours after the operation it was noticed that a peculiar pallor had spread over the child's face, it refused to nurse, seemed restless, although apparently suffering no pain, and died soon afterward. The wound had almost completely united by first intention. Large quantities of cerebro-spinal fluid issued continually from the wound. A large compress or pad of absorbent cotton would be completely saturated in a few minutes. Indeed, while changing the dressing the fluid could be seen trickling from the wound.

Were we justified in performing the operation of excision? Let us see what some of the authorities say:

Holmes,[1] after speaking of the several methods of treating spina bifida, says: "There remains the operation of excising the sac. As several cases of successful excision are on record, it would, I think, be rash to proscribe the operation in a disease so fatal as spina bifida."

On page 841 of the same volume the indications for operative interference are succinctly stated as follows: "If the tumor can be tapped and the fluid drawn off without producing nervous symptoms; if there is no increased sensibility in the usual place of attachment of the cord; if the disease, though increasing, is not attended by convulsions; if the tumor is equable in transparency and consistence throughout; if, on tapping the tumor, the trocar can be passed into the centre of the sac without appearing to set up such symptoms as we expect from touching the cord—we may fairly act on the assumption that the cord is absent. In cases where it is suspected that the cord is present, no treatment should be adopted, except in express deference to the wishes of the child's parents and with a full knowledge on their part of the probability of a fatal result."

Our case was almost identical with the foregoing description. Again, on the same page, the author continues: "When the tumor refills as fast as it is emptied by the trocar, some other method must be

[1] Holmes's System of Surgery, vol. iii. page 842.

practised if the child's life is to be saved." This was true in our case. After each tapping the sac was speedily refilled.

Gross,[1] in speaking of the operation of ligation and excision, says: "Such procedures cannot be too pointedly condemned as being unscientific and certain to prove fatal."

We find this statement in the *International Encyclopædia of Surgery*,[2] in regard to the operation of excision of spina bifida: "The *modus operandi* is of little moment. If the sac contains cord elements the result will prove fatal; if not, success may possibly follow."

What caused the death of the child? It was neither due to shock nor to inflammation of the membranes of the cord. Was the loss of so large an amount of cerebro-spinal fluid, which plays an important part in the animal economy, a sufficient drain on the system to cause the fatal termination?

Gray[3] thus speaks of it: "The cerebro-spinal fluid fills up the subarachnoid space. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres and to prevent the effects of concussions communicated from without."

Ranney[4] says: "The functions of this fluid are to equalize the pressure within the brain, when the amount of blood in that organ suffers variation, as in the respiratory act."

The first day or two after the operation, while success seemed probable, I decided to report the case. After the operation proved a failure I almost decided not to report it; but after considering all the features of the case, it occurred to me that our failures are sometimes nearly as instructive as our successes. I have as yet been unable to find statistics giving the mortality of this operation.

I operated upon this case because the parents of the child had become tired of palliative treatment and desired to have a curative measure adopted. I consented to report this case because of the frequency of this congenital defect and the dearth of literature upon the subject.

THE PATHOLOGICAL ANATOMY OF TIC DOULOUREUX.

BY CHARLES L. DANA, M.D.,
PROFESSOR OF NERVOUS DISEASES IN THE N. Y. POST-GRADUATE MEDICAL SCHOOL, AND IN DARTMOUTH MEDICAL COLLEGE.

INVETERATE trigeminal neuralgia has been caused by local disease, such as a bony tumor, or aneurism, or syphilitic exudation.

The ordinary cases of tic douloureux, however, occurring after middle life, affecting usually and chiefly the second branch of the trigeminus, are not due to such causes. Little is known of its pathological anatomy, it being generally believed that there is no especial change in the nerve or its centres, and that the disease is a neurosis.

Anstie was of the opinion that this, like other chronic neuralgias, was due to an atrophic change in the sensory ganglia. Dr. de Schweinitz has reported one case, in which he found evidence of some degenerative inflammation in the nerve.[1]

Recently the Gasserian ganglion removed in a case of tic, was found to show evidence of degenerative atrophy.

But it may be stated confidently that neuritis and degenerative changes in the nerve are not the usual and ordinary conditions in tic douloureux, for in almost all cases, no matter how old, no permanent anæsthesia occurs. On the other hand, in cases of progressive trigeminal anæsthesia due to degenerative neuritis which I have seen, there is little pain. Nor should we expect a slow parenchymatous degeneration to cause great sensory disturbance.

The question arises, therefore, whether there is any tangible cause of the condition.

My proposition is, that many cases at least are due to an obliterating arteritis of the nutrient vessels of the nerves. My reasons for this are these:

1. The disease occurs at a time of life when degenerative changes in the arteries begin.

2. It affects chiefly and primarily a nerve supplied by one of the terminal branches of the internal maxillary, itself a branch of the external carotid. If it extends, or recurs, it involves a nerve nourished by the inferior dental, also a branch of the external carotid. It rarely affects seriously the supra-orbital nerve, which is supplied by a branch of the internal carotid. Hence the disease follows a certain fixed vascular distribution.

3. I have examined five superior maxillary nerves removed in typical cases of tic douloureux. In none was there any noteworthy change in the nerves.

In three of them striking evidence of arterial disease was found. In the fourth and fifth cases no bloodvessel was present in the specimens.

4. The view that an obliterating arteritis is a factor in this disease is strengthened by therapeutic experience. Nitroglycerin will sometimes relieve pains instantly, and for a long period of time. Aconite, which is so useful in this disease, also lowers blood-tension; while potassium iodide, which sometimes favorably modifies the arterial disease, is occasionally useful in tic.

5. There is unquestionable evidence that removal of the peripheral nerves sometimes cures tic en-

[1] THE MEDICAL NEWS, July 19, 1884.

tirely, and hence that the disease is peripheral, and due to some local peripheral irritation.

6. MM. Quenan and Lepars have recently stated that by a new method of injection they have been able to discover a closer and more extensive relationship between the nerve-trunks and bloodvessels than has heretofore been known, and they suggest in their conclusion that disturbances in blood-supply may be a serious factor in causing neuralgia. The details of their paper are not yet accessible.

My argument stands in this position, therefore:

I adduce positive facts that the trigeminus and its roots, and even nuclei and deep roots, are not diseased, even in old and typical cases.

In all cases where the *vessels* were examined striking disease was found to be present.

Circumstantial evidence is furnished by therapeutic experiment, and by the general etiology and anatomical distribution of the vessels and of the pains.

My argument is necessarily deficient in numbers of cases. If someone finds a superior maxillary nerve, from a case of tic, with a perfectly healthy infra-orbital artery, the case would be weakened.

I believe, however, that such a case, if it occurred, would be of an unusual type.

At present it seems to me that it would be pretty safe for me to assert that a good many of the typical cases of tic douloureux occurring after middle life (and almost all such cases do occur then) are due to an obliterating arteritis of an infra-orbital or inferior dental artery (terminal branches of the external carotid), plus some peculiar vulnerability of the central venous system.

The experience of surgeons in treating tic douloureux by ligaturing the common carotid, shows that pain in the inferior dental branch is affected favorably by this operation, pain in the superior maxillary is affected very little, and pain in the infra-orbital not at all. Possibly ligature of the external carotid may be all that is indicated surgically, for this artery supplies the second and third branches of the trigeminus. I would not expect ligature of the internal carotid to do any good.

The following is a summary of my cases:

Fig. 1.

The argument is defective in that I have not examined the infra-orbital arteries of healthy persons of from forty to sixty years of age. But this is not much of a defect, for the reason that with obliterating arteritis there must, I would admit, be some specific vulnerability of the nerve-centres.

CASE I.—Male, aged sixty-five years, a gardener; a patient of Dr. Robert Abbe's, to whom I am indebted for the nerve. The disease had lasted for four years; no alcoholic or syphilitic history. Pain involved the right superior maxillary nerve, especially the dental and infra-orbital branches.

The nerve was removed two years ago along with the infra-orbital artery as far back as the spheno-maxillary fossa, with the result of curing the case. The central end of the removed nerve was examined by me microscopically. The nerve-fibres were found but slightly affected. The artery, however, showed an extraordinary degree of inflammatory thickening (see Fig. 1). The muscular coat seems unusually thick, as though there was hypertrophy of the muscular fibre. There is a great deal of connective-tissue proliferation and thickening of the external coat. The intima also shows degenerative changes in its cellular constituents.

CASE II.—Michael D. (case of the late Dr. James K. Wood, reported by Dr. Dennis). Disease had lasted five years; no history of alcoholism or syphilis. Pain located in the left superior maxillary nerve. Nerve removed in 1873. Pain recurred in inferior maxillary. Death from opium habit, in 1877. Examination of the intra-cranial portion of the trigeminus by Dr. William Welch showed no evidence of disease, either in the nerve-root or in its nucleus or deep origin. On examination of the superior maxillary nerve by myself, there was found a great deal of fatty tissue about the fibres, and in this are *diseased bloodvessels*.

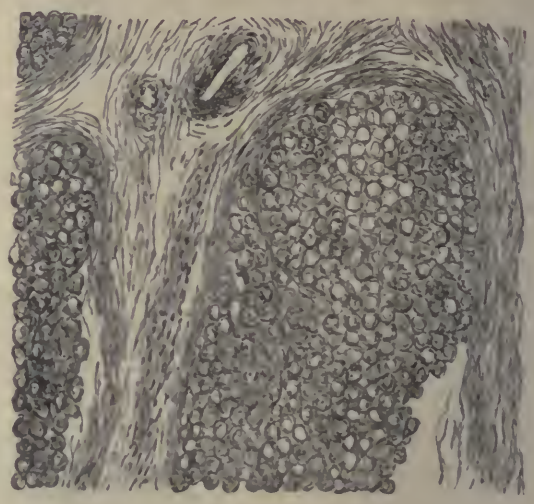
The nerve-fibres have undergone complete degeneration, and appear as broken, swollen tubes of myelin without a trace of axis-cylinders. The change is probably a post-mortem one, however, as the nerve has been kept in alcohol for nearly twenty years.

CASE III.—Emma B. (case of Dr. Wood's, reported by Dr. Dennis). Disease had lasted several years (no details given). Superior maxillary nerve removed by Dr. Wood. Recurrence of pains in the inferior maxillary nine months later. Examination of nerve by myself. No bloodvessel in field. The nerve shows nothing but a slight increase in its connective-tissue support. A few fibres have apparently undergone degeneration.

CASE IV.—Joseph J. (case of Dr. Wood, reported by Dr. Dennis), aged forty-two years; no history of syphilis or alcoholism. Has had malaria. Supra-maxillary neuralgia for several years. Operation and cure (for two years, at least). The supra-maxillary nerve, examined by myself, showed increase of interstitial tissue, with numerous tortuous capillaries in it whose walls are thickened. Small arterial vessels, with greatly thickened walls, due to increase of external and also of muscular coat. The intima also shows disease atheromatous in kind. Nerve fasciculi showed a slight increase in peri- and endo-neurium; occasionally a Deiter's cell among the fibres. Nerve-fibres not affected.

CASE V.—William S. R. T., male, aged fifty years, from Scotland, telegraph operator. Family history of tic douloureux. Had suffered from malaria, but not from syphilis. Not intemperate. Infra-orbital neuralgia for ten years. Had tried drugs of all kinds, and had had two operations at infra-orbital foramen. Operation by Prof. James K. Wood, in 1873. Patient was free from pain in 1876. The examination of the nerve by myself

FIG. 2.



showed a slight degree of degeneration of nerve-fibres. The picture presented is a good deal like that figured by Drs. Mears and De Schweinitz[1] in a section of the inferior dental nerve removed for trigeminal neuralgia. The change is not nearly so marked, however, and may be in part post-mortem.

TWO CASES OF CEPHALIC VERSION IN SHOULDER PRESENTATION.

BY C. S. HOFFMAN, M.D.,
OF KEYSER, WEST VIRGINIA.

MY object in publishing these cases is not on account of the mal-presentation of the children, but on account of the ease by which the cases were transformed into head presentations and delivered.

The first case I made no record of, but I distinctly remember the circumstances, although it occurred a few years ago.

A lady who was the mother of two well-developed children, and who had had easy labors previously, was taken in confinement at 4 o'clock in the morning, when she sent for a midwife whom she had engaged to attend her. The midwife arrived a few minutes after being called, and remained with her all the time. I was called in to see the case at 1 P. M., when I was told by the midwife that the labor was, as she thought, proceeding naturally, but very slowly for the amount of pain the woman was having. At about noon the waters broke, and what was thought to be the foot of a child appeared. Concluding something must be wrong, she had sent for me. The woman had now been in labor nine

[1] THE MEDICAL NEWS, July 19, 1884.

hours, during which time the waters had ruptured, while the foot of the child had been protruding for about one hour. On making an examination I found the left arm of the child protruding from the vulva; the left shoulder well down below the brim of the pelvis; the head in the right iliac fossa. The woman's pelvis was roomy, and the os well dilated. The pains were very strong, especially when I made any attempt to change the position of the child. I at once administered chloroform, and while the midwife continued its administration I folded the forearm of the child upon the arm and easily returned it into the womb. I then passed my hand over its head, and brought this down to the brim of the pelvis, converting the presentation of the child into a vertex presentation of second position. I then applied forceps to the head, and in less than ten minutes from the time my patient was fully under chloroform the head was well down in the pelvis. The balance of the delivery was easy and natural. The child was above the average in size, and as vigorous as could be desired.

My other case occurred a few days ago:

A negress, about twenty-five to thirty years of age, short and very stoutly built, and the mother of three children, all of whom were born alive, though she says her labors have always been tedious and hard. This time she was taken in labor Saturday evening, February 7th, it being the full period of her gestation. She was in active labor all Saturday night and all day Sunday. Sunday evening at about 7 P. M. she noticed something protruding from her vulva, which she discovered to be the arm of the child. The labor continued all Sunday night, and on Monday morning her husband came for me, telling me the history of the case as related. As she lived some distance from town, and not knowing what assistance might be required, I asked Dr. Workman to accompany me. We were unable to get to the woman until about 11 A. M., February 9th, making the period during which she had been in labor over forty hours. We found, as had been represented, an arm protruding. A loop of the umbilical cord was down in the vagina, œdematous and non-pulsating. The right arm and right shoulder were impacted well down in the pelvis. The head was in the right iliac fossa. The child was dead. The woman's pelvis was as roomy as could be expected in a short, stout person. The os was well dilated. The amniotic fluid was well drained off, and the womb tightly contracted. The woman was considerably exhausted. We gave her a couple of ounces of whiskey, and then Dr. Workman administered chloroform. Considering the long time the woman had been in labor, and the tightly contracted condition of the womb, it was a difficult undertaking to turn and deliver by the feet.

Remembering my experience with the case I have just related, I determined first to try to return the arm into the womb, by grasping the head, and bringing it down to a head presentation. Failing in this, I determined next to try to turn and deliver by the feet. If this should fail I had no other resort but embryotomy. As soon as she was fully under chloroform I folded the forearm of the child upon its arm, and then by steady but careful pressure and manipulation succeeded in slightly elevating the shoulder and carrying the arm into the womb. I then passed my hand up over the head, and brought it down into the pelvis, at once applied my forceps, and delivered the woman. In less than three-quarters of an hour from the time we arrived at her house the woman was delivered. Ten days after, the husband told me his wife was well and out of bed.

I am satisfied from the manner in which the womb was contracted down on the child that to turn would have been a very difficult if not an impossible operation. The child was of average size.

It is surprising to me in these cases with what ease the head was rotated after the arm was returned. The ease by which these deliveries were accomlished is to be seen by the short time occupied in performing them.

ORIGINAL ADDRESS.

THE CAUSATION OF DIPHTHERIA.[1]

By WILLIAM H. WELCH, M.D.,
PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY.

The subject which I have selected for this address is so largely a topic of the day, and fills at present so much space in medical journals, that the main facts which will be here presented must appear familiar to those who have followed recent medical literature. Nevertheless, many of these facts are so new and so important, and the disease to which they relate is one of such great interest, that no apology is needed for bringing before you a brief summary of the recent investigations concerning the causation of diphtheria, and the light which these discoveries have shed upon our knowledge of the pathology, prophylaxis and treatment of a disease more dreaded, and justly so, than any other infectious disease always present among us. Although these new discoveries are mainly the results of bacteriological work, it will be my purpose to dwell not so much upon minute bacteriological descriptions, more suitable to the laboratory and to special articles than to a general address of this kind, but rather upon those points which illustrate the application of these discoveries to a fuller and more correct knowledge of the nature, etiology, pathology, diagnosis, prevention, and treatment of diphtheria.

The history of our knowledge of diphtheria illustrates the difficulties which we encounter in endeavoring to reach a full understanding of a disease upon the basis of its symptomatology and pathological anatomy alone. Consider for a moment what are some of the uncertain and still much disputed questions concerning this disease.

Is diphtheria primarily local or constitutional in its

[1] The annual address before the Medical and Chirurgical State Faculty of Maryland, at its ninety-third annual session, held in Baltimore, April, 1891.

origin? Are all pseudo-membranous inflammations of the throat, not directly referable to caustic irritants, diphtheria? Is there a purely local, non-contagious pseudo-membranous laryngitis called croup distinguishable from diphtheria? Are the pseudo-membranous anginas secondary to scarlatina, and less frequently to measles and some other infectious diseases identical with diphtheria? Is there any relation between follicular tonsillitis and diphtheria? May diphtheria occur in a mild form as a simple catarrhal inflammation of the throat? Are pneumonia, acute nephritis, suppuration of the glands in the neck, etc., referable to the direct action of the diphtheritic virus; in other words, what lesions belong to the disease and what are complications? Shall reliance be placed chiefly upon local or upon general treatment?

These are some of the questions which the most careful study of the clinical history and of the anatomy of diphtheria has not been able to answer clearly and unmistakably. Nor are these matters only of theoretical importance. Referring to the two doctrines of the local and of the constitutional nature of diphtheria, Dr. J. Lewis Smith, one of the most painstaking and profound investigators of this subject in this country, says: "It is a matter of great importance—an importance transcending that of almost any other subject relating to the pathology of this dreadful scourge—that we should ascertain clearly and certainly which of the two prevailing theories is true, since the theory influences practice."

I hope to be able to show in the course of this address that this question, as well as others mentioned, have now been answered "clearly and certainly," and that we are in a position to solve other of the problems still remaining in doubt. All of this gratifying widening and deepening of our knowledge has come from the discovery of the microscopic germ which is the specific cause of diphtheria, and from the study of the singular and interesting properties of this germ. There is, perhaps, no other disease, with the exception of tuberculosis, upon which greater light has been shed by the discovery of its specific cause than upon diphtheria.

Permit me to present to you, in the first place, the evidence that the so-called Klebs-Löffler bacillus is really the specific agent of infection in diphtheria; and then to describe the most important properties of this microorganism, so far as they bear upon the subject of this address.

There are three things especially which have rendered difficult the convincing demonstration that a given microörganism is the specific cause of diphtheria.

The first is the uncertainty as to what shall be called diphtheria, and the possibility that included under this name are various affections which may be due to different causes. Hence it might happen that one investigator studying one class of cases—for instance, the pseudo-membranous anginas associated with scarlet fever, measles, etc.—might obtain results different from another who observed another class of cases. In view of this uncertainty, it is clear that conclusions as to the causation of primary diphtheria should be derived from the investigation of cases which all are agreed in regarding as genuine primary diphtheria. When the etiology of this undoubted class of cases has been determined, we are in a position to examine whether the secondary and other doubtful forms of diphtheria have a different causation or not.

A second difficulty has been not in the demonstration of microörganisms in diphtheria, but rather in the abundance of bacteria present in diphtheritic membranes. Of the various species of bacteria found in the false membranes of diphtheria, we must determine which are constantly present and which are inconstant. If we find one species always present in large number and absent in other conditions, the presumption is that this is the specific cause of the disease, and this presumption becomes a certainty if we are able to reproduce experimentally, by inoculation with pure cultures of this germ, a disease in all respects identical with human diphtheria.

Just here we meet the third difficulty, which consists in bringing positive evidence that our experimental disease is in reality identical with human diphtheria. We are accustomed to regard the fibrinous pseudo-membrane on the mucous membrane of the tonsils, pharynx, and air-passages as the most certain anatomical criterion of diphtheria, but we have long known that it is possible to produce experimentally in animals, by a variety of agencies which have nothing to do with diphtheria, false membranes histologically identical with the diphtheritic membrane. Hence the mere production of a false membrane by the inoculation of a germ suspected to be the cause of diphtheria, although it constitutes weighty evidence, cannot be considered absolutely conclusive that such germ is really the cause of diphtheria. But are there not other anatomical changes in the body characteristic of diphtheria beside the diphtheritic membrane? We owe especially to Oertel the demonstration of the fact that the diphtheritic virus is a most peculiar poison to the cells of the human body, and that it produces areas of cell death not only on the surface of mucous membranes, but also in deeper parts, in various lymphatic glands at a distance from the local lesion and in the spleen. These changes can be demonstrated by histological examination. Now, if we find that our suspected germ, beside causing pseudo-membranous inflammations, produces identical foci of cell death; if we find that it injures the kidneys, as we have long known it does in human beings; and if we find that it causes late muscular paralyses resembling the post-diphtheritic paralyses which the clinician regards as of such diagnostic value in doubtful cases of sore-throat, then we shall have evidence strong indeed that this germ is the real specific cause of diphtheria.

It is not surprising that all of these difficulties were not overcome in the first important publications of Klebs in 1883, and of Löffler in 1884. We owe to Löffler the first bacteriological study of diphtheria by the modern culture methods. Although his work was most valuable and accurate, he was compelled to express himself reservedly as to the significance of the bacillus which we now believe to be the cause of diphtheria. No such complete chain of proof was brought forward as Koch presented in his first memorable publication upon the tubercle bacillus two years previously. Hence it came about that the Klebs-Löffler bacillus from the first assumed a doubtful status, and that even to-day it is often referred to in writings on diphtheria as only one among many claimants to be regarded as the cause of diphtheria.

I shall not weary you by following the historical path in which obstacle after obstacle has been removed which stood in the way of the full recognition of the Löffler bacillus as the infectious agent of diphtheria, but I shall simply direct you to the goal which has been reached.

It is now established that this bacillus is constantly present in large number in the pseudo-membranes of all cases of primary diphtheria, and that no other species of bacteria is constantly to be found in this situation. The expectation expressed a year ago by Löffler that the results on this point would not be found to be different in this country from those in Europe has been fulfilled by the bacteriological examination by Dr. Abbott and myself of a series of cases of primary diphtheria occurring in Baltimore city, in all of which we found the Löffler bacillus as the only constant organism, as well as by the latest publication of Dr. Prudden. The occurrence of a bacillus, with all of the properties of the virulent diphtheritic bacillus, in persons not affected with diphtheria is so extremely exceptional that Löffler, notwithstanding years of searching, has been able to find it only once under such circumstances.

The Löffler bacillus can be readily obtained in pure cultivation on artificial media and its properties studied outside of the body. The sum of these properties suffices for its positive and ready identification.

Inoculation of pure cultures of this bacillus is found to be pathogenic for guinea-pigs, cats, pigeons, rabbits, and some other animals. By such inoculation a disease can be reproduced identical in all essential features with human diphtheria, and there is no other species of microörganism known capable of reproducing all of these features. In suitable animals we can cause by inoculating them with the diphtheritic bacillus pseudo-membranous inflammations of mucous membranes indistinguishable from those of natural diphtheria, swelling of adjacent lymphatic glands, multiple ecchymoses, serous transudations, fatty degeneration, and other lesions in the kidney and liver, late muscular paralyses, and foci of cell-death like those in human diphtheria. Upon this last point the investigations in full have not yet been published, but researches have for some time been directed in the pathological laboratory of the Johns Hopkins University, to the detection of areas of cell-death in the internal organs of the animals inoculated with diphtheria, and I may say here that we have been able to confirm and extend in animals Oertel's researches on this subject in human beings.

By the labors, therefore, of many investigators since Löffler's first publication in 1884, including those of Löffler himself, all of the conditions have been fulfilled for diphtheria which are necessary to the most rigid proof of the dependence of an infectious disease upon a given microörganism, viz: the constant presence of this organism in the lesions of the disease, the isolation of the organism in pure culture, the reproduction of the disease by inoculation of pure cultures, and similar distribution of the organism in the experimental and in the natural disease. We are then justified in calling the Klebs-Löffler bacillus, the bacillus diphtheriæ.

Let us now turn our attention to the most important properties of this bacillus. However great may be the scientific interest of the discovery of the specific germ of an infectious disease, this discovery by itself is after all only the realization of the faith of enlightened physicians, that the infectious diseases are all caused by specific living organisms. The practitioner is fully justified in inquiring how this discovery helps him to a better understanding of the disease, to a more certain diagnosis, to a more accurate interpretation of symptoms, to more effective measures of prevention and of treatment. Although these expectations have been met only in part, enough has been accomplished already to show that great practical value has come and is likely to come in still larger measure from the discovery of the bacillus diphtheriæ.

The specific germ of diphtheria is a bacillus, devoid of independent motility, averaging in length about that of the tubercle bacillus. It presents itself both in diphtheritic membranes and in cultures, often in such bizarre forms that these belong to its most characteristic morphological properties. It grows upon our ordinary culture media, best upon Löffler's blood-serum and bouillon mixture, but it will grow even upon steamed potato. As bearing upon a possible source of infection it is important to note that the bacillus will multiply readily in milk. It does not multiply or it does so only very sluggishly at a temperature below 18° C. (about 64° F.). It is killed by exposure for ten minutes to a temperature of 58° C. (136.4° F.). It is not necessary to describe here in detail the peculiarities of its growth upon the various culture media, although to the bacteriologist these are the guides for the isolation of the bacillus in pure culture. The series of cultures which I here exhibit to you illustrate the characteristic appearances. It suffices here to draw the conclusion that, unlike the tubercle bacillus, the bacillus of diphtheria may readily find conditions outside of the body suitable for its multiplication.

But, as is well known, it is not necessary that an infectious organism should actually propagate itself outside of the body in order to produce ectogenic infection. Such infection may occur if the organism simply preserves its vitality. On this point we know that the diphtheritic bacillus, although it forms no spores, is among the more resistant bacilli of the non-spore-forming class, withstanding for a long time drying and other influences injurious to the less resistant forms. The specific bacilli have been obtained in cultures made from diphtheritic membranes preserved dry in a piece of linen cloth for five months. This property is in harmony with the experience that rooms, clothing, and other objects may retain for months the diphtheritic virus in an active state. As the diphtheritic bacilli may live for a still longer period in the moist state, and as moist, damp dwellings have long been held to be particularly favorable for the development of diphtheria, it is probable that statements as to the preservation of the diphtheritic virus in such situations for a year or more are not without foundation.

Of capital importance is the establishment of the fact that the diphtheritic bacillus develops only locally at the site of infection, and does not invade the tissues or the circulation. It is found only in the diphtheritic pseudo-membrane, and not even in the subjacent mucous membrane. Indeed, it is only the superficial parts of the false membranes which contain the bacilli. The determination of this fact gives at once a clear and decisive answer to the long-mooted question as to the primarily

local or constitutional nature of diphtheria. Diphtheria is, without a doubt, local in its origin. The germ which causes this disease not only makes its first appearance and multiplies where the pseudo-membrane is formed, but it does not even subsequently invade the blood and organs. As we shall see later, the constitutional symptoms are due to the reception of a chemical substance or substances of remarkable toxic properties, produced by the local development of the diphtheritic bacillus. This settlement of the controversy as to the local or the constitutional origin of diphtheria is one of the most important outcomes of the bacteriological study of this affection, for the question pertains to a fundamental point in our conception of the disease. Nevertheless, from the point of view from which this controversy has usually been waged, the triumph is, in my opinion, only a partial one for the localists, for, as will be shown later, I believe that there are reasons as strong as ever for the employment of constitutional measures of treatment in combination with the local ones.

From what has already been said, we are prepared to consider for a moment in what ways a person affected with diphtheria becomes a source of danger to those around him, and to the locality. The diphtheritic bacilli are conveyed from the body in particles of diphtheritic exudation, saliva, and other secretions discharged through the mouth and nose. (It is not necessary to consider here the comparatively exceptional localizations of the disease.) In this way the infectious substance may readily become attached to the person and clothing of the patient, and of those around him, as well as to the bedding, furniture, floor and walls of the room, dishes, and other objects. Notwithstanding the statements current in nearly all text-books, there is no evidence that the breath of the patient contains the diphtheritic germ, except as bits of false membrane or secretion may be mechanically expelled in the act of coughing, hawking, or sneezing. It has been proven experimentally that the expired air is incapable, during ordinary respiration, of detaching bacteria from the moist mucous surfaces over which it passes. The specific germs are not so readily conveyed by air-currents from a diphtheritic patient to those near him, as they are, for instance, from a patient with scarlet fever, in which the germs are in all probability thrown off from the surface of the body on light epidermal scales. Nor are the chances of infection of the sources of supply of drinking-water with the diphtheritic bacillus so great as is the case with such diseases as cholera and typhoid fever, in which the stools contain in large number the specific bacteria, and are likely to be disposed of in such a way that under bad sanitary conditions these bacteria may find their way into wells and streams. While there are some accounts intended to show the conveyance of the diphtheritic virus through the drinking-water, we do not hear much of this as a source of infection, and it is not likely that it plays an important *rôle*, although it is probable that the diphtheritic bacillus may sometimes be discharged by the stools.

Diphtheria is one of the infectious diseases the germs of which may be taken into the body by the inspired air. Inasmuch as bacteria cannot, under ordinary conditions, occur as floating matter in the atmosphere until they have been completely dried down so that air-currents can detach as dust the little particles to which they adhere, it is evident that only those infectious germs are likely to be conveyed by the air which are not destroyed by complete drying. As has already been mentioned, the diphtheritic bacillus withstands for months desiccation which is so injurious to the cholera vibrio and to many other species of bacteria. While, therefore, we must admit that air-infection with the diphtheritic bacillus is a real and conspicuous danger, it is well to bear in mind that modern bacteriology has taught us the great lesson that the most frequent and important mode of infection is by contact with infected substances. When we consider the manifold ways in which the diphtheritic bacilli may be widely distributed, and when we consider the habit of young children—who are the most numerous victims of the disease—of handling everything and of putting everything into their mouths, we are led to appreciate that infection by contact must play the leading part in the transmission of diphtheria.

I will now ask your attention to a brief consideration of the most deadly of all the properties of the bacillus diphtheriæ, namely, the power of producing extraordinarily poisonous chemical substances. That the grave constitutional symptoms of diphtheria are referable to such substances has long been surmised, and as soon as it was found that the bacilli causing diphtheria develop only locally it became certain that toxic substances must be formed. The results of the investigations as to the nature and properties of these substances are not only most important for the etiology of diphtheria, but are among the most significant acquisitions of bacteriology in recent years. We owe these results chiefly to the researches of Roux and Yersin and of Brieger and Fränkel.

If bouillon cultures, four or five weeks old, of the diphtheritic bacillus—preferably containing some blood-serum—be sterilized by heating them at temperatures of about 55° C., or if they be deprived of bacteria by filtration through a Chamberland porcelain filter, it is found that the sterilized culture fluid possesses highly poisonous properties when injected, even in small quantity, into animals. The toxic substance is not of a crystallizable, alkaloidal nature of the kind known as a ptomaine or a toxine, for no such substance can be detected in these cultures. The poisonous material, although it has not been separated in a condition of absolute purity, has been shown to be probably of a proteid nature. It is precipitated by alcohol and by saturation with ammonium sulphate and sodium phosphate. It is mechanically dragged down by fine precipitates, such as those of calcium phosphate. It is soluble in water. Obtained in a state approaching purity it appears as a white, amorphous mass of light specific gravity. In the moist state it loses, in great part or entirely, its poisonous properties when subjected to heat above 60° C., but when dry it stands temperatures of 70° C. It is not volatile, and can be preserved for months at least in the dry state without loss of its characteristic properties.

Some idea of the extraordinarily poisonous nature of this substance can be obtained from the statement of Roux and Yersin, that four-tenths of a milligramme of the substance (after deducting the weight of the ashes and of the non-poisonous part insoluble in alcohol) obtained by evaporating to dryness the active culture fluid,

is sufficient to kill at least eight guinea-pigs, weighing each four hundred grammes, or two rabbits, weighing each three kilogrammes. As the major part of these four-tenths of a milligramme is represented by other substances than the diphtheritic poison, it is apparent that the poison must be of appalling potency.

If this poison, or the sterilized culture fluid containing it, be injected into a guinea-pig or rabbit or other susceptible animal, it is found to be capable of producing all of the changes in the body which follows the inoculation of pure cultures of the diphtheritic bacilli, with the exception of the pseudo-membrane. For the production of this membrane the bacilli are necessary, but the other lesions, such as the local œdema after subcutaneous injections, the ecchymoses, the serous transudations, the changes in the kidney, liver, and other parts are observed after the injection of the toxic albumin, as the diphtheritic poison is sometimes called, as well as after inoculation with the bacilli. If the animals live sufficiently long muscular paralyses may develop.

The most remarkable property of this toxic albuminoid substance, or these substances (for we do not know positively that there is only one such substance), is that when injected in a single sufficiently small, but fatal, dose, it may produce no apparent disturbance for days, and the death of the animal may occur many days, or even weeks, or months after the injection. This is a quality which we have not been accustomed to attribute to chemical poisons, and it is evidently one of the greatest practical significance. If it is true that the diphtheritic bacilli are capable of producing at the site of their local development poisonous substances which, when at first received into the system, may cause no manifest harm, but which may destroy life perhaps after days, then it is clear that even if we succeed in killing the bacilli in the pseudo-membrane, the individual may still die of toxæmia.

That the bacilli of diphtheria may produce apparently identical toxic proteids in the animal body has been demonstrated. These poisonous proteids are probably allied in their constitution to the poisonous substances found by Weir Mitchell and Reichert in the venom of rattlesnakes and of other serpents, and belong to a group of interesting chemical products now known to be produced by various pathogenic bacteria and other organisms, and which have been and are still being carefully studied, among others, with especial success by Sydney Martin and by Hankin in England. While there is reason to believe that the diphtheritic poison is a proteid this view cannot be regarded as established until the poison has been isolated in a state of purity. As we know that the poison can be mechanically dragged down by fine precipitates, it is possible that it is intimately united to the precipitates of albuminose without being itself an albuminose. Interesting as it might be to tarry longer at this point, we cannot complete this outline sketch of the properties of the diphtheritic bacilli without the consideration of certain other important characteristics which they possess, and time admonishes us to hasten on.

It is well known that the character of the symptoms, and especially their gravity, vary in a marked degree not only in different cases of diphtheria, but also in different epidemics. There are epidemics of a mild character, and there are epidemics, such as some of those of recent years in the northwestern part of this country, which sweep away nearly all the children of a neighborhood or a town. In estimating the value of different methods of treatment, this is a point not always kept sufficiently in view. The question suggests itself whether there is anything known concerning the attributes of the bacillus diphtheriæ which will explain these differences.

As to this point, it is to be said that this bacillus, as obtained in pure culture from different cases of diphtheria, varies in its virulence, as tested upon animals, to a greater degree than any known pathogenic organism. Diphtheritic bacilli isolated from different cases of diphtheria, will sometimes kill guinea-pigs by subcutaneous inoculation in twenty-four hours; in other cases they require two, three, four, even nine, days to accomplish this result. From two cases of diphtheria of slight severity recently examined at the Johns Hopkins Hospital, Dr. Abbott obtained in pure culture a bacillus identical in its morphology and its behavior on culture media with the diphtheritic bacillus, but incapable of killing guinea-pigs by subcutaneous inoculation. In this respect it resembles the so-called pseudo-diphtheritic bacillus, but it differs from this organism in having been present in the diphtheritic exudate in large number. While observations are as yet insufficient to justify a positive statement, there seems to be a general correspondence between the virulence of the bacilli and the gravity of the case in which they are found, but there are exceptions to this. It is interesting to note that as a case progresses toward recovery a tendency has sometimes been observed toward a diminution in the virulence of the bacilli. It has been demonstrated that the less virulent the bacillus, the smaller is the amount of the toxic proteid which it is capable of producing in cultures, this substance being replaced, according to Fränkel and Brieger, by another albuminoid product devoid of toxic properties. While other factors may be, and doubtless are, concerned in determining the severity of a case of diphtheria, it is evident that the demonstrated variability in virulence of the diphtheritic bacillus affords an explanation of many of the differences observed in the onset and decline of an outbreak of diphtheria and in different epidemics of this disease. The existence of an attenuated variety of the diphtheritic bacillus, which may under circumstances which we do not now understand, acquire virulence, is unquestionably of great significance in the epidemiology of diphtheria.

Roux and Yersin have brought forward a number of reasons for regarding the so-called pseudo-diphtheritic bacillus (that is a bacillus resembling, if not absolutely identical with, the diphtheritic bacillus, in its morphology and its behavior on culture media, but incapable of killing animals) as an attenuated form of the bacillus diphtheriæ. In the two cases of apparent diphtheria referred to, in which a bacillus, which we could not distinguish from the ordinary diphtheritic bacillus, save by absence of pathogenic properties when inoculated into guinea-pigs, there was a thin, grayish, pseudo-membranous deposit on the tonsils, and the symptoms were of a mild character. The bacilli were present in large number and were mingled in each case with a large number of the

golden pyogenic staphylococci. It would be interesting to determine whether the virulence of the diphtheritic bacilli may be modified by the presence of other bacteria. Whether or not we are justified in regarding the two cases of pseudo-membranous angina referred to as genuine diphtheria cannot be decided until the status of the pseudo-diphtheritic bacillus is settled.

I wish now to say a few words concerning the diagnostic value of the bacillus of diphtheria, and this will afford a convenient opportunity of touching also upon the existence of very mild cases of diphtheria and upon pseudo-membranous anginas, which are not due to the diphtheritic bacillus.

While typical cases of diphtheria, especially when occurring during an epidemic, offer no especial difficulties in diagnosis, every practitioner of experience will admit that cases occur often enough which he does not know whether to call diphtheria or not. If the case is a mild one, with whitish patches on the tonsils or pharynx, which soon disappear, and constitutional symptoms are slight, he does not generally venture to make a diagnosis of diphtheria. Still the diagnosis in just this class of cases is of great importance, for such a case may be a dangerous source of infection to others.

Now we possess in the detection of the Klebs-Löffler bacillus a positive means of diagnosis of diphtheria, and it is to be considered how far this means is available to the general practitioner. The bacteriological method of diagnosis involves, first, the microscopical examination, with an oil-immersion objective, of properly stained cover-glass specimens of the suspected inflammatory exudation; second, the preparation and study of cultures from this exudation made upon suitable media, preferably Löffler's blood-serum and bouillon mixture; and third, in some cases the inoculation of a guinea-pig with the pure culture. In many cases the mere microscopical examination of cover-slip preparations from the exudation will suffice, but the diphtheritic bacillus cannot be identified in this way so positively as the tubercle bacillus, for instance; and in just the class of cases where doubt as to the diagnosis is likely to exist, this procedure is most apt to prove insufficient. The examination of the cultures can be made the day following their preparation, and in nearly all cases this will afford a positive answer. The preparation of the cultures requires some training in bacteriological methods, and also a modest outfit of bacteriological apparatus. To a person thus equipped the examination offers no especial difficulties. Now, although Roux and Yersin have attempted to popularize the method, and have urged its general adoption by medical practitioners, I do not think that under existing circumstances it is likely to be widely applied in general practice. The method can be readily employed in hospitals and children's asylums, where it is calculated to be of great service, and in most large cities probably some one will be found who can be called upon to conduct such examinations. As the importance of practical training in bacteriology becomes more widely recognized in medical teaching, a larger number will enter upon the practice of their profession prepared to employ bacteriological methods of diagnosis.

The diphtheritic bacillus has been found in a number of cases of inflammation of the tonsils and pharynx in which the exudation and the symptoms were not sufficiently characteristic to permit a positive diagnosis in any other way than by the recognition of the specific bacillus. We do not possess sufficient information to be able to say how frequent these cases, which are generally of a very mild character, are, or how they can be diagnosticated by a merely clinical or anatomical examination. That they are not infrequent during the epidemic prevalence of diphtheria seems probable from clinical experience.

The view which has been widely advocated, that most cases of so-called follicular tonsillitis, which, as is well known, may prevail as an epidemic and may present marked but not dangerous constitutional symptoms, is a form of diphtheria not supported by bacteriological examination. In these cases the diphtheritic bacillus is usually absent, but under the rather vague name of follicular tonsillitis are doubtless included some cases of genuine mild diphtheria.

Not all pseudo-membranous inflammations of the throat are caused by the specific bacillus of diphtheria. It has been demonstrated by Wurtz and Bourges that this bacillus is absent, and that a streptococcus is present in nearly all cases of pseudo-membranous angina developing in the early stages of scarlatina, so that most cases of so-called scarlatinal diphtheria are not diphtheria at all, if we limit, as seems best, the term diphtheria to the affection caused by the Löffler bacillus. The Löffler bacillus is, however, present in the diphtheria appearing in the late stages of scarlatina and during convalescence, and it seems that scarlet fever is a predisposing cause of the development of genuine diphtheria.

In a series of cases, numbering 24, of pseudo-membranous inflammations of the tonsils, pharynx, and larynx, designated at the time as diphtheria, Dr. Prudden found in all but two a streptococcus, and in none the Löffler bacillus. These cases were, for the most part, either secondary to scarlatina, measles, whooping-cough, or erysipelas, or developed under the same epidemic influences as these diseases, so that these cases probably should not be regarded as genuine diphtheria. This is the view now held by Dr. Prudden himself in his latest publication, according to which renewed observations in cases of primary diphtheria have convinced him of the causative significance of the Löffler bacillus. Roux and Yersin, whose work has contributed largely to the present recognition of the Löffler bacillus as the cause of diphtheria, have also examined with negative result, so far as this bacillus is concerned, a few cases with pseudo-membranous deposits on the tonsils and pharynx of such a character that the clinician had no doubt of the existence of diphtheria. We must admit, therefore, that pseudo-membranous inflammations of the throat resembling diphtheria occur, both secondary to infectious diseases and apparently primary, in which the Löffler bacillus is not found. The further etiological study of these cases and their more precise characterization as to clinical history and pathological anatomy constitute a promising field of investigation. Until certain points have been cleared up by such investigation, there may be a certain amount of confusion as to the conception of diphtheria, but this affection seems to me even now sufficiently well characterized as to its symptomatology, pathological anatomy, and etiology to constitute a definite and independent disease which need not be confounded with other diseases.

A few words may be appropriately introduced here as regards the use of the term diphtheria. The term diphtheritis or diphtheritic inflammation is used in an anatomical sense to designate a certain kind of pseudo-membranous inflammation of a mucous membrane which may be produced by a variety of causes. The designation of certain other varieties of pseudo-membranous inflammations of mucous membranes as croupous and as pseudo-diphtheritic still further complicates the terminology. It is now generally recognized that it is best to limit the use of the word diphtheria to a definite disease and not to an anatomical process. This disease may appear in the form of each or all of the varieties of pseudo-membranous inflammations mentioned. It has for some time been clear that the boundaries of the disease which should be called diphtheria cannot be sharply drawn save on etiological grounds. So long as these grounds were lacking the boundaries were uncertain, vague, and fluctuating. We now possess definite criteria for the recognition of the disease, and it seems to me that instead of saying that diphtheria may be caused by a variety of microörganisms, a statement which is undoubtedly true if we understand by diphtheria all pseudo-membranous inflammations of the throat, it conduces to clearness and definiteness to confine the term diphtheria to the disease caused by the Klebs-Löffler bacillus. This will not necessitate material deviation from ordinary usage. The etiological basis of classification of disease is the surest and best, and in this case it will doubtless be found to correspond to a symptomatic and anatomical entity.

The data at present at hand are insufficient to settle the burning question as to the existence, independent of diphtheria, of a disease called membranous croup, supposed to be of a purely local, non-contagious character. Not a few cases of pseudo-membranous laryngitis without membranes on the tonsils or pharynx have been examined with the result of finding the Löffler bacillus. One such case, diagnosticated by the physician as croup, will be found in the series reported by Dr. Abbott and myself. In this we detected in large number the diphtheritic bacilli on the mucous membrane of the pharynx although no membranous deposit was visible, and similar results have been recorded by others, so that there is no doubt that diphtheria may occur with membranous inflammation limited to the larynx. In Dr. Prudden's first series of cases there were some instances of pseudo-membranous inflammation confined to the larynx and trachea in which streptococci, but no Löffler bacilli were found, so that it is probable that pseudo-membranous laryngitis, without involvement of the tonsils or pharynx may be produced by the streptococcus. But whether or not membranous croup may occur in the sense advocated as a purely local, non-contagious affection cannot be said to have been settled by bacteriological investigations.

An account of the results of the bacteriological study of diphtheria would be incomplete without some reference to pathogenic bacteria, which are frequently, although not constantly, found associated with the Löffler bacillus in diphtheritic exudations. These associated bacteria may be the cause of grave complications. Diphtheria is no exception to the rule that all necrotic and ulcerative processes on mucous surfaces where bacteria normally occur open the way to the invasion of pathogenic bacteria, especially to the widely distributed pyogenic streptococci and staphylococci. Mention has already been made of the probable causation of certain secondary pseudo-membranous anginas by a streptococcus. The same or apparently the same streptococcus is very commonly present in diphtheria. It is usually held to be identical with the streptococcus pyogenes. This organism, unlike the Löffler bacillus, is capable of invading the blood and tissues. The most frequent and important complication produced by this streptococcus in diphtheria is broncho-pneumonia, which develops as an aspiration pneumonia, as has been shown by the investigations of Prudden and Northrup. The common pus-producing bacterium, the staphylococcus pyogenes aureus is, next to the streptococcus, the most common pathogenic bacterium complicating diphtheria. It is to the invasion of these secondary bacteria that such complications of diphtheria as acute ulcerative endocarditis, suppuration of lymphatic glands, inflammations of serous membranes, and erysipelas are referable.

A matter which, although not new, has attracted much attention in recent years, may prove to be of such importance in the etiology of diphtheria that I will direct your attention to it for a few moments. Evidence has been brought forward intended to show that diphtheria may be communicated to human beings by domestic animals afflicted with this disease. The animals chiefly concerned are cattle, cats, and fowls. There have been reported in England during the last decade epidemics of diphtheria in which the evidence is strong that the diphtheritic germ was conveyed in milk. There are two theories as to these milk epidemics. One is that the diphtheritic virus got into the milk from persons affected with diphtheria, the other is that the cows yielding the milk were affected with diphtheria. This second daring hypothesis Klein has attempted to support by experiment. He claims that by the inoculation of two cows subcutaneously on the shoulder with a broth culture of the bacillus diphtheriæ he has succeeded in producing genuine infection with the appearance of vesicles and pustules on the udders and the elimination of the specific bacilli by the milk. These experiments should be received with great caution, as they are in opposition to all that we know concerning the exclusively local development of the bacilli at the point of inoculation. We possess no satisfactory evidence that cattle are ever affected with a natural disease identical etiologically with human diphtheria, although it is known that an affection sometimes called diphtheria may appear in calves.

That cats may acquire diphtheria and may be a means of transmitting the disease to human beings is a widely-spread belief. Medical literature contains many instances in which, on the one hand, cats appear to have contracted a disease by eating substances contaminated with the discharges from diphtheritic persons; and, on the other hand, children seem to have become infected with diphtheria by handling sick cats. Noah Webster, in his curious book on *Epidemic and Pestilential Diseases*, published at the end of the last century, noted the coincidence of cat distempers with malignant angina. In the recently published *Annual Report of the Local Government Board of England*, Klein has brought to-

gether the evidence to be found on this point. Inasmuch as cats are among the animals most susceptible to inoculation with cultures of the Löffler bacillus, acquiring a disease resembling human diphtheria, there is no *à priori* reason why they may not be the subjects of a natural disease etiologically identical with diphtheria. But the possibility of the experimental production of a disease in an animal is no proof of the natural occurrence of such disease; and thus far there is not satisfactory evidence that diphtheria occurs as a natural disease in cats. What is necessary to settle this question is to make careful bacteriological studies in suspected cases of diphtheria in cats. The matter is of sufficient interest and importance to merit careful study, and we should be glad of the opportunity of making examinations in suitable cases which may come to the notice of physicians in this vicinity.

Pigeons also are susceptible to inoculation with the Löffler bacillus, and it is well-known that a membranous inflammation of the mouth, fauces, and trachea occurs as a destructive epidemic in chickens, turkeys, pigeons, and other birds. This so-called diphtheria of fowls has not, however, been found to be caused by the same microörganism which causes human diphtheria, so that notwithstanding some rather striking observations according to which human beings have appeared to contract diphtheria from fowls, there is no positive proof of the dissemination of genuine diphtheria in this way. It may be that human beings may become infected by the germs producing the so-called diphtheria in domestic animals, but if so, there is no proof that the disease produced is etiologically identical with the disease caused by the Löffler bacillus.

We have now passed over, gentlemen, in rapid survey, some of the leading factors concerned in the causation of diphtheria. The limits of an address do not permit an exhaustive consideration of the subject even from the bacteriological point of view. Many circumstances of great importance in the etiology of diphtheria, such as the influence of unsanitary surroundings, particularly those of a domestic character, and the often dominant *rôle* of school attendance upon the dissemination of the disease could not be considered. These, however, are etiological factors which can be more profitably discussed from an epidemiological than a bacteriological point of view.

I have already made such demands upon your patience that I have not left myself sufficient time for any adequate consideration of the prophylaxis and treatment of diphtheria—subjects, indeed, which would furnish ample material for a separate discourse. I am glad to see that the subject of the treatment of diphtheria is to be presented in a special paper before this meeting. I cannot refrain, however, from directing your attention to a few of the general principles controlling methods of prevention and of treatment of diphtheria, and from pointing out the directions in which our increased knowledge of the causation of diphtheria leads us in our search for more effective measures to these ends.

The very fact that we are no longer groping in the dark, but that we know the enemy, his strength and his weakness, should inspire our courage and hope, should make us forge new weapons and sharpen our old ones, and should point out where to ward off attack and where to force the battle.

The possibility of making an early diagnosis of diphtheria by the aid of bacteriological examination enhances the chances of success in coping with this disease, both in prevention and in treatment, and, as already intimated, provision should be made in hospitals and children's asylums for making such examinations.

Inasmuch as the diphtheritic bacilli are present only in the false membranes and other local products of the disease at the site of infection, and are distributed outside of the body primarily through these, it is apparent that the patient should be strictly isolated; that unnecessary fabrics and other objects, especially such as cannot be readily disinfected, should be first removed from the room where the patient is placed; that care should be taken to prevent, as far as possible, the soiling of the person and clothing of the patient, of the attendants, and of the physician, as well as that of other objects in the room, with the discharges of the patient; that opportunity should not be afforded for the desiccation of these discharges, which then may contaminate the air, and that efficient measures of disinfection of the room and of all objects which by any possibility can become infected should be employed. That the enforcement of the measures indicated is capable of restraining the spread of the disease, even in crowded infants' asylums and hospitals, has already been demonstrated by actual experience. They require for their accomplishment education on the part of the community, of physicians, and of sanitary authorities in the principles of disinfection, and an intelligent appreciation of the dangers to be guarded against. I seize this occasion, as I have others, to urge the importance in cities of public disinfecting establishments, constructed according to improved modern principles, and of a corps of men in the employment of boards of public health, trained in proper methods of disinfection.

The length of time that the patient should be quarantined depends evidently upon the duration of the period in which active diphtheritic bacilli remain on the mucous surfaces attacked. As to this point we possess some definite information, which shows that the period varies within wide limits. In some cases the bacilli can no longer be found after the false membranes have completely disappeared; in many cases they vanish within three or four days after the local inflammation has subsided, but they have been found as much as fourteen days after the inflammation has gone, and when the mucous membrane appeared healthy. In a case reported by Löffler, the bacilli were found three weeks after the return of the temperature to the normal, and were present for a month altogether in a state capable of carrying infection. It is evidently not possible to set a precise limit for the period of isolation of the patient. Löffler suggests that the patient should not be permitted to mingle with others or to return to school for at least eight days after the disappearance of all local manifestations, and he reckons four weeks from the beginning of the disease as the period for keeping the children out of school. Where it is possible to do so, the length of this period can be controlled by bacteriological examinations of the mucous membrane of the throat.

We have thus far considered the patient as the immediate source of infection. The evidence already men-

tioned in favor of the occasional dissemination of the diphtheritic virus through the milk suggests at once the importance of controlling, not only the condition of the milk as received for distribution, but also of inspecting the sources of milk supply. Evidently milk should not be permitted to be sold from dairies attached to households where there are cases of diphtheria.

It does not seem to me permissible to throw out altogether the possibility of the conveyance of diphtheria by domestic animals, especially by cats, which are likely to be fondled by children even more when the animals are sick than when they are well.

In considering what can be done to render children less vulnerable to diphtheria, and to ward off an attack after exposure to the disease, the question arises, what conditions of the individual we may regard as predisposing causes. Clinical experience, as well as experiments upon animals, indicate that morbid states of the mucous membrane of the throat, such as ordinary catarrhal inflammations, swollen tonsils, sensitiveness to "catching cold," the existence of measles and scarlatina, are predisposing factors. At all times, but especially during the epidemic prevalence of diphtheria, it is important to hold in check these morbid states as far as possible. Experiments upon animals would seem to indicate that some lesion of the mucous membrane is essential for the lodgement and multiplication of the diphtheritic bacilli, but it would be entirely unjustifiable to transfer directly to human beings the results of these experiments without warrant from clinical experience, and while this experience shows the importance of such lesion, it also shows that perfectly healthy children may be attacked by diphtheria, so that we have no right to assert that in human beings infection with the diphtheritic bacilli cannot occur without preëxisting alteration of the mucous membrane. The frequency and readiness with which the tonsils become the seat of the diphtheritic process may be explained by the peculiar anatomical structure of these parts, as has been shown by the researches especially of Stöhr and of Hodenpyl. The rarefaction of the covering epithelium and the emigration of leucocytes to the surface found as a normal condition, seem to render the tonsils particularly vulnerable to the lodgement of the diphtheritic bacilli, and the lymphatic structures, here normally laid almost bare, are favorable for the absorption of the toxic products of the bacilli, as has been pointed out in the recent interesting paper of Hodenpyl, "On the Anatomy and Physiology of the Faucial Tonsils."

The prophylactic value, in persons liable to exposure to diphtheria, of cleanliness of the teeth and mouth and of the frequent use of weak antiseptic mouth-washes, nasal douches, and gargles is worthy of the attention of physicians. For this purpose Löffler recommends aromatic waters, weak sublimate solutions (1 : 10,000 to 1 : 15,000), or, perhaps better, solutions of mercuric cyanide (1 : 8000 to 1 : 10,000); also, chloroform water, chlorine water (1 : 1100), thymol (1 : 500 parts of 20 per cent. alcohol). The use of some of these solutions evidently involves danger of poisoning in children unless special precautions are taken.

The suggestion recently made by Dr. Jacobi, that, in addition to caring for those sick with diphtheria, places of refuge should be provided for the temporary stay of children sent from home to escape infection, seems practical and calculated to meet the circumstances of many families.

The dominant *rôle* often played by schools in the spread of diphtheria throughout a community renders especially urgent the introduction of a system of daily medical inspection of the schools.

The importance of letting air and sunlight into dark, damp dwellings, and of attending in general to matters of domestic sanitation, is a lesson plainly to be drawn from the history of such places as nests of diphtheria.

If the researches relating to the etiology of diphtheria which have been so fruitful in recent years have not added to the list of agents—whose name is legion—employed in the treatment of this disease, they have given precision to the indications for treatment. From what has been said concerning the localization of the diphtheritic bacilli, and the peculiar characters of the toxic substances produced by them, it is apparent that the strongest indications exist, on the one hand, for the earliest possible local treatment by germicides, and, on the other, for the destruction of the poison in the system, and, in the absence of any antidote, for supporting measures of treatment which shall enable the body to withstand the effects of the poison.

The superficial situation of the specific bacilli in diphtheria seems to render this disease especially favorable for effective local antiseptic treatment, but the difficulties encountered in actually destroying the germs in the diphtheritic deposits, even when these are accessible to local applications, emphasize the fact that the obstacles to thorough disinfection within the human body are exceedingly great. Many of our most powerful antiseptics, when they come into contact with the tissues and fluids of the body form precipitates which render them largely inert, and for this and other reasons they penetrate but slowly or not at all beyond a very superficial extent. But above all we are hampered by the fact that nearly all disinfectants are many times more poisonous to the cells of the human body than they are to bacteria.

But notwithstanding the difficulties mentioned, and still others suggest themselves, it has been shown both by bacteriological examinations and by clinical experience that local disinfectant applications in diphtheria are useful and may cause the specific bacilli to disappear. An important experimental study of the action upon the diphtheritic bacilli of many germicides and agents used in treating diphtheria has been recently published by Löffler, who endeavored to imitate as far as possible in test-tube experiments the conditions present in the mucous membrane when affected with diphtheria. I can only refer you to Löffler's work and his recommendations. Any attempt to consider here therapeutic agents would lead us far beyond the limits of our subject as well as of our time.

Even if it were within the power of the physician to bring about the complete destruction of the diphtheritic bacilli after the disease has taken firm hold, he would nevertheless in many cases be called upon to combat the effects of the toxæmia resulting from the absorption of the toxic albumin already produced by the bacilli. In this respect there is an analogy between diphtheria and tetanus. In both of these diseases the specific bacteria develop only locally at the site of infection, where

they produce substances of extraordinarily poisonous power which enter the circulation. In the case of tetanus we are familiar with the fact that even the complete removal of the infected part will not prevent a fatal issue after a certain amount of poison has been produced and has entered the system. Experiments already mentioned have shown that animals may be killed by the injection of an amount so small of the toxic albumin produced by the diphtheritic bacilli that for several days no symptoms are manifested. The physician certainly cannot neglect the dangers of intoxication by such a substance as this.

The interesting experiments of Behring and Kitasato upon the production of immunity against tetanus and diphtheria, encourage us to hope that we may in time come into the possession of direct antidotes to the chemical poisons of these diseases. These experiments have shown that the blood and the blood-serum of animals naturally or rendered artificially immune against diphtheria, possess the remarkable property of neutralizing or destroying the toxic substances produced by the diphtheritic bacilli, and that immunity depends upon this property. The same is true of tetanus. Whether or not any therapeutic application in human beings can be successfully made of this property of the blood of immune animals, has not yet appeared.

Failing any such antidote, it should be the aim of the physician to assist nature to withstand the poison by supporting the strength of the patient in every way possible by remedies and food.

I have attempted, gentlemen, in this address to show, although necessarily in an imperfect and fragmentary manner, that the discovery of the bacillus diphtheriæ and the study of its properties has rendered our knowledge of diphtheria in many ways more accurate and fuller, has settled many questions of controversy, and has dissipated some errors. The new light has not yet penetrated into all of the dark corners, but when we consider what has been gained in less than a decade, we are justified in expecting that here also obscurity will disappear, and that diphtheria will become in all respects one of the best understood, and, we may hope, one of the most successfully combated of the grave infectious diseases.

MEDICAL PROGRESS.

Ergot for Gonorrhœa.—ROICKI, in the *Gazette de Gynecologie*, considers ergot as an excellent infection for the rapid cure of chronic gonorrhœa. He administers it at the same time by the mouth in the form of pills, and by urethral injection after the following formula:

℞.—Ergotin . . . . . 4½ grains.
Distilled water . . . 9 ounces.

Use as an injection several times a day.

These injections are very well borne. The same treatment is also applicable for other urethral hæmorrhages.

Salicine for Pelvic Pain.—CHÉRON states that in pelvic pain during the course of metritis or salpingo-ovaritis as well as in pelvic cellulitis and peritonitis, particularly if these troubles are associated with rheumatism, that salicine is of value. In those women who, after the menopause, have uterine pain and discomfort in the lumbar or sacral region, with occasional flushes of heat and neuralgic dartings, a careful interrogation as to any history of rheumatism should be sought for, and if this disease is found to be present salicine administered. The dose which he ordinarily recommends is fifteen grains, to be divided into three parts. Very soon after the drug is administered the pain decreases. Chéron generally directs that one drachm of salicine be divided into twelve capsules. One of these capsules may be given morning, noon, and night, the patient taking a glass of water at the same time, to prevent irritation of the stomach.

Treatment of Infantile Chlorosis.—ELOY gives the following summary of the best treatment, in his opinion, of this condition. He points out that with children, as well as adults, medication should be chiefly hygienic, and associated with the use of arsenic and iron. The hygienic treatment consists in the use of outdoor exercise and baths, though he does not approve of the sojourn by the sea, but prefers residence in the mountains. Gymnastic exercise, and those movements which tend to increase the respiratory capacity and develop the muscles of the thorax, are particularly indicated. The baths, when administered, should be, as a rule, salt baths, and cold water should be most carefully, if ever, employed. The diet should be carefully arranged; only foods which are readily digested should be given, and those meats which are particularly nutritive administered. As gastric dilatation, alterations in the gastric juice or constipation may all be causes of chlorosis, they should be remembered when treating such cases. The medicinal treatment consists in the administration of small doses of quinine and the following prescription, particularly if constipation is constantly present:

℞.—Phosphate of soda . . 1½ drachms.
Phosphate of potassium . ½ drachm.
Red wine . . . . 6 ounces.
Syrup of bitter orange . 1 ounce.

A teaspoonful to a dessertspoonful after each meal.

In other cases it may be well to administer, in solution or syrup, the phosphate of calcium in small doses. If the child is old enough to take bitter substances, it may use the following:

℞.—Tincture of cascarilla
" gentian } of each, 1½ drachms.
" rhubarb

Sometimes the tincture of gentian may be replaced with tincture of calumba with advantage. For the improvement of the digestion the following may be employed:

℞.—Dilute hydrochloric acid . 15 minims.
Syrup of bitter orange-peel 1 ounce.
Tincture of bitter orange-peel 1 drachm.
Infusion of cascarilla . . 2½ ounces.

A teaspoonful after each meal.

It may also be well to employ some of the aërated waters. In regard to the salts of iron, Simon uses the lactate of iron; but in other cases the phosphate of iron may be given. Small doses should, of course, be given,

as iron under these circumstances should not be given in large enough amounts to produce constipation. Arsenic, when administered, should be given in small doses, and carefully watched lest it produce irritation of the kidneys or gastro-intestinal tract.

Treatment of Amenorrhœa.—

℞.—Bichloride of mercury . . . 3 grains.
Arsenite of sodium . . . 3 "
Sulphate of strychnine . . 1½ "
Carbonate of potassium } of each 45 "
Sulphate of iron }

Make into sixty pills and give one pill after each meal. —*Revue Méd.-chir. des Mal. des Femmes.*

Prescription for Eczema of the Anus and Genital Organs.—Lustgarten advises, in *La Semaine Médicale*, the following ointment:

℞.—Oleate of cocaine . . 15 to 30 grains.
Lanolin . . . . 1 ounce 2 drachms.
Olive oil. . . . 2½ drachms.

Use externally.

Make an application of this ointment twice daily, and after each application powder the affected part with any absorbent powder whatever. Warm soap baths will aid in curing the disease. In pruritus ani, suppositories of cocaine can be employed with advantage.

Aphrodisiac Pills.—According to the *Journal de Médecine de Paris*, Lutaud employs the following pills for the purpose of producing sexual stimulation:

℞.—Powdered nux vomica . . ¾ grain.
Bromide of iron . . . 15 grains.
Phosphorus . . . . ⅙ grain.
Excipient, a sufficient quantity.

Make into twenty pills and take one each night.

In addition to this treatment the patient should resort to hot and cold douches and gymnastic exercise, massage, and systemic tonics, and frequently coca will be found of value, as in the opinion of Lutaud this drug possesses very distinct aphrodisiac powers.

Treatment of Gonorrhœa by Bicarbonate of Soda.—According to the *Journal de Médecine de Paris*, Casselan during the past four years has employed a solution of bicarbonate of soda in the strength of 1 : 100 in the treatment of gonorrhœa. He has treated thirty-three cases and obtained thirty-three cures in from two to three weeks by the employment of injections of the solution named. He bases his treatment on the belief that the virulence of the disease is in direct proportion to the acidity of the secretions.

Influence of Acute Fever upon the Course of Pulmonary Phthisis.—According to the *Revue Internationale de Bibliographie*, Chetmouski believes that a high temperature due to another disease very distinctly influences the course of pulmonary phthisis. This Russian clinician, in support of his views, refers to the case of a woman, aged thirty years, who was suffering from very distinct evidences of pulmonary phthisis, who developed eysipelas of the face accompanied by high fever. Simultaneously with the development of the intercurrent disease the pulmonary symptoms immediately diminished, and during the next eight days the bacilli disappeared from the sputum. The cough was decreased and an ulceration of the palate underwent cicatrization. In another case occurring in the person of a physician, aged thirty years, in whom there was consolidation of the apex of the right lung with bacilli in the sputum, typhus fever manifested itself. The fever lasted fourteen days, and convalescence was rapid. Immediately before the fever the patient's weight was 140 pounds, three months afterward 170 pounds, and the cough had almost disappeared.

The Treatment of Typhoid Fever.—Smakovsky, during the space of two and a half years has treated 700 cases of typhoid fever in the following manner:

℞.—Calomel . . . . . ½ grain.
Sugar . . . . . 4 grains.

This is to be made into ten powders and one powder given each hour until the evacuation from the bowels becomes copious and soft. The patient is also given a gargle, composed of a solution of chlorate of potash, to prevent mercurial stomatitis. If there are evidences of feebleness of the heart, the calomel is stopped and small doses of the infusion of digitalis are administered. After the calomel has produced its antiseptic and alterative influence the diarrhœa, if it has become excessive, may be controlled by the use of the following powders:

℞.—Subnitrate of bismuth . . 2 grains.
Naphthalin . . . . ½ grain.
Sulphate of quinine . . 1 "

One of these powders is to be given four times a day. For the cough Smakovsky recommends:

℞.—Aqua ammonia . . . 1 drachm.
Tincture of eucalyptus . 1 ounce.
Essence of peppermint . 10 drops.

Ten drops to be given every two hours. This prescription is also of advantage in acting as a disinfectant of the mouth. The Russian investigator just named is convinced that the mortality of typhoid fever under such treatment is very much lessened. — *L'Union Médicale.*

Ointment for Intertrigo.—

℞.—Boric acid . . . . . 7 grains.
Lanolin . . . . . 12 drachms.
Vaseline . . . . . 3 "

This ointment is to be applied to the diseased area, which is first cleaned by the use of a mild soap.

Purgative Pills.—

℞.—Aloes . . . . . 15 grains.
Resin of scammony . . . 7 "
Resin of jalap . . . . 7 "
Calomel . . . . . 7 "
Extract of belladonna . . 3 "
Extract of stramonium . . 3 "

Make into twenty-five pills and give one to two a day.

CURRENT LITERATURE.

SATURDAY, MAY 16, 1891.

TACHYCARDIA AT THE MENOPAUSE.

PROFESSOR E. HEINRICH KISCH defines tachycardia as a purely nervous disturbance of the heart function, independent of every organic disease of the heart and vessels, and characterized by a motor change of the heart function, by which a marked, and at times extraordinary, increase in the frequency of the contraction of the heart occurs. It is found associated with anæmia, cachexia, neurasthenia, and with diseases of the stomach, diphtheritic angina, diseases of the lungs, brain, spinal cord, and sexual organs.

Kisch directs attention to a form of tachycardia which occurs in women at the menopause. He gives brief accounts of the previous observations on this point by Stokes, Moon, Groedel, Clément, and Boerner. His own experiences have been obtained at the health resort in Marienbad, where women at the climacteric, with their manifold difficulties, make up the chief contingent. At this time of life, if the menses begin to appear at longer or shorter intervals than the normal period, cease altogether for two or three months, or, if the blood excreted assumes an abnormal character, a woman, whose heart up to that time was acting perfectly normally, complains of palpitation which occurs in paroxysms. This palpitation appears at times without any cause, at times after an insignificant cause, which before did not excite nerve action. The attacks occur in any position, walking, sitting, lying, and even during sleep. The feeling of accelerated and strengthened heart-beat is described as very annoying, and is at the same time associated with a feeling of anxiety, with the sensation of pressure upon the breast, beating in the carotids, and pulsation of the abdominal aorta. Moreover, the patient feels as though the blood was surging toward the head, and has fleeting "beats" and violent headache. Occasionally, toward the close of the paroxysm of tachycardia, there are bright spots before the eyes, noises in the ear, dizziness, and, but rarely, faintness.

The pulse is increased in frequency from 120 to 150, and in Kisch's cases was generally strong, well filled, and regular. Sphygmographic tracings show a pulse of considerable volume, low tension, and sub-dicrotic or dicrotic. The heart-sounds are pure. At times, during an attack, the face, throat, and breast become suddenly red. Bright red spots appear suddenly upon the parts named, and disappear usually in a few minutes; they are associated with burning feelings; at times sweat breaks out upon the head and back. These attacks of tachycardia may occur several times a day, or cease for several days, and may last from several minutes to a quarter of an hour.

The tachycardia is also usually associated with a condition of bodily and mental disquiet, incapacity for regular activity, restless sleep interrupted by dreams, and a general nervous excitability. Kisch does not agree with Clément and Boerner that anæmia is always present in these women. In most of his cases there was plethora. There was neither marked dyspnœa nor cardiac asthma present; symptoms of stasis were very rarely observed; œdema of the feet was present in individual cases, though the urine was always free from albumin.

Kisch says he has seen, in the past five years, twenty-eight cases of paroxysmal tachycardia in women at the climacteric. Of these patients 25 were between forty and fifty years of age. The menses were irregular in 26, and had completely ceased in 2. One patient was unmarried, 2 were sterile, the remaining 25 had borne several children. A sudden cessation of the menses had not occurred in any case. In 12 cases, in addition to the paroxysmal tachycardia, there was disturbance of the stomach and bowels, which Kisch has described as uterine dyspepsia. He thinks it noteworthy that in three of the women there had been, at the beginning of menstruation in childhood, nervous palpitation, which subsequently completely disappeared.

The duration of the disease may be from a few weeks to two years or more. It may persist as long as the irregularity of the menses persists, but may also extend beyond this period, and may still occur when menstruation has entirely ceased; but Kisch has not observed any bad sequelæ of significance.

Kisch has found that the systematic employment of gentle purgatives, conjoined with appropriate diet, exercises a very favorable influence for the amelioration of the attacks. His course consists in residence in mountain air, bland food, active bodily movements, cold washings, and moist applications to the belly. He finds the sulphate of soda waters of Marienbad very effective. Bromides, in small doses, are given for the disagreeable feeling of palpitation, and as a quieting remedy.

As to the etiology, Kisch traces it directly to changes occurring in the ovaries at the time of the climacteric.—*Prager med. Wochenschrift*, March 11, 1891.

PATHOGENESIS OF THE AMŒBÆ OF DYSENTERY.

KARTULIS, of Alexandria, complains that specialists in parasites have ignored the importance of the amœba in dysentery, notwithstanding the fact that his researches have been confirmed by observations in Russia, Bohemia, Greece, and America. He maintains that the amœbæ occur not only in all true cases of dysentery, but also always in dysenteric liver abscesses. He has repeatedly sought for the amœbæ in hundreds of cases of other intestinal affections, but has never found them.

After a number of experiments Kartulis found that the best medium for the cultivation of the amœbæ was prepared by boiling for fifteen minutes twenty or thirty grammes of fresh straw in two litres of water. The fluid is then filtered and sterlized. Large-sized test-tubes, holding 50–100 c.cm., may be used, and are filled with the fluid. A few drops

of the slimy masses in a fresh dysenteric stool are then mixed with the fluid in the tubes, which should be kept in an incubator at a temperature of 86° or 100° F. After the lapse of twenty-four or forty-eight hours there forms on the surface of the tube a film like spider's web, which consists of freshly developed amœbæ, in addition to many bacteria. The amœbæ grow best when the vessels are left exposed to the air. The amœbæ of the cultures are much smaller than those of the stools, have a lively movement in wandering spore form, but throw out no pseudo-pods. Ciliæ are absent, but nucleus and vacuoles are very distinct, especially when the bodies are stained with aniline colors. Here and there are seen some amœbæ, which are like in form and size those used for inoculating the tube. Very often, also, there are seen small forms, round, homogeneous, and glistening, which have a rapid and dancing motion. These take the aniline colors intensely, and Kartulis regards them as free nuclei.

The spores gradually develop to large amœbæ. The amœbæ then execute movements by throwing out pseudo-pods. Toward the fourth and fifth days there are seen between the lively amœbæ, forms which are much smaller, about the size of a white blood-corpuscle. They are round, quiet bodies with a fine contour, small nucleus, and fine protoplasm. The forms become smaller gradually, form two contours, which appear yellowish, with dark protoplasm. Their sizes vary between 5 and 7 m. As amœbæ develop from these forms, there is no doubt that they are spores. Within eight or eleven days the spores increase; the amœbæ are very sparingly present.

In order to develop the spores further it was found necessary to add neutral, or slightly alkaline, bouillon to the fluid in the culture vessel. Kartulis has seen old spores, kept at the temperature of the room for four months, develop in this medium. He has never been able to develop amœbæ from the stools of non-dysenteric patients. His efforts to obtain pure spores were unsuccessful. Only once did he succeed in carrying the amœbæ through three cultivations free from other microörganisms.

Efforts to inoculate rabbits and guinea-pigs, either with fresh dysenteric stools or with cultures by the amœbæ, were negative. Dogs and cats have been successfully inoculated by the bowel. Kartulis gives in detail his experiments upon cats. He concludes from his experiments that the amœbæ of dysentery are the sole causes of dysentery.

As control experiments he cultivated other bacteria found in dysenteric stools, among them the bacterium coli and the bacillus of the so-called green diarrhœa, and injected them into the bowel of young cats.

He also cultivated upon gelatin plates several microörganisms from dysenteric stools, and after he had convinced himself that there were no longer any amœbæ alive, he injected the cultivations *en masse* into the bowels of young cats.

He filtered dysenteric stools through flannel, which retains the amœbæ, and injected the filtrate into the rectum of cats.

A pure culture of the bacillus of Chantemesse and Vidal, obtained from their laboratory, was also injected into the bowels of young cats.

Finally, cats were fed upon the organisms mentioned. All these experiments had a negative result. Not one of the animals was taken sick with dysentery, and only in one instance was there a slight transient diarrhœa.

It yet remains for some one to find the amœbæ outside the body. Kartulis thinks it is probably to be found in water.—*Centralblatt für Bacteriologie und Parasitenkunde*, March 21, 1891.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Forty-second Annual Meeting, held at Washington, D. C., May 5, 6, 7, 8, 1891.

[Continued from p. 540.]

Fourth Day—General Session.

The closing session of the American Medical Association was held in the Opera House on May 8th, at 10.15 A.M. Dr. W. L. Schenck, of Kansas, not being present, his address on State Medicine was read by title, and referred to the Publication Committee. The President announced the following committee to memorialize Congress for the establishment of the new cabinet officer, the Secretary of Public Health: Drs. C. G. Comegys, Ohio, *Chairman;* J. F. Hubbard, Indiana; N. S. Davis, Illinois; J. C. Culbertson, Ohio; Dr. Richardson, Louisiana; W. B. Atkinson, Pennsylvania; C. A. Lindsley, Connecticut; C. A. Hughes, Missouri: W. T. Briggs, Tennessee; H. D. Didama, New York; Thomas B. Evans, Maryland; A. J. Stone, Minnesota; J. P. Logan, Georgia; W. W. Kerr, California; Charles Dennison, Colorado; W. L. Schenck, Kansas; P. O. Hooper, Arkansas; H. J. Swearinger, Texas; Wirt Johnson, Mississippi; T. F. Wood, North Carolina; J. N. McCormick, Kentucky; J. T. Reeve, Wisconsin; H. O. Walker, Michigan.

The report of the Committee on the Jenner Vaccination Centennial was received. Replies to the inquiries sent out by the committee to leading medical men of the various States were received from twenty-two of the States. The committee recommended the preparation of an eulogy on the great discoverer, and the reading of papers appropriate to the subject, and suggested as the day of celebration the 14th of May, 1896. The eulogist is to be selected by the committee, as well as an editor and compiler, the latter to collect and compile the literature of the subject, and to assume charge of all the scientific matter, and to publish all the material thus collected in a sumptuous volume with suitable illustrations.

Dr. N. S. Davis, of Illinois, moved that the report be adopted, and offered as a resolution that the committee be continued for another year, that the 14th of May, 1896, be appointed as the day of celebration, and that the meeting of the Association for that year be so arranged as to include the above date. Carried unanimously.

The President annnounced the following committee

to investigate the relation of contract railroad surgeons in the United States to the code of ethics of the medical profession, and to decide what action should be taken by the Association in reference to corporations employing surgeons only under such rules as were laid down by them: Drs. J. Ford Thompson, District of Columbia; R. G. Ellegood, Delaware; J. D. Fernandez, Florida; W. S. Powell, Georgia; B. M. Griffin, Illinois; J. F. Hibbard, Indiana; G. F. Jenkins, Iowa; W. L. Schenck, Kansas; J. M. McCormick, Kentucky; A. Garcelon, Maine; G. L. Taneyhill, Maryland; A. L. Norris, Massachusetts; J. E. Emerson, Michigan; P. A. Millard, Minnesota; T. F. Wood, North Carolina; G. P. Conn, New Hampshire; D. Benjamin, New Jersey; J. B. Roberts, Pennsylvania; W. P. Porcher, South Carolina; T. J. Hoppell, Tennessee; D. R. Wallace, Texas; D. C. Hawley, Vermont.

The subject of the incorporation of the Association elicited some interesting discussion. Dr. Hibbard, of Indiana, moved that a committee of seven be appointed to consider the question of the incorporation of the Association, and to report at the next annual meeting. Carried.

President Taylor, of the American Pharmaceutical Association, and Professor Remington, of Philadelphia, were invited to the platform, and made short addresses.

The report of the Secretary on State Medicine was received, and adopted as read.

Dr. N. S. Davis, chairman of the Judicial Council, reported that the subjects assigned to the Council were under judicious consideration, and that the report would be submitted at the next annual meeting.

The President announced the appointment of the officers of the various sections, and introduced Dr. R. H. Marcy, of Boston, the President elect, who delivered a short address of thanks, and appreciation of the honor conferred upon him.

The General Session then adjourned.

SECTION OF THERAPEUTICS AND PHARMACY.

The second day's meeting of the Section of Therapeutics and Pharmacy discussed the following proposition of Dr. Rice, of New York, to create "A Joint Committee on Therapeutics and Pharmacy:"

The new movement of establishing closer and official relations between the two professions of medicine and pharmacy promises to yield beneficial results, and has been started at a time when its desirability, or rather necessity, is generally recognized. Both professions have many interests in common, and both have to supplement each other by their special knowledge and attainments. Many are the topics—ethical, legal, historical, politico-economical, hygienic, statistical, educational, social, and particularly scientific (omitting "financial")—which can and will be profitably discussed at joint meetings of representatives of the two professions; and some of these topics may even be said to form burning questions which have hitherto been treated by the medical and pharmaceutical press, mostly in an *ex parte* manner. It is hoped that these may hereafter be brought to a solution satisfactory to all.

But the discussion of professional topics, or the reading of papers thereon, at the joint annual meetings, does not seem to be sufficient to infuse life into a co-partnership such as it is proposed to establish and maintain between the two professions. Something else of a more lasting and permanent interest—something of tangible utility, so to say, seems to be wanted to serve as a firmer bond. In the judgment of the writer, such a bond can be established—and, indeed, its want has long been felt—by the official interchange of, and decision on, professional or scientific problems between the two professions. The physician as well as the pharmacist each possesses, if properly trained, a fund of special knowledge, often laboriously acquired and constantly augmented by daily practice and experience, which, in these days of rapid progress, can no longer be expected to be met with, combined in one and the same person, but which has to be gathered and studied by specialists for the benefit of the other members of their own, or a kindred profession. Yet it is an indisputable fact that many important facts which have long been known to, or recognized by one profession, and which yet virtually concern the other, remain often entirely unknown, or only imperfectly known to the latter for a long time. If there were an official channel, through which such needful information could be conveyed, at regular intervals, from one profession to the other, much would thereby be gained. It may be well to mention an example by way of illustration. Many physicians are in the habit of prescribing aconitine without specifying what kind they intend. They are not aware that there are four or five different kinds in the market, each of them in vogue or preferred in some particular country or locality—one being the pure, crystallized alkaloid of exceedingly great power; another an amorphous substance of comparatively feeble strength; another one, made by a different process, or perhaps from a different kind of aconite, being of an intermediate strength, etc.—and that they are liable to have the most powerful dispensed when they perhaps intended the weakest, or *vice versa*. Would it not be useful to present to the medical profession, once a year at least, a concise summary of important matters of this kind, which would suggest themselves from time to time? As a rule, physicians do not read pharmaceutical journals or circulars issued by chemical houses; hence, information regarding subjects like that above-mentioned often reaches them only when some serious accident has happened. If there were a source of information on topics of this kind, prepared by pharmacists specially for the benefit of physicians, much good would result. On the other hand, physicians often observe objectional features connected with the form or efficacy of pharmaceutical or Galenical preparations—as, for instance, deficiency of therapeutic action due to improper menstrua, improper vehicles, improper coating, etc. The same medium of communication could be used for drawing the attention of the pharmacists to these matters.

If it is conceded that such a mutual exchange of information or of problems is desirable, it will not be difficult to devise a plan by which it may be carried out. The writer suggests the following, at least as a basis upon which something better may be erected:

1. The American Medical Association, through its proper Section [or in any other way that may be determined on] may annually appoint seven [or any other number] members, who, together with a like number

of pharmacists, who may be appointed by the American Pharmaceutical Association, shall constitute the "Committee on Therapeutics and Pharmacy."

2. This committee shall elect a chairman and vice-chairman, only one of whom shall be chosen from the same profession. These two officers shall also be the chairmen of their respective sections (medical and pharmaceutical) in the committee.

3. The committee may either hold joint sessions at such times as may be agreed upon, or it may transact its business by correspondence.

4. Either section of the committee shall be authorized and instructed to consider any professional questions or problems which may be submitted to it by the other; and, after deliberation, to give such an opinion, or such a decision, as the subject may warrant, from the standpoint of the profession rendering the opinion or decision.

5. The section of the committee making the request or appeal shall bring the reply or decision of the other to the knowledge of the whole of its own profession, or, when this is unnecessary or inadvisable, at least to the notice of those to whom it more particularly applies.

6. The committee, or, if so determined by it, either or both of its sections separately, shall annually report, at the joint meeting of the two professions [or, say, to the Section on Materia Medica and Pharmacy of the American Medical Association], the nature of the questions and problems mutually submitted, if any, and the respective opinions or decisions rendered. These decisions shall be subject to a revision, if one is called for, at this meeting.

7. Each section of the committee shall annually present a report upon professional topics which it may be thought particularly necessary to bring to the attention of the other profession. Thus, the Section on Pharmacy may present, for instance, a report on new remedies, accompanied by practical suggestions as to their best mode of administration, as to precautions to be observed in prescribing them, as to incompatibilities to be avoided, and similar topics. And it may submit questions or problems involving *therapeutics as it affects pharmacy* to the other section, with a view of having them answered or decided. The Section on Therapeutics may, in its turn, present problems or questions involving *pharmacy as it affects therapeutics* to the other section, for solution or answer.

In presenting this plan, the writer had in view scientific, professional topics rather than ethical ones. There is no doubt that the latter will form an abundant source of discussion, and that this will, if properly conducted, bring the two professions closer together; but it will, under most circumstances, be preferable to relegate such topics to the general annual meeting, there to be fully discussed and decided, rather than to have them passed upon by a small subcommittee, the action of which may, after all, not be finally indorsed by the Association. On the other hand, a reversal of any decision by the committee, on scientific topics, rendered after proper study and discussion, is scarcely to be apprehended.

It may not be found practicable to carry out the above plan, or something similar to it, at once. Moreover, at this first meeting of the two professions, there may not be sufficient time to discuss it properly. In this case, it may be held over for the next meeting, and those who take an interest in the matter may, in the meantime, carefully examine it, so as to be prepared to offer improvements, should it ever be brought up for action.

Section of Practice of Medicine and Physiology.

Dr. J. S. Nowlin, of Shelbyville, Tenn., read a report on an "Epidemic of Cerebro-spinal Meningitis." From the symptoms in these cases, and the results from the use of quinine, the speaker drew the conclusion that the so-called cerebro-spinal meningitis is really a manifestation of malaria.

Dr. Dock said he did not believe the author meant to imply that all epidemics of the disease in question are malarial, since some of them occur in places and at times when the severe manifestations of malaria do not appear. It was important, however, to bear in mind that malaria can produce any and all the symptoms common to inflammatory diseases of the central nervous system. These cases can be properly distinguished by the microscopic examination of the blood, and the recognition of them is of the greatest importance, since in the malarial cases quinine must be used, no matter how severe the symptoms are, nor how greatly they resemble those of inflammatory disease; and not only is this without harm, but with the result of early recovery.

Dr. W. B. Davis, of Cincinnati, read a paper on "The Prevalence of Albuminuria in Persons Apparently Healthy," indicating the belief that albuminuria is very common, and not pathognomonic of nephritis.

Dr. Eccles, of Brooklyn, said he had found albumin in the urine of persons without nephritis.

The Secretary read a paper by Dr. J. F. Jenkins, of Tecumseh, Mich., on "The Treatment of Spasmodic Asthma by the Fluid Extract of Euphorbia Pilulifera."

Dr. Aulde described his method of using the drug, and the success following it.

Dr. Karl von Ruck, of Asheville, N. C., presented a paper on "Professor Koch's Method for the Cure of Tuberculosis, and its Results in Pulmonary and Laryngeal Cases," claiming for the remedy, in connection with other means, a positive and curative therapeutic action.

This was followed by a paper by Dr. S. P. Kramer, of Cincinnati, with "A Report of Cases Treated with Tuberculin in the Good Samaritan Hospital," the results being favorable.

Dr. Simonton, of California, said he thought the reaction now taking place in regard to this remedy would subside, and that the profession would settle down to a realization of its value as the best remedy for tuberculosis in proper cases. Its diagnostic value, the speaker said, was not absolutely fixed, but was sufficient to make it one of the methods to be used.

Dr. Osler gave an outline of the results obtained in the Johns Hopkins Hospital. On the whole, his experience had been disappointing.

Dr. Eccles thought that Koch would yet discover the cure for tuberculosis; that he was at present in the position of Columbus on his second voyage.

Dr. Welch gave a description of the histological appearances in the cases in which tuberculin had been used.

The Chairman described the beneficial results obtained by injecting a toxic substance from a hitherto undescribed bacterium in phthisical subjects. Drs. Von Ruck and Kramer concluded the discussion.

DR. CHAS. H. SHEPARD, of Brooklyn, N. Y., read a paper on "The Action of the Turkish Bath in Disease."

DR. GEORGE DOCK, of Galveston, Texas, gave an abstract of a paper on "The Malarial Parasites, and the Forms of Disease in which They Occur in Texas."

Dr. Osler spoke of the great practical value of such studies, and of their special value in the elucidation of the nondescript fevers of the South. He said that in certain cases he had been unable to distinguish between typhoid fever and malarial remittent, except by the microscopic examination of the blood. He considered it especially gratifying to see that in Germany, where scepticism of the significance of the discovery of Laveran had long prevailed, they were now coming around, and that the situation has been accepted in Koch's laboratory.

DR. W. J. HERDMAN, of Ann Arbor, read a paper on "Electricity Therapeutically Considered," advocating the use of commercial currents rather than the products of instrument-makers.

Dr. Davis thought the use of such currents dangerous, on account of the possibility of falling wires.

Dr. Herdman showed that by the use of a fusible metal plug such accidents would be harmless.

Several papers were read by title and several more referred to the publishing committee.

The Chairman announced that at the request of Dr. W. W. Johnston, of Washington, the committee appointed last year to investigate the Fevers of the South would be continued for another year.

Dr. Woodbridge, of Ohio, chairman of the committee of three appointed to confer with similar committees from other Sections, reported that the Section chairmen were requested to appoint committees of three, to advise with the Section officers on papers submitted to the Sections, and that the original conference committees be continued for another year.

The report was adopted and the Chairman appointed as the advisory committee, Drs. Osler, of Baltimore; Herdman, of Ann Arbor; and Dock, of Galveston.

The Nominating Committee reported the election of the following Section officers for the ensuing year: Dr. Eads, of Washington, chairman; Dr. French, of Cincinnati, secretary.

On motion of Dr. Woodbridge, of Ohio, a vote of thanks was tendered the officers, and the Section then adjourned.

SECTION OF NEUROLOGY AND MEDICAL JURISPRUDENCE.

The meeting was opened by a paper on "Paretic Dementia and Life Insurance," by DR. JAMES G. KIERNAN, of Chicago. He said that the increase in paretic dementia had raised a question as regards life insurance. As an instance, he cited the case of a man who was taken to a noted alienist by his brother. Upon a careful examination of the case, the alienist pronounced it one of paretic dementia, and said that the patient would not live more than three years. The brother at once had the afflicted brother's life insured, concealing his condition from the insurance company's examiner, who was not sufficiently skilled to detect the disease. Later the patient died, and the company was compelled to pay the insurance. He spoke of other instances of the same character. According to the speaker, many of these mistakes are made by examiners who are inefficient, and have been appointed through influence rather than professional merit. According to a legal decision by the Iowa courts, insurance companies are responsible for these mistakes, and must pay the insurance. Dr. Kiernan thought it unjust that the insurance companies should have to pay in cases of this kind, but also blamed them for employing medical examiners who were not capable of detecting the early symptoms of this disease.

DR. N. ROE BRADNER, of Philadelphia, next read a paper upon the "Private Treatment of Insanity." He said that our public asylums were institutions of the greatest value, but that the time had come when the private treatment of the insane must demand greater attention. Dr. Bradner objected to our public asylums on the ground that the medical attention was not sufficient, as the physicians in charge always had many more patients than they could properly attend to, and as a consequence many cases, which might be benefited by treatment, became incurably insane because of this neglect. He considers that many of our public asylums are simply places of detention. His reasons for favoring the treatment of the insane in private institutions are, that the physicians in charge do not have a greater number of patients than they can properly attend to; that the educated and refined are not thrown together with the lower classes of society, as is often the case in public institutions; that the restraint is not so severe, and is better adapted to each patient. Another objection to public asylums was the class of attendants found in many of these institutions, who are often secured because of their "brute force" and the cheapness of their service. Dr. Bradner thinks that the attendants and physicians in these institutions should be especially educated.

The speaker then took up the consideration of a new law proposed in Pennsylvania by Judge Brewster, providing for a jury of twelve laymen, who should judge as to the sanity of a person before his committal to an asylum. He said that a law similar to the one proposed by Judge Brewster was now in operation in Illinois. His objections to this law were that laymen were not capable of acting as judges in these cases; that there was loss of time in the treatment of acute mania, which should be promptly treated, and that it was a great injustice to the families of these afflicted persons to give such publicity to their unfortunate condition.

In conclusion, he said that the private asylums of our country will increase in number, which, he thinks, will be a great benefit to society.

Dr. Kiernan, of Chicago, and Dr. Hughes, of St. Louis, both thought that Dr. Bradner's criticism on the public asylums of this country was unjustly severe.

The next paper was upon the "Studies of Cranial Degeneracy and Aberrant Maxillary Development in the Criminal Class," by DR. G. FRANK LYDSTON and DR. E. S. TALBOT, of Chicago, Ill.

Dr. Lydston took up the part of the subject relating to cranial degeneracy, which, he said, had not been studied to any extent in this country. He believes the external conformation of the calvarium was not always indicative of the cerebral development, but in many cases it formed a very good basis for judgment. He

said that simplicity in the type of the cerebral gyri was always indicative of cerebral degeneracy. In the criminal classes the striking feature of the skull is its greater breadth and decrease in the height of the vertical index, and its asymmetry. A condition that he has noticed in the skulls of the criminal class is a peculiar appearance as though it had been twisted upon itself. He then considered the conformation of the skulls of various races, after which he exhibited a series of skulls of criminals.

In conclusion, he said that the criminal usually had a bad heredity, and in addition to the cerebral aberration in these cases there was often physical degeneracy. The most aberrant types of skulls were found in criminals of foreign birth. Another peculiarity that he has discovered is the relatively greater aberrant development of the nose among criminals than in the ordinary individual. In the majority of instances where there is defective bony development there will be found cerebral degeneracy.

Dr. Talbot took up the second part of the paper and spoke upon aberrant maxillary development in the criminal classes. He showed a number of drawings illustrating the peculiarities of the inferior and superior maxilla in skulls of criminals. He also said that in conjunction with a defective cerebral development, there was usually either a deficiency or excess in the growth of the osseous system. His studies have been very extensive upon this subject. Among the various classes of society he had found an abnormality in the growth of the maxillary bones as follows: In the insane 90 per cent. have normal maxillary bones; the Hebrew race 74 per cent. normal; of a large number of Harvard dispensary patients, 60 per cent. were normal; in idiots, 55 per cent. were normal; in the blind, 50 per cent.; and in the deaf and dumb, 45 per cent. were normal; lastly, in the criminal class, among whom only 34 per cent. were found to have normal maxillary bones.

Dr. O. Everts, of Cincinnati, next read a paper entitled "Increase and Prevention of Insanity;" after which Dr. W. H. Willing, of Philadelphia, exhibited two batteries and read a paper upon "Electro-diagnosis in Brain and Nerve Injuries."

Dr. Stephen Lett, of Guelph, Canada, read a paper upon the "Treatment of Opium Neuroses." He condemned the abrupt mode of treatment in the strongest terms, and favored the method by gradual reduction. His method of treatment is according to that of Dr. Hubbard, of Brooklyn, with a few modifications. He thinks that the "vice theory" of the opium habit should be discarded, and that it should be considered purely as a disease. He says that there is no drug that can cure this condition, and that substitutes are dangerous and should not be employed. He first ascertains the amount of opium used by the patient in twenty-four hours, and then reduces this to an equivalent of morphia, which is always substituted regardless of the preparation of opium which the patient has used. The rate of reduction depends upon the character of the case. In those cases where large quantities of opium are used the reduction is faster, while in cases where the amount used is small, the rate of decrease is proportionately slow. In a case where twenty grains of morphine are used in twenty-four hours, he reduces the amount at the rate of one grain in about three days. When the amount is reduced to one grain, three or four weeks are required before it is entirely stopped. As a result of this gradual method of treatment there is no shock, no gastric disturbance, little or no diarrhœa, no restlessness, and the sleep is good. The speaker does not favor the use of bromide of potassium, alcohol or cocaine during the treatment, but depends entirely upon nourishing food to sustain his patient's strength.

Dr. W. S. Watson, of Matteawan, N. Y., followed with a paper on "Opium Inebriety, its Legal Recognition and Treatment." This speaker advocated the same plan of treatment as Dr. Lett, with some slight modification.

Extracts from a paper sent to the Neurological Section by Dr. R. Burkart, of Bonn, Germany, on "Brain Diseases from Opium," were read by Dr. J. B. Mattison, of Brooklyn, N. Y.; following which he read a paper written by himself on "The Prevention of Opium Inebriety." This speaker spoke in the highest terms of the use of codeine and narceine, especially the former, instead of morphine. He claims that codeine has all the advantages of morphine without its disadvantages. This drug, according to the speaker, produces sleep and allays pain without inducing that peculiar effect that is so fascinating to the morphio-maniac. He does not deny that the codeine or narceine habit may be contracted, but thinks it is far less likely to follow the use of these drugs than is the morphia habit from the use of morphine.

He says that one-fourth of a grain of codeine hydrochlorate, hypodermically, or one-half of a grain of the sulphate by the mouth, are perfectly safe.

No bad effects follow the use of this drug, and it is in every way superior to morphine.

OBITUARY.

Dr. Joseph Leidy, M.D., LL.D., Professor of Anatomy and Director of the Biological Department of the University of Pennsylvania, died early on the morning of Thursday, April 30th, of uræmia and pachymeningitis.

Dr. Leidy was born in 1823, and during the early years of his life lived upon a farm, where he had the opportunity of developing his great love for the study of Nature. After having been educated in the common schools, he studied medicine in the University of Pennsylvania, and was graduated in 1844, studying anatomy in the meantime under Dr. James McClintock and Dr. P. B. Goddard. During his student days, and afterward for several years, he was an active assistant of the well-known investigator and chemist, Dr. Robert Hare, and also of Professor Horner, who then held the Chair of Anatomy in the University of Pennsylvania. Before he had studied medicine, Dr. Leidy had fully mastered the subject of botany, ample evidence of which is given in his later contributions to science. To give in the brief space which we have at our disposal anything like a complete biography of this celebrated man would be absolutely impossible. During the fifty-seven years that he was a member of the medical profession he contributed to science no less than eight hundred papers, which were at once widely diverse and eminently scientific. While he was known to medical

students as a professor of human anatomy, his intimate knowledge of the formation of man's body was as nothing to his wonderful knowledge concerning all forms of animal life, both microscopical and otherwise. In addition to being a comparative anatomist, he was *facile princeps* palæontologist of the United States. His investigations upon this subject provided the doorway through which all other researches have been carried on. Beginning at a time in the history of this country when no one dreamed of the vast scientific discoveries which have since been made in the West, he not only determined correctly the nature of all those fossils, as well as other remains of extinct species which were brought to him, but prophesied with singular fidelity that other discoveries would confirm his opinions, although years might elapse before they were made.

One of the most remarkable facts in regard to the career of Dr. Leidy, was the invariable confirmation of his views. Frequently a space of twenty or thirty years would elapse during which he would remain steadfast in his beliefs against all criticism, and come out victor in the end. As a helminthologist, Dr. Leidy occupied a position in the first rank, and was so regarded by Deising, of Vienna, the highest authority on that subject, who practically devoted his whole lifetime to this one subject—the study of helminthology. One of Dr. Leidy's most important contributions to this branch of zoölogy was his discovery of the Trichina spiralis in the pig, which Leuchart admits suggested to him his discovery of trichinosis in man. Dr. Leidy's study of the parasites affecting the lower animals was equally as thorough as were his researches concerning the animals affecting man, and the intestinal canal of the cockroach and centipede and other similar forms of life were the subject of a number of contributions to the publications of the Smithsonian Institution. In addition to the intimate knowledge of the subjects which we have mentioned, Dr. Leidy was one of the first authorities in the United States upon the subjects of geology and mineralogy. His knowledge of the value of precious stones was that of an expert. His power of observation and of remembering what he had seen were almost beyond the comprehension of ordinary individuals. It is said of him that on one occasion a rare plant was brought to him which had been found in Chester County, Pa., and that after examining it with some care, he remarked that he remembered to have found one of the same character thirty-five years before on the south side of a small strip of woods, which proved to be the position from which the second plant had been brought.

While Dr. Leidy did not make great epoch-making discoveries, his scientific work and the hundreds of minor discoveries which he made have placed him head and shoulders above all other naturalists which America has ever produced, and it is doubtful if the world has ever seen a man who was so thoroughly equipped and so intimately in touch with so many branches of natural science as was the subject of this sketch. In addition to the American honors which were conferred upon him, Dr. Leidy was a member of a large number of learned societies in Europe, and as long ago as 1865 was elected to membership in the following foreign bodies: Imperial Society of Naturalists, Moscow; Imperial Leopold Charles Academy of Sciences, Jena; Royal Zoölogical and Botanical Society, Vienna; Royal Academy of Sciences, Münich; Royal Bohemian Society of Sciences, Prague; Biological Society, Paris; Geological, Zoölogical, and Linnæan Societies, London; Natural History Society, Dublin.

The most prominent contributions from the pen of Dr. Leidy are as follows: *Flora and Fauna within Living Animals*, 1 vol. 4to., pp. 67, plates 10, 1853; "Freshwater Rhizopods of North America," *U. S. G. Survey of the Territories*, Wash., 1879; *Ancient Fauna of Nebraska*, 1 vol. 4to., pp. 126, plates 24, 1853; *Memoir on the Extinct Sloth Tribe of North America*, 1 vol. 4to., pp. 68, plates 16, 1855; *Cretaceous Reptiles of the United States*, 1 vol. 4to., pp. 135, plates 20, 1865; *Extinct Mammalian Fauna of Dakota and Nebraska, together with a Synopsis of the Mammalian Remains of North America*, 1 vol. 4to., pp. 472, plates 30, 1869; *Contributions to the Extinct Vertebrate Fauna of the Western Territories*, 1 vol. 4to., pp. 358, plates 37, 1873; *Description of Vertebrate Remains from the Phosphate Beds of South Carolina*, 4to., pp. 52, plates 5, 1877. The greater part of his more important works have been issued through the Smithsonian Institution, the Academy of Natural Sciences of Philadelphia, and Hayden's United States Reports of Geological Surveys of the Territories.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 9, 1891.

BRADLEY, G. P., *Surgeon.*—Detached from "Mohican," and placed on waiting orders.

T. C. WALTON, *Medical Inspector;* GEORGE A. BRIGHT, *Surgeon;* and J. M. STEELE, *Passed Assistant Surgeon*, ordered to Naval Academy, to examine applicants physically for admission.

DICKSON, S. H., *Surgeon.*—Ordered to the "Constellation."

LEACH, PHILIP, *Passed Assistant Surgeon.*—Detached from the Naval Academy, and ordered to the "Constellation."

RUSH, W. H., *Passed Assistant Surgeon.*—Detached from the "Saratoga," and await duty to sea.

ATLEE, L. W., *Passed Assistant Surgeon.*—Detached from Navy Yard, League Island, and ordered to the "Saratoga."

BROWNELL, C. D. W., *Assistant Surgeon.*—Ordered to Navy Yard, League Island.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment, provided request for reprints be noted by author at top of manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

NAPHTHALIN IN TYPHOID FEVER;

Based on Its Employment in One Hundred Consecutive Cases.

BY L. WOLFF, M.D.,

PHYSICIAN TO THE GERMAN HOSPITAL OF PHILADELPHIA; DEMONSTRATOR OF CHEMISTRY, JEFFERSON MEDICAL COLLEGE, ETC.

WITH the recognition of the bacterial origin of typhoid fever and the seat of the characteristic microörganisms in the glandular apparatus of the lower part of the ileum, the endeavor to combat bacterial growth at its peculiar location and thereby to prevent the formation by it of the toxic agents which give rise to the typical symptoms of that disease, intestinal antisepsis soon became a factor in the therapeusis of this affection.

Carbolic acid, thymol, iodine, mercuric and mercurous chlorides and iodides were employed for this purpose, and, with the exception of calomel, were soon relegated to the oblivion they seemed to deserve. That calomel alone remained and proved its worth in practical application, is probably due to its insolubility and its gradual conversion only in the lower part of the small intestines, where it no doubt forms antiseptic compounds. It appears, therefore, that the methods of intestinal antisepsis were not so much at fault as the selection of the proper antiseptics. Carbolic acid, iodine, thymol, naphthol, corrosive sublimate, etc., are evidently taken up in the upper part of the digestive tract, or early in the digestive act converted into compounds which promptly find their way into the absorbents. In the extreme dilutions in which they can circulate in the blood, even though they were not also promptly eliminated, they cannot possibly exert a sterilizing action on the soil of the bacterial growth. Deducing from the undoubtedly favorable action of calomel in enteric fever, the choice for an intestinal antiseptic should fall upon one that is not readily soluble nor taken up by the absorbents, until it had reached that part of the intestines which is the seat of the etiological microbe. It might be asked, Why not employ calomel, if its action has proven so beneficial? To which must be responded, that its continued use for any length of time is certainly impossible, both on account of its irritant action on the intestinal mucous surfaces, as well as the early-appearing constitutional symptoms, which must at once contra-indicate its employment.

Rossbach, of Jena, some time ago (*Berliner klin. Wochenschrift*, 1884, No. 42) recommended naphthalin as deserving of trial as a suitable intestinal antiseptic agent in typhoid fever, arguing in its favor the good results obtained with it in different enteric affections, both catarrhal and ulcerative. He claimed for it that by its use he was enabled to disinfect the enteric intestinal canal, and that the fæces under its use passed perfectly odorless, or with only a predominating odor of naphthalin. He further claimed for it insolubility in water, acids, and alkalies, also strong antiseptic powers; and that while toxic in its effect upon insects, it certainly did not exert, even in large doses, toxic or deleterious action upon man. Also, that it was almost always readily tolerated by the stomach, not disturbing the appetite or digestion, and that albumin never appeared in the urine after its use. The same author quotes also the statistics of a number of cases of typhoid fever which had been treated with naphthalin and which had terminated abortively inside of two weeks, while in the late cases it had exerted no marked influence over the disease. In another paper on the same subject (*Berliner klin. Wochenschrift*, 1885, No. 14) he treats further of the action of naphthalin and its untoward effects, and attributes the latter largely to the use of the impure drug or to the idiosyncrasy of the patient. Some of the unpleasant results were strangury, and even præputial œdema observed in two tuberculous patients. He already points out the dark coloration of the urine under its use, and thereby admits the elimination of some of it by the kidneys. He claims that the rare untoward symptoms were by far outweighed by the decided beneficial results obtained by its use. In his remarks on this subject at the Congress for Internal Medicine at Berlin in 1884, Rossbach also states that if taken internally it was to some extent eliminated with the urine, either as naphthalin or converted into naphthol, which Baumann and Herter declared was not the case in dogs to which had been given five grammes of naphthalin. They held, therefore, that it must pass off as naphthalin in the aqueous vapors, but did not explain the condition of the organic sulphates under its use. It was stated by Rossbach that the urine of patients taking naphthalin was preserved from decomposition for weeks; also, that Schlescher had obtained a naphthol reaction in such urine.

E. Sehrwald, of Jena, in an exhaustive paper on

"Naphthalin in Typhoid Fever" (*Berl. klin. Wochenschrift*, 1889, No. 19), from experiments made in the laboratory of the medical clinic of Professor Rossbach, reviews the uses and action of naphthalin, and especially its effect on bacterial life in artificial cultures. He inclines to the view that naphthalin possesses inhibitory action on the development of microörganisms, and though he admits that at ordinary temperature this is very little, he claims to prove that it is increased by greater surface contact, such as might be produced by shaking and peristaltic action; also, that at the temperature of the body its action on the microörganisms is much more intensive, and that it acts most probably in its gaseous state by inhibiting the growth and is destructive to the life of the germs. It is therefore more energetic on aerobic bacteria and those propagating on solid soil than on the microörganisms vegetating in fluids. He seeks to explain in two ways the beneficial results from naphthalin as an intestinal antiseptic, by the constant peristalsis and the elevated temperature, which causes the fluids thereof to come constantly in contact with the gaseous naphthalin so generated. He states that while the microbes of the fæcal masses are by this antiseptic reduced to one-half without the body, they are reduced to one-third or one-fourth in it, and after evacuation very soon again reach the former proportion. A most significant deduction made by Sehrwald is that naphthalin acts even more forcibly on the typhoid bacilli, reducing them to one-tenth their quantity, and reducing them still further when they have been already reduced by the exhibition of calomel. On account of the mixed character of the infection of typhoid fever and the more energetic manner in which naphthalin acts on the bacilli thereof, and the control of calomel over some of the other bacteria of that disease, he recommends the joint administration of the two drugs in typhoid fever.

Notwithstanding the painstaking experiments of Dr. Sehrwald and his logical deductions, the weak antiseptic powers of naphthalin appear to give no great assurance as to the probable results to be obtained by its use in enteric fever. Having for some time employed naphthalin in the typhoid fever wards of the German Hospital of Philadelphia, and having become satisfied as to its decided beneficial influence on the course of this disease, I have made a number of researches at the laboratory of the Jefferson Medical College as to its action and conversion in the digestive tract. It is hardly to be supposed that we can look for its action as being germicidal when it is at best even a very weak antiseptic. That it is quite insoluble in the fluids of the body would be another objection against its use as an antiseptic. We cannot suppose that it should prove directly antagonistic to bacterial life, but we may infer that, if it were soluble, it should permeate the tissues and transform them into unsuitable soil for microbic propagation. From Dr. Sehrwald's experiments we would look for the active typhoid bacilli in the contents of the intestines, rather than in the solitary glands and the Peyer's patches of the ileum. What we may look for in the intestinal contents are the soluble products of the pathogenic microbes over which naphthalin or any other antiseptic can have no control; whereas the factors thereof are nested in their glandular beds, propagating there at the expense of the culture soil they offer, and secreting in their destructive process the toxin which gives rise to its pathognomonic symptoms.

It seems to me that an intestinal antiseptic must be intended rather to affect the soil than the bacterium directly, as probably no chemical agent could do this in non-toxic doses. To such an agent naphthalin must be converted before it can produce a local antisepsis and be absorbed. It has been stated by Rossbach that he had given the napthalin in doses ranging from one and one-half grains to as much as seventy-five grains per day. He urges the larger doses because only with them does the naphthalin become apparent in the fæces. Why should the smaller doses not be eliminated by the bowels, and what becomes of them? To determine this I made, jointly with my assistant, Dr. M. V. Ball, a series of experiments, in which we commenced taking naphthalin in smaller doses, and gradually increasing it until we could demonstrate its presence in the stools in its pure state. We made also control experiments with the stools of typhoid patients, and found that naphthalin in doses not exceeding five grains every four hours would not appear in the fæces. We further demonstrated that in the five-grain doses the odor of naphthalin was not apparent in the exhalations of the lungs or skin, but that derivatives of naphthalin could be promptly and continuously detected in the urine. The question of the elimination of the naphthalin derivatives from the body has been gone over so extensively, and the tests are so purely chemical, that I will omit them, as they have been published elsewhere by my assistant, Dr. Ball (Prize Essay, Jefferson Medical College, 1889). I will only state that we invariably found naphthol-sulphuric acid, or rather napthol-sulphurates, in the urine. With ferric chloride they gave a red color, turning to brown, while with diazobenzol-sulphurate of sodium a beautiful red color promptly appeared. From these experiments it may be inferred that in five-grain doses or less all the ingested naphthalin leaves the body in the urine (excepting the probably small quantity escaping in vapor form). This deduction naturally leads to the question of how this conversion of naphthalin can

and does take place? It is a well-known fact that in the small intestines there is constantly found and produced more or less hydrogen peroxide, and thence it passes into the blood and even into the urine. It is also a fact that naphthalin forms directly with hydrogen peroxide a hydrate known as naphthol, which, according to its relative position, may be either of the α or β variety, and, furthermore, that the product of naphthalin is a very powerful antiseptic. It may be assumed that it is the naphthol locally produced which exerts the inhibiting power over microbic life, while the value of naphthalin rests in its being insoluble and being converted only at or near the site of the infection. That it is thence absorbed and eliminated as a sulpho-compound might lead to the question why naphthol itself should not be at once administered. This can be answered to the effect that as naphthol is soluble (about 1 to 1000), it will no doubt be absorbed in the upper portion of the digestive tract, probably little, if any, reaching the lower part of the ileum.

I have made the foregoing experiments and researches to justify my continuance with the treatment of my typhoid patients by this remedy. Before proceeding with my own clinical observations I will quote from the inaugural essay of Dr. Ludwig Wilhelm Goetze, published in the *Zeitschrift für klinische Medicin*, Berlin, 1885, in which he reports thirty-five cases of typhoid fever treated with naphthalin, of which three terminated abortively in three days, ten within ten days, and four within two and one-half weeks; a total of seventeen cases, or 50 per cent of the total number so treated. Of the thirty-five cases three died, so that the total mortality in this series would have amounted to 8.5 per cent. Of these the reporter claims that two deaths were not to be attributed to the typhoid condition, but to severe complications, leaving a mortality of 2.8 per cent. in an epidemic which was considered of a severe type.

My service in the medical wards of the German Hospital during the last three years brought to my observation a rather larger number of cases of typhoid fever than is usually met with in medical practice. While it is well known that some typhoid epidemics assume a more serious character than others, and that the death-rates vary as a consequence, irrespective of any treatment, I selected for my observations on intestinal antisepsis with naphthalin, one of the more severe, if not the most severe epidemic we had experienced for some years. The cases so treated were selected, but received the same medication, as follows: On admission, calomel with soda was administered in grain doses each three hours for six hours, or until its laxative effect forbade its further use. This was immediately followed by gelatin capsules containing five grains each of purified and finely-powdered naphthalin every four hours, alternated only with a few drops of dilute hydrochloric acid. No other medication was permitted, excepting chemical antipyretics and cold sponging for hyperpyrexia. The diet consisted of milk, alternating with meat broths containing raw eggs; stimulants were administered as required.

I submit herewith a *résumé* of one hundred consecutive cases treated in this manner. An analysis of this series of cases shows the following results: Of the one hundred patients fifty-six were males and forty-four females; their average age was 24.7 years; the mean duration of the febrile period was 24.4 days: this may seem large, but when we take into consideration that some had long sieges of fever and others had two or three relapses, it explains the reason for such a protracted average fever period. A notable fact is that in the one hundred patients so treated sixteen cases ran an abortive course, *i. e.*, they defervesced before the end of the second week. Only three of the patients had intestinal hæmorrhage, which, however, in two of the cases occurred shortly after they were transferred to me and subjected to naphthalin treatment. The total mortality was 10 per cent. Two cases were brought in comatose and never rallied, and died within three days after admission. Of the complications resulting in death was one with facial erysipelas, one with glosso-pharyngeal paralysis, one with acute pulmonary phthisis, one from heart failure in consequence of valvular heart lesion. Of the other four remaining fatal cases, two died respectively within four and five days after admission, never having responded to treatment. I may, from the foregoing, fairly assume that the mortality of these cases under naphthalin treatment did not exceed 2 per cent. It is not probable that the total death-rate from typhoid fever in general hospitals will ever be reduced much below 10 per cent., as severe cases admitted late in the disease, or with complications which no longer admit of treatment at their homes, will under any treatment prove more or less fatal.

To understand the value of my figures here given I must refer to the death-rate of typhoid fever at the German Hospital of Philadelphia for the five years prior to the epidemic during which I made the observations the results of which I have herein submitted. According to the statistics of this hospital the death-rate from typhoid fever in 1884 was 23.4 per cent.; in 1885, 11.4 per cent.; in 1886, 20.4 per cent.; in 1887, 17.4 per cent.; and in 1888 it was 13.2 per cent.; while the one hundred cases which I have here reported followed in 1889 with a total death-rate of 10 per cent. As a comparison made of the death-rates under various

treatments I can quote no better statistics than those of Liebermeister, in Basle, which he gives as follows:

On the indifferent plan, 27.3 per cent.; on incomplete antipyretic treatment, 16.2 per cent.; on complete antipyretic treatment, 10.2 per cent.; no specific treatment, 28.7 per cent.; calomel treatment, 12.4 per cent.; iodine treatment, 12.9 per cent.

As a result of my observations I would also state that naphthalin has no direct influence on the fever temperature; it is often surprising, however, how soon after its continued administration a lysis will take place and a normal temperature will be reached. That this is due to the inhibiting effect of the drug on the morbid process and its etiological elements may be inferred from the fact that if in such cases the medication be discontinued directly on defervescence, a renewal of the febrile process will generally take place. It was at first a matter of some surprise that the relapses were so frequent, there being nine cases showing renewal of fever and some of them had even two and three relapses. After that, I continued the naphthalin for some time after complete defervescence, and the frequency of relapses was greatly diminished. In only one of the cases did I find continued nausea and persistent vomiting, necessitating an interruption in the naphthalin treatment, which, however, was resumed subquently without further trouble. One of the favorable results of naphthalin treatment is the control it exerts over the excessive and exhausting diarrhœa. After its continued use for some time it may even be found necessary to administer laxatives or exhibit laxative enemata to overcome resulting constipation. There seems to be no repugnance on the part of the patient against the drug, unless it is administered in suspension instead of in gelatin capsules. The appetite is in no manner impaired by it, and I have had no occasion to observe any irritation of the uropoëtic apparatus with the purified naphthalin I invariably employed. I have carefully watched its effect on the heart, but found that it is in no way impaired or depressed by it.

In conclusion, I may sum up my deductions as follows: That the treatment of typhoid fever should always be under two heads—one for the infection and the other for the toxæmia resulting therefrom. There seems to me no room for doubt that at the onset of the disease the administration of naphthalin may inhibit the development of the pathogenic microbes to such an extent that the fever itself will run an abortive course. Further, that at any period of the disease we may restrict the growth of the etiological factors in a measure, that an over-production of the chemical toxins may be prevented, and thus the fever run a mild course. This is possible, in my estimation, only with chemical agencies which, innocent in their immediate action on the organism, will be chemically altered in the lower part of the digestive tract, and there exert their antiseptic action on the soil of the pathogenic microörganisms. Of these agencies naphthalin and calomel are the principal representatives, and of the two, naphthalin must have the preference for its non-toxic character. Whether naphthol directly administered in keratin-coated pills be preferable, I am not prepared to state, although I know that, if ingested in suitable quantities for intestinal antisepsis, it produces local irritation, reflex vomiting, and diarrhœa. The gradual but continued development of naphthol from naphthalin *in situ* seems more calculated to produce intestinal antisepsis without the accompanying irritation of masses of naphthol.

Although I feel justified from the foregoing in recommending the use of naphthalin for the treatment of the specific infection of typhoid fever, I do not wish it to be understood that I recommend it as the sole treatment of this disease. No chemical agent so far known can destroy the characteristic toxins without also destroying life, and naphthalin can in no manner influence the already absorbed typhotoxin nor combat the symptoms it produces. For the toxæmia there is no specific remedy save speedy elimination and the stimulation of the vital organs against it. Though not within the province of my paper, I would say that, in my opinion, this is best obtained by cold baths; but I should think myself as much remiss to depend upon combating simply the specific poison in the body without attempting to limit its production, as I would be by attending to intestinal antisepsis alone without regard to the dangerous symptoms which the absorbed poison has already produced.

ACUTE DELIRIUM: ITS ETIOLOGY, PATHOLOGY, AND CLINICAL FEATURES, AS STUDIED AMONG THE INSANE.

BY W. P. SPRATLING, M.D.,
OF MORRIS PLAINS, NEW JERSEY.
FIRST ASSISTANT PHYSICIAN NEW JERSEY STATE ASYLUM FOR INSANE; MEMBER OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

BEFORE proceeding to a more general consideration of the features embodied in acute delirium, it may be wise to offer an explanatory note bearing upon the title of this paper. We would call attention to the fact that when we say acute delirium, as studied among the insane, inference naturally draws one to conclude that the cases studied were actually insane. That they were so stamped by reason of a legally qualified commitment, which placed them for treatment in a hospital for the insane, is a fact beyond dispute. But this alone, and I say it with all respect to those charged with the

examination and commitment of such cases, does not make them insane in the true sense of the word, and in the sense that insanity should be strictly accepted and rigorously held to. We are getting too prone to magnify and overestimate mild and comparatively harmless deviations in the mental operations of an individual from what we conceive that person's normal psychological standard to be. We do not claim that the "curve of health," lately discovered by Dr. Oliver Wendell Holmes, can be so deflected or extended as to include in the normal variations of man's physical welfare such a disease as acute delirium. It would be worse than folly to go that far. We do, however, venture to assert that pure and simple cases of acute delirium, characterized by their usual symptoms, abrupt in invasion, destructive in tendency, and evincing the many profound physical manifestations of disturbed organic life, should not be held to constitute a true form of insanity. We submit as a matter of fact that the objective symptoms in cases of acute delirium vastly outweigh the subjective. While the objective symptoms are sufficient to fill out a long list, the subjective ones are confined to a low delirium in nearly all cases. This low, unceasing, monotonous delirium should not be, in itself alone, sufficient to constitute insanity. Typhoid and many other febrile conditions are characterized by a like delirium, and yet the stigma of insanity, so considered by the ignorant, is not forced to rest on such cases. Acute delirium, with its concomitant symptoms, often goes under different names, of which acute delirious mania constitutes one of the most frequent designations employed by alienists when such cases are received into hospitals for the insane.

To the student of diseases of the human mind, the condition of acute delirium is especially interesting. A fair percentage of acute cases admitted into hospitals for the insane is composed of such. It is also known that the rate of mortality among this class of cases is high. We have often been astonished to see how quickly a strong, vigorous, and hearty individual, whose disease may only have existed twenty-four or forty-eight hours prior to admission to the hospital, becomes within a week or ten days a victim to the ravaging powers of this disease. All, of course, do not die; many recover; others lapse into a chronic condition in which they evince mental symptoms pathognomonic of no distinctive type of insanity, but sooner or later pass into secondary or terminal dementia. In THE MEDICAL NEWS of January 31, 1891, Dr. James Hendrie Lloyd invites us to a new field of reflection concerning the causative elements of acute delirium. He is inclined to the opinion that the disease is due to an infectious process or the action of some irritant poison. In a proportion of cases we fully agree with him, and even do so more readily in those cases in which we can directly detect a culpable source of infection, as, for example, in puerperal cases; for here we have no embarrassment, as a rule, in ascribing to the proper cause any manifestations of delirium or erratic mental action, should it occur within the first month, or even later, after childbirth. We also know that certain exopathic poisons, in gaseous or microscopic form, when taken into the system, produce distressing bodily derangements, attended in some instances with marked delirium. Dr. John B. Chapin, in the same issue of THE MEDICAL NEWS, calls attention to the fact that sewer-gas emanations from old privy vaults and other impure exhalations give rise to bodily and mental symptoms, some of which are characterized by acute delirium. Such agencies constitute exopathic chemical poisons, and it is generally quite easy to establish, in such instances, the causal relationship between the disease and its proximate cause. On the other hand, we frequently encounter typical cases of acute delirium, the causes of which we find it impossible to determine. In many of these cases we can readily exclude, so far as a careful and exhaustive inquiry will enable us to do, every possible cause, or source of exopathic infection, and so we are left to assume that the cause for the disease comes from one or the other of the following sources: either from the action of endopathic chemical causes, which arise either *sui generis*, or have their origin as the result of new compounds formed within the economy, or from causes purely psychological. The psychological causes of morbid mentality have long been recognized. Credit has always been given to excessive exercise of the mental faculties when deeply disturbed by grief, shock, or remorse, for producing unwholesome deviation of mental action and oftentimes fixed insanities. How mental action deranges itself, or the source from whence it comes, is as interesting a question as "Why does not the stomach digest itself?" If we could once establish the essential method of production of mind, or its mode of origin from the highest types of the bio-plastic elements of the brain, or if we could understand and demonstrate the probable or true chemical metabolism that takes place in the cells of nervous matter when mental force is being evolved, then we would be in a far better position to formulate some basic principle upon which diseased mental action in general goes on. We are inclined to the opinion, though our conceptions may be totally erroneous, that the chemical constituents of nerve-tissue suffer some deleterious chemical change when that nerve, or nervous tract, is required to transmit currents of thought, so to speak, which are excessively intense,

imperative, and morbid in character. We furthermore believe that the duration of application of these intense and essentially poisonous impressions, determines whether the mental symptoms that supervene shall be lasting in character, or whether suitable remedial agencies, or the beneficent action of that great healer, Time, will suffice to eradicate them. From among the number of cases of acute delirium that have been admitted to this hospital during the past four years I have selected the following five. These five cases embrace the operations of three distinct causes—distinct so far as the source from which the causes *a priori* arose. The first was evidently due to an infection derived from without, the delirium in this case following an attack of la grippe. The second was due to puerperal sepsis, in conjunction with intense psychological disturbance. The third was purely psychological. The fourth originated in consequence of a specific infection, operating conjointly with religious excitement; while the fifth is shrouded in much doubt as to its real cause. It occurred in a woman six months after the birth of her child, the mother being in the meantime in good health, both mentally and physically.

Case I.—J. H., a native-born American, thirty-five years of age, married, and a laborer by occupation. His illness began on February 17, 1890, with an attack of la grippe, at that time epidemic in the country. The attack began two weeks before his admission to the hospital, and he had been delirious four days when admitted; delirium set in on the tenth day of the disease. Prior to his admission his delirium was quite active, being attended by a good deal of motor excitement. Soon after admission the character of his actions underwent a material change; he refused food and drink; his tongue became dry, brown, fissured, and hard, and sordes covered the teeth; breath very offensive; eyes restless and wavering in expression; the lines of the face drawn and prominent. It was impossible to fix his attention for a moment; he was never quiet, tossing to and fro on the bed, constantly muttering unintelligible sounds. He was put upon supporting and stimulating treatment, which had to be carried out entirely by artificial means, by the use of the stomach-tube and rectal injections. He gradually failed, and died on the eighth day after his admission to the hospital. An autopsy held some hours after death revealed no special pathological changes. Along the median line of the dura a number of hæmorrhagic spots were noted, the dura being somewhat thickened in the same locality, and slightly adherent just here to the pia. The vessels of both the dura and pia were greatly congested. The puncta vasculosa throughout were plainly marked. The brain weighed forty-eight ounces, and its substance was in good condition.

Case II.—C. McC., a young married female, twenty-six years of age, a native of Ireland, the mother of three children, and a silk-finisher by occupation. Prior to this illness patient had always enjoyed robust health; she had no trouble, either during or after any of her child-bearing periods, dependent upon this condition. During the two and a half weeks prior to her admission to the hospital she was a constant attendant at mission meetings held in the Catholic church of which she was a member. She attended these meetings closely, and appeared deeply interested in them. The first evidence of mental derangement was noticed one evening upon her return from the service, when she was "excited" and "talked strangely." The next morning she appeared normal, and went about her household duties as usual until 9 o'clock, when the first marked outbreak occurred. She raved about "Christ and crucifixion," and continued in this excited, delirious condition for four days, when she was admitted to the hospital. Shortly after admission she became less active in speech and action. The delirium continued, and was characterized by all its usual symptoms. She persistently refused food and medicine, talked incessantly about religious matters, and never slept unless under the influence of some hypnotic. There was a slight elevation of temperature, the skin was hot and dry, the lips and tongue deeply furrowed with brownish-colored fissures, sordes covered the teeth, and her breath was very offensive. Her face wore a restless, apprehensive, and, at times, a pleading expression. Emaciation rapidly appeared, and she continued to fail, and died from exhaustion on the sixteenth day after the beginning of her disease. An autopsy held ten hours after death showed intense general congestion, involving both conjunctivæ, the scalp, the membranes covering the brain, and all the internal organs. The pia and arachnoid were intensely congested, the former being adherent to the convolutions of the posterior frontal and postero-parietal regions. This adherence was most marked along the median fissure. The vessels, cord, medulla, pons, and corpora quadrigemina were also congested. Brain-substance of normal consistence.

Case III.—The one due to purely psychological causes was that of J. A. T., a young native-born American, twenty-three years of age, and a stenographer by occupation. He had been ill four weeks when admitted to the hospital suffering from a pronounced type of melancholia. He was brought here on account of his trouble suddenly taking an unfavorable turn. He became much worse twenty-four hours after admission, and rapidly passed into a condition of acute delirium. The cause of his primary mental depression, as given, was that he had wronged a young woman, and thought he would be forced to marry her. Prior to this misdeed he had never had any mental trouble whatever. About three years before this he had an attack of typhoid fever, and experienced the usual delirium. From the beginning of the delirium after his reception here he steadily failed. All physical powers seemed to actually melt away. Motor and mental activity seemed to go on under the highest pitch of intensity. His fancy was most active. He dreaded being captured and tried for a wrong, and constantly exercised his motive powers to flee from his environments. His

efforts in this direction soon ceased on account of complete physical exhaustion. He was put upon a stimulating and nutritious diet, administered every two hours, and choral was used in twenty-grain doses to overcome restlessness and insomnia. Later on, heart stimulants were called for. All treatment, however, proved futile, and he died on the eighth day after his admission into the hospital. An autopsy was not permitted.

CASE IV.—J. D. C., a man, twenty-eight years of age, native-born American, married, an engine-driver by occupation. The cause of illness in this case was held to have been an infection derived from without, operating conjointly with a psychological disturbance, springing from religious excitement. "Malaria" was given as the agent of infection, from the fact that the patient worked in a low-lying, swampy district, known to be miasmatic. Religious excitement, consequent upon his attending a "revival," was also regarded as semi-responsible for his subsequent delirium. When admitted here, on the 21st of last January, he had been ill for a week. The symptoms at that time constituted the more ordinary signs of simple melancholia. Two days after admission his condition greatly changed. He suddenly became very aggressive toward other patients, went dancing and surging around the ward, and evinced some hallucinations of sight and hearing. Four days later this condition terminated as suddenly as it began, and he passed into a state of active delirium. The following are some notes of the case taken from the house records:

February 5. Delirium active; forcible in his bodily movements; tries to escape from the room whenever the door is open; mutters constantly, giving expression to semi-intelligible words bearing upon his previous life.

7th. No improvement; appetite very good; is given milk, whiskey, and eggs in combination every two hours. Eyes restless and apprehensive in expression; tongue dark-brown in color, dry, and deeply fissured; lips parched, cracked, and swollen; slight elevation of temperature; delirium continues.

9th. Improving; less restless; takes food better; restraint unnecessary; sordes disappearing from the teeth; tongue more moist and delirium subsiding; takes plenty of food.

15th. Able to be up and around the ward; all sensory and motor excitement gone; has fallen into a sullen, fixed mental state, that seems liable to become chronic. He will not speak, and has a positive aversion to being disturbed for any purpose whatever. Manifests a vicious tendency at times toward other patients.

He is still here, in fine physical condition, but I have little hope of the final restoration of his mental faculties.

While his delirium was just as active, and the objective symptoms just as prominent, as in some of the preceding cases, I am inclined to attribute the cause of his restoration, as far as it has progressed, to the great amount of nourishment he was forced to take, to the mixed character of the cause of his illness, and to his remarkable powers of physical endurance.

CASE V.—D. B., a married female, twenty-five years of age. She has one child, which was nearly six months old at the time of the mother's admission here. This patient's mother was insane, though nothing is known of the character of her insanity. The factor of heredity, combined with the puerperal state, and the hard work of the mother as sole attendant of her child, can doubtless be laid down as the causes responsible for the present acute attack. She was brought here on February 19th last, five days after the beginning of the disease. General excitement marked the inception of the attack. Shortly after admission she manifested symptoms of acute delirium, though not of an active type. Motor symptoms predominated. She could not be kept in bed; would get up and walk aimlessly about the ward, muttering incessantly to herself. Her attention could not be fixed. Her face, tongue, eyes, and lips, in fact, every feature, bore the symptoms of acute delirium. She would not eat, and on feeding her with the stomach-tube the extreme sensitiveness of the stomach, probably through reflex irritation, caused everything to be promptly rejected. She was then fed by nutritious enemata. A copious injection of warm water was first given, and after this had passed away eight ounces of milk, whiskey, and eggs were given three times daily. She was fed in this manner for about ten days. Insomnia for awhile was controlled by morphia, hypodermically; but at the end of a week she slept without it. Immediately she began to improve, and has continued to do so since. At present she has some timid delusions, if I may so express them. By this I mean delusions about which she is apparently in doubt as to whether she should or should not speak. I hope these will soon fade entirely away.

STRICTURE OF THE RECTUM, WITH THE REPORT OF A CASE.[1]

BY S. GANT, M.D.,
OF KANSAS CITY, MO.,
LECTURER ON PHYSIOLOGY IN THE UNIVERSITY MEDICAL COLLEGE OF KANSAS CITY; LATE HOUSE SURGEON OF NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

STRICTURE of the rectum may be congenital or acquired. The congenital form is usually described under the title of malformation, and will not be considered in this paper, which is intended as a study of the acquired forms of stricture. These strictures may be classified as follows: 1, Those due to pressure from outside the bowels; 2, spasmodic; 3, non-venereal; 4, venereal; and 5, cancerous. A tumor of any kind in the pelvis will not infrequently

[1] Read before the Medical Society of the Missouri Valley, Omaha, Neb., March, 1891.

so press upon the rectum as to obstruct its calibre. There has been a great deal of discussion by the authorities as to whether we ever have a spasmodic stricture. The majority of them, however, have great doubt as to its existence, especially if the constriction is above the sphincters. A stricture which disappears on anæsthetizing the patient is a so-called spasmodic stricture. Non-venereal strictures are divided into the dysenteric, inflammatory, and traumatic. Dysenteric ulceration is one of the most frequent causes of stricture, which, when it is extensive, sometimes results in multiple strictures. A stricture may be the result of proctitis, acute or chronic, when sufficiently severe to cause changes to take place in the coats of the rectum. A simple traumatism may lead to the same result, either by causing ulceration and cicatrization, or by exciting a chronic inflammation in the sub-mucous and connective tissue. The more prominent kinds of traumatism which may result in a stricture are operations upon hæmorrhoids, foreign bodies, applications of strong acids, kicks and falls, some surgical operations, and injury produced by the head of a fœtus during childbirth. There is another form of stricture which may result from a thickening of the folds of mucous membrane which are normally present.

Venereal strictures may be divided into the cicatricial and neoplastic. Venereal ulcerations which by subsequent cicatrization are capable of producing stricture are the chancroid and later syphilitic ulcers. The chancre and mucous patch may be excluded, since their influence in causing stricture is rather a matter of surmise than of proof. There is a form of venereal stricture which does not undergo ulceration primarily—this may be called neoplastic. In this class we find the gummata, the ano-rectal syphiloma, and a later manifestation, in which we have a deposit of new material in the rectal wall as a result of the inflammatory condition.

In studying the pathological anatomy of stricture there are several points to be observed, for changes will be found not only in the stricture itself, but above and below it, and in the surrounding parts. The mucous membrane at the point of constriction will usually be found destroyed, and the connective tissue increased in quantity, thus increasing the thickness of the rectal wall. Later, the mucous membrane will show ulceration in all stages, from a simple congestion in some points to a complete destruction in others, due probably to retained fæcal matter. The ulceration may extend up and down the bowel, or cause a perforation.

There is a low form of peritonitis which frequently accompanies stricture. The rectum below the stricture seldom remains unchanged. Hæmorrhoids, vegetations, excoriations, fistulæ, and cutaneous tags of greater or less size usually follow in close proximity as a result of the discharge from the disease above.

Stricture proper is not met with so frequently as is supposed. The fact that a patient complains of constipation, or passes ribbon-like stools, is in nowise a clear indication of stricture, for we have such symptoms from ulcers of the rectum and sometimes from an irritable sphincter. Stricture is more common in the female than in the male. Bryant found, in 48 consecutive cases, that 32 were in women. Of this number 20 were under thirty years of age, 15 being women, who were mostly, if not all, syphilitic. Twenty-two were over forty years old, one-half being men, and most of them of a cancerous nature.

Allingham in his work reports seventy cases. Of this number sixty were women. Out of the seventy, thirty-five had undeniable syphilis, while five had symptoms (but not decisive) of having contracted the disease, which leaves thirty who had undoubtedly never contracted syphilis. He found that about the same proportion of males had syphilis. From these statistics it can readily be seen that stricture is very frequently a result of syphilis.

One of the first things to direct our attention to stricture is a continual uneasiness about the rectum, which is usually followed by pain attending the passages; great efforts at stool are attended with unsatisfactory results; constipation is present in the early, and diarrhœa in the later stages, after ulceration has commenced; lumpy stools, containing pus, blood, and mucus, are passed; there is great straining at stool, with a sensation as if the bowel had not emptied itself; the stools are tape or ribbon-like, and as the stricture becomes smaller we have complete stoppage and dyspeptic symptoms. A stricture may or may not obstruct the entire calibre of the rectum. The most extensive disease is found in cases of syphilitic deposits, syphilitic sclerosis, or dysentery. In making the diagnosis, first get a complete personal and family history; follow this up by getting the subjective symptoms; after this comes the digital examination, by which you will nearly always detect the stricture, for most of these troubles are located in the lower part of the rectum. If the stricture is high up we have different symptoms. The patient will complain of pain in the abdomen, groin, and down the limbs, and obstinate constipation, with occasional diarrhœa. A stricture in this locality is very difficult to diagnose, and it must be looked for with great care, for I distinctly remember perforating the rectum while trying to make a diagnosis with a rubber bougie. The case, fortunately for me, did not die. If bougies are used, the flexible, soft rubber one should be chosen, and then used with *great caution*. I prefer a long, soft rubber tube to the bougie. Dr.

Kelsey says that he knows of no other way than this, and by exploratory laparotomy, in which a stricture in this locality which cannot be felt by external manipulation can be certainly diagnosed.

The prognosis in stricture is unfavorable so far as a cure is concerned. All we can hope to do in a great many cases is to prolong life by keeping the stricture in such a condition that the patient may have a reasonably comfortable stool.

The treatment of stricture should be local, constitutional, medicinal, and operative. The first question to determine is, Has the patient syphilis or not? If you have reason to believe that your patient has syphilis, put him on the mixed treatment at once; yet you should be careful, and not use the iodide of potasium and mercury indiscriminately. Should you do this it is possible that you will make as many mistakes as those who think all strictures are of a cancerous nature, and direct their treatment accordingly. Cicatricial tissue, though the result of specific disease, is beyond the reach of specific treatment, but where you see the case in the early stage much improvement will be gained by a thorough course of mixed treatment, by which means a gummatous deposit or a syphilitic sclerosis may be checked. Mercury, in the form of ointment, may be used, but it will be found very irritating if there be much ulceration. There are many ways in which the comfort of your patient may be increased without recourse to operative treatment, and these should not be overlooked in the surgeon's eagerness to operate. Careful attention to the diet is needed, which, so far as possible, in conjunction with other liquid and semi-solid food, should be milk in large quantities. The bowels should move at least once a day. The mineral waters, Rochelle or Glauber's salts, will be sufficient in most cases to cause an action. Purgatives are contra-indicated because of the straining and tenesmus which accompanies their action. The general health should be looked after, and cod-liver oil used if indicated. The most important thing, however, is rest in the recumbent position, and to allow your patient to walk as little as possible. When the ulceration is deep and contraction has commenced, you should be guarded about the prognosis; yet a good deal of hope may be instilled into your patients if they will give themselves up to your treatment for a greater or less length of time. If they are indiscreet they may undo in a day what you have gained in a month. One of the best ways of applying medication to a stricture is by means of the pile-pipe, which has a large base, gradually tapering toward the apex, and perforated with numerous holes. You fill the reservoir in the base of the tube with ointment, and then by turning the screw in the base force the remedy out on all sides equally. Allingham's favorite prescription is the following:

℞.—Bismuthi subnit. . . . . ℥j.
Hydrarg. subchlorid. . . . . ℈ij.
Morphiæ . . . . . grs. iij.
Glycerini . . . . . ℥ij.
Vaselini . . . . . ℥j.—M.

Sig.—Use in pile-pipe.

This is a sedative application, and I think a good one. The subacetate of lead, opium, and belladonna, in the form of suppositories or ointments, will be found serviceable. All sorts of astringents may be used; zinc, copper and nitrate of silver will all do good in some cases; occasionally fuming nitric acid is beneficial. By these means, combined with gentle dilatation, the life of a patient may in many cases be prolonged in comfort. If your patient complains of abdominal pain, put on hot fomentations. This, in a general way, covers the medicinal treatment.

The various surgical procedures at our command are the following: Dilatation, divulsion, colotomy, and proctotomy or rectotomy.

Before operating on a stricture, impress upon the patient the fact that he has a very serious trouble, and that the probabilities are that he will never be entirely well. If you choose to operate by dilatation use the soft rubber bougies. The dilatation should be intermittent, and not constant, because of the ease with which the rectum becomes irritated and peritonitis follows the application. Dilatation may be aided many times by nicking the edge of the stricture before passing the bougie. The one selected should be of a size to pass the stricture readily without much pain, and if there is any doubt in your mind as to the size to use, authorities say choose the smaller, the object being to cause absorption by gentle irritation. The treatment by gradual dilatation has been superseded by more radical measures. Some favor rapid divulsion; I do not, for I have seen some very serious complications following that operation. If the stricture is of a cancerous nature excision is indicated. Excision may also be resorted to in cases of benign strictures low down with happy results. I performed this operation once in a case of benign stricture, and the patient made a splendid recovery. Colotomy is to be performed in cases where the stricture is almost complete, and causes abdominal distention. I have assisted in performing the operation three times with very good results. The lumbar region is the usual site chosen, and the left side, for anatomical reasons. Should the obstruction, however, be high up the bowel, it may be performed on the right side. I have never witnessed a colotomy in the inguinal region. Allingham, who has performed

a great many of these operations, has performed inguinal colotomy but twice, both operations being infants, where they were not successful. Colotomy was performed upon ten of the patients referred to in the first part of this paper, by Allingham, and he says most of them did well. Five or six were still living at the time of writing. The main drawback to this operation is the disgust shown by the patients to having a false anus in the lumbar region. This feeling gradually wears off, and Allingham reports that two of his female patients married, after having the operation done, and made good wives. In case the stricture should heal after operation the false opening can then be closed.

I wish now to refer to Verneuil's operation, or, if you chose, proctotomy. This is often done as a substitute for colotomy. The operation consists in dividing the whole stricture, from its upper edge down to the coccyx and through its entire depth, thus forming a deep drain through which all discharges flow freely, the incision heals up, the ulceration ceases, and the stricture is sometimes cured. The operation may be done with the knife, with Paquelin's cautery, or the écraseur. If the knife is used, and a free gush of blood follows, pack the rectum with antiseptic lint. If the cautery or écraseur be used there will be very little hæmorrhage. By Verneuil's operation we got through-drainage through the triangular-shaped wound, and, at the same time, we get complete rest from the division of the sphincters. I think this the most practical and humane way of treating a bad case of stricture of the rectum. I remember in one case to have seen night-sweats arrested in forty-eight hours, and the patient rally, eat and drink, and get well from that moment. I have recently performed the operation three times, and the results were very satisfactory indeed. I wish in this connection to report the last case in which I performed this operation:

Mrs. P., referred to me by one of my professional neighbors, widow, aged thirty-five; good family history; has been long troubled with her bowels; never passed fæces of natural form; always in small, broken lumps, or sometimes had the ribbon-like stools; often passed blood, mucus and pus; has been emaciated for some time, but said she was perfectly well, except the bowel trouble. She dates her present trouble back two years, at which time she was operated on for hæmorrhoids by one of the famous quacks of our city, who cures all rectal troubles without the knife, cautery, or ligature, presumably by the laying on of the hands.

On examination I found an almost complete stricture about one and a half inches above the anus. I could not pass a No. 4 soft rubber bougie through it, and it was exceedingly painful to the touch. I found the edges of the stricture in a ragged condition from the severe ulceration. I placed the patient under chloroform, and with the sharp blade of a proctotomy knife passed to the upper edge of the stricture, I divided all tissues down to the coccyx; had very little hæmorrhage; dressed the wound with dry dressings, and in a few weeks it had entirely healed, and she could have a comfortable stool.

In conclusion, I wish to mention electrolysis, which it is claimed does good in the treatment of strictures of the rectum. Dr. Kelsey says, so far as producing absorption is concerned, it is a delusion, but he has seen some good from its counter-action, combined with rest and dilatation.

TWELFTH AND GRAND AVENUE.

MEDICAL EXPERT TESTIMONY.

BY JOHN J. REESE, M.D.,
PROFESSOR OF MEDICAL JURISPRUDENCE AND TOXICOLOGY IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

THE recent Schmidt criminal trial at Media, Pa., has excited no little interest in the community. To the medical profession its chief interest and importance centres in the very remarkable discrepancy, not only between the expert testimony for the prosecution and that for the defence, but likewise in some important particulars in the evidence offered by the State's experts. Probably no case on record in the annals of criminal jurisprudence affords a more striking illustration of the imperfect and unsatisfactory character of our present system of so-called "expert testimony."

Here we have the spectacle of four highly respectable practitioners of from ten to thirty years' standing—one of whom had, during an experience of twenty years, performed many thousand post-mortems, and examined over 300 cut throats, and whose opportunities and studies in the lines of anatomy, pathology, and microscopy have been unequalled—all uniting and testifying to certain appearances presented by the wounds upon the dead woman's neck, but not agreeing among themselves in relation to certain other appearances, the examination having been made within a day or two after the death.

Among the points specially noticed and testified to by these gentlemen, were the situation, the nature, the direction, and the extent of these wounds. They all coincided in the opinion that certain of the injuries—those which penetrated to the vertebræ—were inflicted by a stabbing, or *thrusting*, of the lethal weapon, whilst the others were undoubtedly of the nature of incised wounds. And, further than this, two of those witnesses expressed their opinion that the right carotid artery had been cut, or partially severed, by a wound inflicted on the right side of the neck, which had extended around to the front of the throat.

Now, these are points of purely anatomical signi-

ficance, about which one might suppose there could be no possibility of doubt or opinion. But what a remarkable spectacle was presented to the court and assembled crowd of on-lookers when the defence produced before their astonished gaze the very neck of the dead woman, which had been dissected from the dead body by their experts, and which now, after nearly four months' interval, they were permitted to offer in open court for the inspection and personal handling of each juryman!

It appears that the body was secretly exhumed by the defence some weeks after burial, and without the knowledge or authority of the court or the prosecuting attorney; and that during the interval their experts made their several investigations, and now, on the witness stand, these experts, in number and professional standing and ability the equals of their opponents—three of them well-known professors in our medical schools—came forward and declared that the right carotid artery was *not cut at all*, but was uninjured, and that "the wound at the back of the neck" was only superficial, and did *not* penetrate to the bone. In relation to this latter assertion, it is to be remarked that it is somewhat misleading, as it implies that the other experts had asserted to the contrary; whereas, these latter had distinctly stated that it was the *second* wound of the neck, counting from the back (not the one farthest back), that had the nature of a stab, and which penetrated to the spine, and had probably caused the fatal shock.

Now, let us ask the question, what impression is such an exhibition of so-called "expert testimony" calculated to produce on the minds of the court and jury, and of the legal profession generally, to say nothing of the popular sentiment? Is it not likely to very much weaken the respect and confidence in all such testimony, and to bring it into disfavor, much to the detriment of justice? But, in passing we may remark, What impression would the average juryman gain by looking at, and even *handling*, an anatomical specimen nearly four months old, taken out of a jar of alcohol before his eyes? Would he not be very apt to both *see* and *feel* pretty much as the expert should describe and manipulate the parts before him?

This diversity in expert testimony, especially in criminal trials, is calculated to occasion much doubt and uneasiness in the mind of the medical jurist, and, as already observed, its frequent occurrence has greatly prejudiced the courts and counsel against all medical expert evidence. That this should be the result is, of course, greatly to be regretted, and the question that presses for earnest consideration is how to remedy this mischievous condition of things? This question has occupied the thoughts of distinguished men in both the professions of medicine and law, but no practical advance or improvement has resulted so far, at least in our country.

One thing is very certain: if *all* the experts were equally well grounded by experience, ability, and education, on the special points involved in the case before them, and if they were all equally honest and truthful, and supposing the question was simply one of *facts*—anatomical, pathological, or chemical—which could easily be demonstrated to the eye or touch, it would seem to be impossible that there could be any difference of opinion, since truth is undivided and uniform. Universal consent and agreement *must* be awarded to *facts*, if proved to be facts. Even theories and speculations, deduced from these facts, ought not to differ widely, if at all, with experts equally well educated and equally well equipped for their service, and equally honest, truthful, and unprejudiced.

But it is probable that under our present system of *voluntary* experts, taken pretty much at random from among the crowd of doctors, many of whom lack the needed experience and training, we shall never attain to that perfect harmony and unanimity of expert testimony so desirable, especially in criminal trials. The true remedy, as it appears to us, is to change the system radically, so as to make the medical expert *a State officer*—appointing so many for each State, divided off into judicial districts. Let these "experts" be physicians of known and approved moral and professional character; not novices, but thoroughly trained and experienced in all the details of anatomy, pathology, chemistry, and microscopy, not omitting also surgery and gynecology. They should devote their exclusive time and attention to their State duties, relinquishing all practice as physicians, and, of course, they should be amply compensated for their services. The expert should possess a laboratory properly furnished in which all needful experiments could be performed. He should be present at every criminal trial within his district, and sit with the judges as the *amicus curiæ*, ready at all times to give his expert opinion in cases requiring it. This opinion, be it observed, should be formed and sustained only after thorough previous examination, *made by himself* (perhaps assisted by others) of all the points connected with the case, such as (supposing it to be a homicide case) the examination of the body and surroundings where it was first discovered; the thorough autopsy; the toxicological examination, if poisoning be suspected; the microscopic researches for blood and seminal stains; for hairs and fibres of fur, and for other matters; also the full details in cases of infanticide, fratricide, rape, and legitimacy. He should further be prepared, either in his individual capacity or as a member of a regularly constituted commission, to give an expert opinion in cases of lunacy

or of alleged insanity in a prisoner in a capital case.

The above is an outline or sketch of what we conceive to be the true office and position of the medical expert. It will be recognized by many of our readers as taken in the main from that adopted and practised for many years in Prussia, and with so much satisfaction. It ought not to be difficult to engraft this admirable system upon our criminal jurisprudence. It would certainly challenge the approval of both the professions of law and medicine. One practical difficulty might seem to present itself: How should such "State experts" be appointed? One thing is very positive at the outset: the appointment should be entirely kept out of the sphere of politics. For this reason it would be extremely unsafe to entrust it to the Legislature; and probably, for the same reason, it would be better not to leave it in the hands of the Governor. Therefore, it might be deemed the wisest course to leave the appointment with the Supreme Court of the State, which might make it, after proper deliberation and inquiry, upon the recommendation of the leading physicians of the different judicial districts. This appointment should be for life or, "during good behaviour." It ought not, under any circumstances, to be subject to the caprice or dictum of any new judge who might come upon the bench subsequent to the appointment. The incumbent should only be removed "for cause."

If the above plan could be carried out in our State the following signal advantages would be attained: *First*. It would insure the presence and work of a recognized expert in every important criminal cause. *Secondly*. It would put an end to the disgraceful "war of the experts," which has excited so much ridicule and contempt, both in and out of court. This it would do by entrusting the whole case (so far as it pertains to expert testimony) to the State expert, who is sworn to conduct the whole necessary examination in all its details, without fear or favor, for either side; absolutely impartial; having no pecuniary compensation or other expectation to bias or tempt him to act as a partisan for either the prosecution or defence. Everything here must, of course, depend upon the absolute confidence reposed in the State officer by both sides. Given such confidence, no further or additional expert testimony would be required or deemed necessary; there would be a quiet and satisfactory acquiescence by both sides in his opinion given on the witness stand. But, if from any cause the defence should elect to have, *in addition, their own* expert witness, the above arrangement need not offer any objection. As a matter of fact, however, we are of the opinion that very few *voluntary* experts would care to measure lances with or oppose the State expert, always supposing the latter to be as near perfection as we would have him to be. If the former witness be "a good man and true," he would in all probability agree with the State's witness; but if he should differ with him, the strong probability would be that his testimony would be overbalanced by the authority and weight of the other, supported as it would be by his recognized experience and official character. *Thirdly*. It would create much greater confidence in the community in the decisions of the court and jury in criminal trials. At present there is a widespread feeling that these decisions are very materially influenced by the diverse opinions expressed by the medical experts of the opposite sides. This feeling would then be laid at rest. *Fourthly*. The expense incurred in criminal trials would probably be diminished, certainly not increased, by the adoption of the above proposed plan. The defense would be entirely relieved of all expenditure for expert testimony, unless they choose voluntarily (and, as we have shown, unnecessarily), to incur it. When we consider the number of homicide trials occurring every year in our populous districts, and the great expense incurred by the State in the payment of its different expert witnesses, it is believed that the aggregate amount would probably exceed the salaries deemed proper for the recognized State experts. These salaries need not necessarily be the same for all the appointees. Those holding the position in districts of country thickly populated, and requiring more constant attention to duty, would be likely to receive a higher compensation than others whose duties would be less onerous and exclusive. Doubtless, all the working details of the plan above sketched out would soon be satisfactorily adjusted if only the plan itself could be adopted. It is certainly much to be desired that this subject should receive from the proper authorities that consideration to which it is entitled.

CLINICAL MEMORANDA.

TOXICOLOGICAL.

Two Cases of Nutmeg Narcosis.—The following cases of nutmeg narcosis may be of interest as showing the alarming, if not fatal, result of the aromatic, if taken in large quantities.

The drug was taken in both instances by women residing in a house of questionable character, and with the object of producing abortion. The first case took one and a half nutmegs. As the symptoms were not alarming, no medical aid was summoned; but twenty-four hours later, when I was called to see the second case, the first gave me the following history:

Case I.—One and a half nutmegs were powdered and taken in half a glassful of hot water. Two hours later the patient experienced severe burning pain in the stomach,

which continued one hour longer and was followed by a dreamy, half-unconscious condition, giving way to complete unconsciousness, which lasted six hours. She was then aroused by one of the inmates of the house violently shaking her. This procedure was necessary at short intervals for several hours. She then began to vomit, when she was given whiskey by her friends. Her recovery was so complete that when I was called to see her companion, twelve hours later, there was no evidence of the condition remaining.

CASE II.—As the quantity taken by the previous patient had not had the desired effect, my second patient concluded to take twice the amount, which was done in the same manner. Three nutmegs, being ground, were taken in hot water. About two hours later she experienced severe burning pain in the epigastric region, some nausea, but no vomiting. One hour later, or three hours after the aromatic had been ingested, she became entirely unconscious and was still in this condition eight hours later, when I was called. The appearance of the patient when I first saw her was alarming, to say the least. It was with the greatest difficulty that she could be aroused at all, and then only sufficiently to get an incoherent muttering. Respirations were 9 per minute, both expiration and inspiration being greatly prolonged; pulse 100 and feeble; temp. 100° F. Head buried backward in pillow; eyes turned upward and bulging and pupils evenly dilated; the extremities were cold; both the nails and lips were purple, showing venous stasis; there was relaxation of the sphincter of the bladder and rectum. She was sufficiently aroused by our efforts to empty the stomach with the stomach-pump, which was found impossible owing to the clogging, to allow the administration of an emetic of fifteen grains each of powdered zinc and ipecac, which thoroughly emptied the stomach in about twenty minutes. Strychnine and brandy were then freely given. Consciousness returned slowly, and at the end of twelve hours complete recovery took place.

In neither case did the drug have the slightest tendency to produce abortion, though the patient assured me she had known it to do so. This statement I am inclined, however, to doubt. The powerful narcotic symptoms observed in Case II., with the history of less marked symptoms in Case I., where a smaller quantity had been taken, prove, I think, without doubt, that nutmegs, if taken in larger quantities, say four or five of them, may produce death from paralysis of the respiratory centre.

ORIGINAL LECTURES.

THE HEART: ITS MURMURS, THEIR DIAGNOSIS AND TREATMENT, AND THE ACTION OF THE CARDIAC TONICS AS A CLASS.[1]

BY WILLIAM HENRY PORTER, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

LECTURE I.

GENTLEMEN: To-day I propose to discuss with you the subject of cardiac lesions, commonly known as valvular affections of the heart, and at a subsequent clinic the physiological and therapeutic action of the drugs commonly regarded as cardiac tonics and stimulants. But, first of all, it is absolutely essential that we should understand accurately the anatomical position and physiological mechanism of the heart, and also the pathological lesions following the mechanical defects in the action of this organ. We shall then be able to diagnosticate these disturbances accurately, and apply our therapeutic measures upon a thoroughly rational basis, with scientific accuracy, and not empirically or because somebody said so, and without a well-grounded reason.

In order to obtain a clear conception of, and to readily recognize, the various cardiac murmurs, we must have a thorough knowledge both of the exact position of the organ and of the mechanico-physiological laws governing its mechanism. This is especially true in regard to those murmurs which are located at the mitral orifice, where there is no organic lesion of the valve-segments.

We must become thoroughly familiar with the topographical arrangement of the heart. If, as is usually the case, the anatomical position of the heart is taken from frozen sections, it will appear upon a lower plane than that which it actually occupies during the life of the individual, and unless due allowance is made for this sinking, which occurs with all the viscera, and especially with the contents of the thorax, after death, great errors in diagnosis will, of necessity, be committed.

During life, too, the heart cavities and great bloodvessels are distended with blood, naturally causing the viscus to occupy a higher position in the chest than would be the case under other circumstances.

While the patient is alive, therefore, the heart may be said to occupy a triple oblique position in the thoracic cavity, or one corresponding to a line drawn from right to left, from above downward, and from behind forward —a position which will have for its central axis a line represented by transfixing the body from behind forward, from above downward, and from right to left, starting posteriorly at the sixth dorsal vertebra, passing through it and the chest cavity, and coming out on the anterior surface of the chest in the fifth intercostal space three and a half inches from the median line of the sternum.

The base of the heart will correspond to a line drawn obliquely across the sternum from the first intercostal space of the left side to the second intercostal space of the right side, and the apex of the organ will be found just within the anterior chest-wall, behind the fifth intercostal of the left side at its junction with the sixth rib, three and one-half inches from the median line of the sternum.

The left side of the heart is the most posterior; this is especially true of the left auricle, which is also the most inferior portion of the organ lying adjacent to the anterior surface of the eighth dorsal vertebra deep down in the space between the diaphragm and the spinal column. Exception, however, may be taken to this statement by some anatomists, for they make that part of the right auricle which extends down to join with the inferior vena cava, as it passes through the foramen quadratus, the most inferior portion of the heart, but when taken as a whole, the auricular cavity of the left side is decidedly upon an inferior plane to that occupied by the right

[1] A series of lectures delivered at the New York Post-Graduate Medical School and Hospital.

auricle or the left ventricle. As a result of this posterior and inferior position of the left auricular cavity, the current of blood passing from it into the left ventricle naturally flows from behind forward, from right to left, and slightly from below upward, or directly across the chest cavity; but never from above downward. The course of this current corresponds to a line drawn from behind forward through the eighth dorsal vertebra, through the

FIG. 1.

chest, and coming out in front at the junction of the fourth rib and its corresponding costal cartilage. I have named this line, for convenience, the left auriculo-ventricular axis. From this description you will readily see that the tricuspid valve is situated well to the posterior limit of this left auriculo-ventricular axial line. All murmurs, therefore, that occur at the left auriculo-ventricular orifice are produced and transmitted by the current of blood passing in one or the other directions of this axis.

For convenience the etiology will be taken up later with the descriptions of the murmurs.

The pathological lesions that can be produced, in connection with valvular defects in the heart, are most completely illustrated by starting with a mitral incompetency and following it through all the succeeding steps.

The first mechanical change in the mechanism of the heart, acting as a pump, is the leakage of a certain amount of blood back from the left ventricular cavity into that of the left auricle. This causes a small amount of depletion in the general arterial system, and a filling of the left auricle from the left ventricular cavity at the same time that the normal flow is coming in from the lungs, through the pulmonary veins. As a necessary sequence the left auricle will be over-filled and caused to dilate. The auricular cavity will now contain an abnormally large volume of blood, which necessitates a certain amount of compensatory hypertrophy on the part of the muscular wall of the auricle, to enable the organ to free itself from this unduly large volume of blood within its cavity.

When this step in the process has been accomplished, the left ventricle will have an abnormally large volume of blood thrown into its cavity, which will cause in turn a moderate amount of dilatation and hypertrophy of the left ventricle. This primary hypertrophy enables the left ventricle to throw the requisite quantity of blood into the aorta and to keep up the normal arterial tension, and at the same time sustain the backward leakage, which is constantly increasing the dilating force brought to bear upon the left auricle, and being resisted by its compensatory hypertrophy, until, finally, the blood is forced back upon the pulmonary system of vessels, and a certain amount of engorgement of the capillaries in the lungs is developed and maintained. This condition necessarily increases the amount of work which has to be accomplished by the muscular power of the right ventricle.

The constant over-distention of the pulmonary capillaries keeps up a perverted nutritive condition of the lungs, which, in connection with the impeded circulation, gives rise, after a time, to the development of new connective-tissue formations, and a general interstitial thickening of the pulmonary structures. Accompanying this there is always a change in the coloring-matter of the blood, which causes it to be decomposed and deposited in the newly-formed tissue, giving to it a distinct reddish-brown color.

This peculiar lesion of the lung is known by the name of brown induration of the lungs, sclerosis, cirrhosis, pulmonary induration, or the chronic interstitial pneumonia of heart disease. The first is, perhaps, the most accurate, anatomically speaking, for it describes the macroscopic appearances perfectly, while the last is probably the least accurate, with the exception that it points to its etiology. This process, however, is not inflammatory in the strict limitation of the process, as it is now understood.

This increased volume of blood in the pulmonary circuit is followed, as we have already found, by hypertrophy of the right ventricular wall, and so long as this compensatory enlargement can be maintained the mechanical workings of the heart, practically speaking, are performed with sufficient effectiveness; the only mechanical and physiological defect being a leakage at the mitral orifice and the pulmonary engorgement, both of which, mechanically speaking, are compensated for by the augmented power of the heart.

The right ventricle, however, is dependent upon the aortic tension for its nutritive supply, and as the arterial pressure is not raised above the normal standard, but tends to fall below, the right heart is apt to degenerate. The fall in the blood tension, together with the impaired oxygenating capacity of the lungs, and the generally deteriorated nutritive state of the system will, in turn, diminish the nutritive supply distributed to the right side of the heart, and the compensatory hypertrophy of the right ventricle is not fully sustained, the muscular fibres composing the organ progressively degenerate, and its cavity becomes dilated, until the segments of the pulmonary valve are pulled apart and prevented from completely closing the pulmonary orifice.

The engorged pulmonary vessels now force the blood

back through the incompetent valve of the pulmonary orifice, into the right ventricular cavity, or, stated in other words, the ventricle cannot free itself, and its cavity is filled from the two sides—from the right auriculo-ventricular opening and from the pulmonary artery. As the tricuspid valve is never competent, and the venous tension behind it is commonly rated as a zero pressure, while the pulmonary arterial tension is now abnormally high, the aspiration force of the respiratory act and the pumping action of the right heart is quickly overbalanced. The blood, of necessity, flows back into the right auricle and into the superior and inferior vena cava with each contraction of the right ventricle. This regurgitation into the general venous system is made apparent by the pulsation of the jugular veins synchronously with the cardiac systole.

The result of this backward pressure upon the venous system is to cause, at first, a marked hepatic congestion, and there is a similar condition throughout the whole entero-hepatic circuit. The liver, in consequence, becomes enlarged, and the hepatic cells in the centre of the acini become stained brown, similar to the lungs, from the same kind of decomposed blood-coloring matter being deposited in the protoplasmic mass composing the hepatic cells. This condition is known as a pigmented or nutmeg liver. If this hepatic engorgement lasts for a considerable time, a false nutritive condition is established in the liver, and a slight amount of newly-formed connective tissue is developed, together with some fatty infiltration of the hepatic cells composing the outer portion of the lobules of the gland. This form of hepatic sclerosis is usually limited in extent, and never assumes the characteristic appearances of an alcoholic cirrhosis. It is a microscopic rather than a macroscopic change. In this way a moderate amount of hepatic sclerosis and fatty infiltration of the glandular cells of the liver is added to the well-marked and extensive congestion and pigmentation of the organ.

As a result of this entero-hepatic engorgement, both the intestinal and hepatic digestive functions become impaired, and general nutrition is poorly sustained.

When the liver has reached the limit of its expansibility, the kidneys and venous system at large commence to be positively engorged. The congestion of the kidneys causes a development of new connective tissue in the interlobular structures, or a renal sclerosis is developed, and without the intervention of any inflammatory action. After a time the epithelial cells of the uriniferous tubules become smaller and granular, until, finally, sufficient damage is produced in them to cause albumin and casts to appear in the urine, which before was only scanty and high-colored as a result of the impaired nutritive condition of the system and the local renal engorgement.

Finally, all the veins of the body become over-filled, and dropsy of the lower extremities or a general anasarca is developed.

To overcome this universal vascular engorgement and œdematous condition of the system at large, the action of the left ventricle is increased, or its muscular wall hypertrophied, but owing to the general nutrition being so much impaired, this secondary hypertrophy of the left ventricle, as it is called, is rapidly followed by dilatation of its cavity, and death of the individual, being, as it were, the last act in the circle of events, and that, too, one of short duration.

With the other mechanical defects implicating the aortic and mitral valves, the round of changes will be of a similar character, but starting at a different point, some to reach the maximum quickly, as is the case in regurgitation at the aortic valve when due to organic and progressive lesions, or more slowly, as is frequently witnessed in the case of an aortic stenosis.

With these pathological changes clearly in mind, you will readily see that the chief object in treating cardiac lesions must be direted toward the development of a higher nutritive state of the system, and the development of an increased working-power in the muscular walls of the various cavities composing the heart, until the mechanical defect is fully compensated for, and the vascular congestion removed, or reduced to the minimum.

The causes of organic obstruction, giving rise to a mitral direct—stenotic—murmur at the bicuspid orifice, are acute endocarditis with roughening of the valve segments by out-growing vegetations, or congenital malformation; or chronic endocarditis, with or without calcareous depositions, all of which narrow the mitral orifice, and prevent a free egress of blood from the left auricle into the left ventricle.

The common law which governs the seat of development and the transmission of all cardiac murmurs may be stated as this: The abnormal sound, called a murmur, is heard with greatest intensity just beyond the point of its development, and is transmitted from this point forward or backward in the direction of the current of blood, which, together with the valvular defect, is the cause of the murmur. Forward and backward, in this instance, refer to the current of blood and not to the antero-posterior positions of the body.

With a narrowing of the bicuspid or mitral orifice, which is due to an organic lesion, an abnormal sound is produced in the line of the left auriculo-ventricular axis, by the obstruction to the normal current of blood in its passage from the left auricle to the corresponding ventricular cavity, and has often been called a presystolic murmur. This is true so far as the ventricle is involved, but, in reality, it is a systolic murmur of the auricle, and is developed at the height of a rigorous auricular contraction. If, however, for any reason the muscular power of the auricle becomes enfeebled, the murmur may entirely disappear, to be again reëstablished when the contractile power of the muscular tunic of the auricle is regained. This transitory character of the mitral direct murmur has led some to deny its existence, but frequent and well-defined clinical observations of cases with a distinct mitral direct murmur, substantiated by the post-mortem findings, prove, beyond a doubt, that such a murmur is produced and heard; that by it we are enabled to say with certainty that a bicuspid stenosis exists during the life of the individual, and that it will be found when the necropsy is performed.

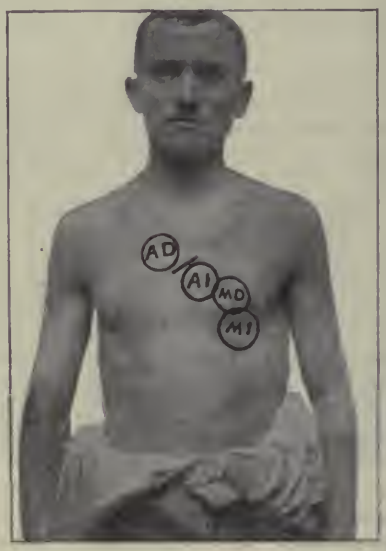
This abnormal sound is also called a mitral obstructive or direct murmur. The latter is the term which I have chosen to employ in the chart before you, and also in the diagrams upon the patient.[1] It is so named be-

[1] Ring lettered M D, Figs. 1 and 2.

cause the blood which produces the murmur is flowing in the normal direction against an abnormally small or roughened auriculo-ventricular inlet. This murmur, which is dependent upon these two conditions, is heard with greatest intensity just in front of, or over, the left ventricle, at the point where the left auriculo-ventricular axis strikes the anterior surface of the chest-wall, or over the junction of the fourth rib and its adjoinining costal cartilage.

It is a high-pitched sound, and is practically not transmitted, being heard over the limited præcordial area, confined within the circle marked M D in Figs. 1 and 2. It is usually of short duration, but may be somewhat prolonged, if the obstruction be very great and the time

FIG. 2.



occupied by the auricle in emptying itself be considerable. Occasionally a case may be examined in which the murmur is prolonged, and more widely transmitted and heard outside this limited zone, but the nature of its production is such that, under ordinary circumstances, it is more apt to be limited, both in regard to its duration and in the area of its transmission.

The etiology of the mitral indirect or regurgitant murmur at the bicuspid orifice, which has been developed from organic lesions, is acute and chronic endocarditis, with their resulting changes; rupture of a segment of the valve; rupture of a chorda tendineæ, and acute and chronic dilatation of the left ventricle, all of which tend to prevent a complete closure of the left auriculo-ventricular orifice during the ventricular systole. To this list congenital malformations might be added, but these abnormalities are more likely to cause a direct than an indirect murmur, or the two together, rather than a simple and single mitral regurgitant murmur.

With an incompetency of the bicuspid orifice due to organic changes, the abnormal sound is produced by the blood being forced back from the left auricle against the normal current. The mitral indirect murmur is distinctly heard at the apex, within the circle marked M I on the chest of our patient and in the chart.[1] It is transmitted to the left, and is usually lost at the anterior axillary line, but is heard with equal intensity posteriorly at the superior border of the eighth dorsal vertebra, or between this point and the inferior angle of the scapula, as indicated in the posterior view of our patient.[1]

According to the ordinary law of the production and transmission of cardiac murmurs, already given you, this murmur should only be heard posteriorly; but occurring as the result of the left ventricular contraction, or where the left ventricle and heart, as a whole, are becoming solid bodies, and impinge more forcibly against the anterior and bony chest-wall, which is also a dense body, they together obey the general physical law of transmission of sound by dense bodies, and bring

FIG. 3.

the sound distinctly to the anterior surface of the chest-wall, within the circle lettered M I in our chart and on the patient's chest.[2]

In my early days as a student of medicine we were taught that a systolic murmur at the apex, or one heard within the circle lettered M I in the chart and on our patient, if transmitted to the left and heard distinctly behind at the ring lettered M I, Fig. 3, always indicated an organic lesion of the valve guarding the mitral orifice. This statement, however, I have found frequently does not hold true at the necropsy examination, and still less frequently so at the bedside or in the clinic.

A functional obstructive murmur at the mitral orifice is often heard in cases where there is considerable aortic insufficiency. The blood regurgitated from the aorta into the left ventricle rapidly fills the lower portion of the cavity, and floats up the inferior, or, at least, one of the bicuspid segments, too quickly against the incoming current of blood from the left auricle, and produces an obstruction, which, at the height of the auricular contraction, gives rise to a short, but quick, sharp, and decided obstructive or mitral direct murmur. This abnormal sound is differentiated from one due to organic narrowing at the valve by its disappearance where the

[1] Ring marked M I, Figs. 1 and 2.

[1] Ring marked M I, Fig. 3.

[2] Ring lettered M I, Figs. 1 and 2.

heart's action is stimulated, its working power increased, and the amount of actual regurgitation diminished, or, in part, compensated for by a prolonged systolic act on the part of the left ventricle, and a diminished diastolic pause.

Murmurs due to organic changes at the bicuspid orifice have been pretty thoroughly understood for a long time, but that condition in which positive and indisputable evidence of mitral insufficiency is obtained upon physical examination during the life of the patient, and later the necropsy revealing a perfectly normal and competent valve, and the absence of any left ventricular dilatation, is not generally understood nor described.

The etiology of this class of murmurs has been in doubt for a long time, and has given rise to an endless amount of discussion *pro et con*—some, in fact, have gone so far as to doubt the diagnostic value of physical signs in connection with cardiac disturbances, on account of this contradictory evidence between the living and dead subject. The difficulty, however, is not so much with the rational and physical evidences, as it is with the interpretation placed upon the signs and symptoms presented by each case. My experience, which has been somewhat large, both at the bedside and clinic, and at the post-mortem table, has been such that I am convinced that we are justified in saying, that when the rational and physical signs presented in connection with cardiac valvular disease are correctly expounded, our diagnosis will be accurately confirmed in the vast majority of instances; when it is not, the fault is with the interpretation placed upon the symptoms presented.

This functional regurgitation at the bicuspid orifice producing a mitral indirect murmur, is the abnormal sound which is of the greatest importance on account of its frequent occurrence, and because it is so often mistaken for a sound due to positive organic changes. This murmur has been explained by an over-powerful contraction of the left ventricular wall, causing an over-closure, and a forcible sliding of the valve-segments upon one another, and thus producing a sound; but while this might hold true in a few instances, it is not sustained, in the majority of cases, by the necropsy findings. To have friction enough to cause so loud a sound would necessitate a roughening of the valve, and this would lead to positive thickening of the leaflets. This, however, is not the case; for at the necropsy the valves are found to be perfectly smooth, thin, and absolutely free from any lesion. The physiological signs also disprove this theory, for a murmur produced by too tight closure would not give rise to any leakage or regurgitation of blood at this orifice, and consequently there would be no distinct murmur heard posteriorly, as is the general rule.

A sound heard at the apex circle, with and after the first sound of the heart, not transmitted nor heard behind, might justly be attributed to such a condition, and frequently we do meet with just such cases, in which there is a distinct intra-ventricular systolic hum or murmur, caused by over-vibratory tension of the bicuspid segments, and their attached chordæ tendinæ, dependent upon excessive muscular activity. But with this abnormal sound there is no leakage at the left auriculo-ventricular orifice, thus ruling it out of the regurgitant class of lesions and murmurs. Those cases in which a positive murmur is heard in front, over the mitral indirect area, and in which the murmur is transmitted to the left, and is heard posteriorly with equal intensity, near the junction of the seventh and eighth dorsal vertebræ, or midway between these bones and the inferior angle of the left scapula, and where the necropsy reveals no organic lesions in the segments of the bicuspid valve or its attachments, and where there is no dilatation of the left ventricular cavity, but in which the gross appearance of the valve and of the heart itself is normal, are conditions of special interest to us from a clinical and practical standpoint.

If we stop for a moment and consider the anatomico-physiological mechanism of the heart, the explanation is easy. As is well known, the ventricular wall is composed of seven distinct layers of muscle fibres, or for convenience and simplicity they may be considered as four. We have, connected with these layers, two sets of papillary muscles, one springing from the anterior and the other from the posterior wall of the ventricle, to which the bicuspid segments are guyed by their chordæ tendinæ. Where everything works in unison, the two segments of the valve float toward the auricular cavity, and their margins are brought into juxtaposition at a given point, and held there by the equal and synchronous contraction of the two sets of papillary muscles and the tension of the attached chordæ tendinæ. In this way the auriculo-ventricular orifice is perfectly closed and regurgitation absolutely prevented.

If, for any reason, the innervation of the heart is unequally distributed to the different papillary muscles, or the muscular layers become unequally nourished, their unity of contraction is disturbed, and instead of this perfection of action just described, one set or layer of muscles contracts more forcibly or more quickly than the other, and the papillary muscles shorten irregularly and unevenly.

When the ventricle contracts, this result is developed: one segment or the other, failing to stop at just the exact point to meet its opposite, is forced on into the auricular cavity, while its opposing fellow-segment is drawn more completely into the ventricular cavity; consequently, instead of complete closure of the orifice, an actual gap or insufficiency is produced, just as perfectly as if a piece of the valve was wanting. Through this opening a positive escape of blood from the ventricular to the auricular cavity takes place, which gives rise to all the physical signs of an organic insufficiency with regurgitation. The temporary results are the same as if there existed positive and irreparable defects. The rational signs are also the same in both instances. If permitted to continue, the results may be the same as those developed from positively organic lesions.

Organic and functional insufficiency at the bicuspid orifice can easily be differentiated during life, not by their rational and physical signs, however, but by an appropriate plan of treatment. If the cause of the latter be a deficient innervation, by giving such remedies as will restore the nerve-power distributed to the heart, the signs and symptoms will be found quickly to disappear, all regurgitation will be prevented, and the patient will be relieved from all unpleasant symptoms. When due to defective nutrition, with a lack of, or an uneven innervation and irregular muscular action, true cardial stimu-

lation and an increased nutritive vitality will cause a like satisfactory result. If, on the other hand, the physical signs are due to positive defects in the valve, the same line of treatment will often decidedly improve the condition of the patient, but it will not cause a disappearance of the physical evidences. It may shorten the duration of the murmurs, but the abnormal sounds will be more easily and accurately recognized. In this way we can easily differentiate between the two conditions, and draw the correct deductions from the signs and evidences presented. A positive diagnosis should never be made until the results of treatment, continued for a few days, have been noted and the case examined a second or third time.

The administration of digitalis in the functional class will permit a disappearance of the murmur, as you will clearly see when we come to study, at a subsequent clinic, the so-called cardiac tonics and stimulants as a class. The continued use of digitalis may convert a functional case into one where we may have an irreparable condition.

HOSPITAL NOTES.

WOMAN'S HOSPITAL OF PHILADELPHIA.

SERVICE OF JOHN B. ROBERTS, M.D.,
PROFESSOR OF SURGERY.

Reported by MARY E. ALLEN, M.D.,
DEMONSTRATOR OF SURGERY.

Tuberculosis of the Right Kidney; Nephrectomy Attempted, but Abandoned; Death.—This patient, forty years of age, was admitted to the hospital April 23, 1890, suffering with a tumor upon the right side in the hypochondriac region.

The patient's mother died of consumption. The patient had pleurisy on the left side when nineteen years of age, from which she seems to have recovered perfectly, and then married at twenty. Two years ago the patient had pneumonia, and has never been well since, her chief suffering seeming to be dyspepsia, which obliged her to live upon liquids most of the time.

During the summer previous to her admission to the hospital she experienced, while at work, a sudden and severe pain over the region of the liver which passed down into the right leg. After this she was confined to her bed for fourteen weeks. During this time the urine was very scant and cloudy, and she experienced a burning sensation after urination. She also suffered from alternate constipation and diarrhœa, the stools, however, being only occasionally light colored. Her weight was ninety-five pounds. She had lost forty-seven pounds during the last two years, and consequently showed marked emaciation.

The tumor was about the size of a fœtal head at term, and extended backward, and became more prominent when pressure was made over the region of the kidney of that side. It was, therefore, pretty certainly determined that it was connected with the kidney in some manner. It might, however, be a distended gall-bladder full of stones, and merely raised when pressure was made over the kidney from behind. Dr. Roberts stated that should the kidney itself be involved, it might be either as an abscess of the kidney, a stone in the kidney, as cancer, or as tubercular disease.

The incision made in the semilunar line of the right side and over the most prominent part of the tumor was at first about three inches in length, but was subsequently enlarged to six inches.

This point for the incision was chosen by Dr. Roberts after consultation with Dr. W. W. Keen, who by request was present at the operation. If there was pus, of course a posterior incision was the most desirable, on account of better drainage, and the extra-peritoneal position. The uncertainties were, however, so great that the anterior opening was determined upon. As soon as the peritoneum was opened, the omentum protruded, but could not be slipped up, because it was adherent to the anterior surface of the tumor. It was, therefore, cautiously cut and torn until the tumor proper was visible. This appeared to be a thin-walled sac, full of whitish liquid, perhaps pus.

An endeavor was now made to evacuate the contents with a sharp trocar and canula of large size without success, as the liquid was too thick to run. Sponges were then packed around the tumor to isolate the peritoneal cavity, and a free incision was made, through which the thick, curdy contents were evacuated. There was more than one cavity, however, and the walls between them were too thick to allow of opening them all into one, and thus to empty the tumor entirely. Neither was it possible to break up the posterior adhesion and extirpate the kidney, though this was thoroughly tried. A clamp was, therefore, placed within the opening already made, and the peritoneal covering of the tumor stitched to the peritoneal edge of the abdominal wound. After thoroughly cleansing the abdominal cavity with filtered boiled water, at a temperature of 110°, the peritoneal edge of the wound was also stitched to the skin, so as to close all raw surfaces as far as possible, and to wait for inflammatory adhesion to take place.

It was the intention of Dr. Roberts to then incise the tumor freely and thoroughly evacuate it. Two drainage-tubes were placed within the abdominal cavity at the angles of the wound, one passing backward and the other downward, to remove any oozing that might result from the attempts at radical removal. Great difficulty was also experienced in stitching the tumor to the peritoneum, as its external walls were so thin that even the slight hold taken by the needle ruptured them in one place, and the cheesy contents began again to pour out from a new cavity. It was, however, caught on sponges, a second clamp adjusted, and the operation continued.

During the operation the patient was very feeble, necessitating the administration of hypodermic injections of whiskey, digitalis, ether, and aromatic spirits of ammonia, to prevent her from dying; she was, therefore, in a very precarious condition when put to bed, and lived only twenty-four hours after the operation.

The post-mortem examination was performed through the incision made at the time of the operation, and although she lived such a short time, union between the peritoneal surfaces had already taken place. There was no evidence of hæmorrhage into the abdominal cavity. The tumor was removed with great difficulty post-mortem, being strongly adherent to the liver, diaphragm, intestines, and spinal column, and it proved to be the right kidney, greatly distended in pockets by the

tuberculous, cheesy deposits, in some of which calculus, sand, and concretions were found.

The patient's death was due to the shock of the operation.

MEDICAL PROGRESS.

Treatment of Ophthalmia Neonatorum.—LA PERSONNE, in the *Journal de Mèdecine de Paris*, gives the following treatment for the prevention and cure of this condition. The vagina is to be washed out by an antiseptic solution before labor in order to free the birth canal from any products which may produce irritation of the eyes of the child. Immediately after birth, at the time at which the bath is given, a solution of carbolic acid in the strength of 1 : 100, or the following prescription of corrosive sublimate should be employed:

℞.—Corrosive sublimate . . . 1 grain.
Tartaric acid . . . . 2 grains.
Distilled water . . . . 8 ounces.

A few drops of this solution should be dropped into the eye.

In other cases the following may be employed:

℞.—Nitrate of silver . . . 1 grain.
Distilled water . . . . 3 drachms.

Prescriptions for Sore-throat.—According to the *Journal de Médecine de Paris*, CAPART recommends the following prescriptions in this condition. For a simple catarrhal sore-throat he advises a gargle, such as the following, to be used every hour:

℞.—Borax . . . . . 15 grains.
Salicylate of soda . . . 30 "
Decoction of althea . . . 7 ounces.
Honey of roses . . . 1 ounce.

If after using this for twelve or twenty-four hours the affection continues an astringent gargle is of value, made up as follows:

℞.—Alum . . . . . 1 drachm.
Alcohol, Powdered glycerin } of each . 3 drachms.
Distilled water . . . . 10 ounces.

In cases in which there is sore throat with herpetic spots upon the pharynx it is ordered that the patient shall go to bed and shall keep pieces of ice in the mouth, while poultices are applied externally and lemonade, strongly acid, should be administered. In these cases the following prescription should also be used:

℞.—Chlorate of potash . . . 45 grains.
Distilled water . . . . 1 ounce.
Simple syrup . . . . 2 drachms.

A teaspoonful to a tablespoonful may be given every hour, and if the patient is an adult the quantity of the chlorate of potassium may be increased. Where there is much swelling of the throat with tonsillitis of the phlegmonous form accompanied by great pain, five or six leeches should be applied back of the angle of the jaw and ice kept in the mouth. The following powders should also be administered internally.

℞.—Salol, Sugar of milk } of each . . 30 grains.

Divide into three powders and take one every hour.

Or a gargle may be employed as follows:

℞.—Salicylic acid . . . . 15 grains.
Acetate of sodium . . . 7 "
Distilled water . . . . 10 ounces.
Syrup of roses . . . . 1 ounce.

In cases in which there is a tendency to a return of the sore-throat, a gargle composed as follows is useful as a prophylactic:

℞.—Crystallized carbolic acid . . 1 drachm.
Alcohol . . . . . 5 drachms.
Essence of peppermint . . 15 drops.

Ten drops of this mixture should be placed in a half glass of water morning and night and used as a gargle.

Or the following may be employed:

℞.—Salol . . . . . 1 drachm.
Alcohol . . . . . 5 drachms.
Essence of peppermint . . 5 drops.

A teaspoonful in a tumblerful of water three or four times a day as a gargle.

The Use of Atropine in the Treatment of Localized Muscular Spasm.—Dr. W. M. Leszynsky read a paper with this title before the New York Neurological Society, February 10, 1891. The speaker reported, in March, 1884, a case of clonic torticollis successfully treated by the subcutaneous administration of the sulphate of atropine. The first case of the present series was that of a man, thirty-seven years of age, who had, three years previously, muscular spasm beginning on the right side of the neck, which developed six weeks after an abscess had been opened at the angle of the jaw on the right side. The force of the spasm was increased by mastication and closure of the jaw, and it was more active upon mental excitement. He was frequently aroused from sleep by the severity of the paroxysm. There was no complaint of pain, but only of numbness in the right lower lip. He was treated by means of medicine and electricity for four months without relief. There were well-pronounced clonico-tonic spasms affecting the right platysma, and forcibly drawing downward the fascia about the chin and the lower angle of the mouth. The clonic character of the spasm predominated, and was almost constant. The muscle was hypertrophied to nearly four times its normal size, and its outline was distinct and well-defined. There was an area of complete anæsthesia one and one-half by three centimetres at the border of the lower lip near the angle of the mouth on the right side, which extended inward upon the mucous membrane and the alveolar process of the lower jaw. The mechanical irritability of the facial muscles was well marked, and the jaw-jerk was demonstrable. There was no apparent caries of the teeth or abnormality in other portions of the body. The treatment was commenced by the application of a cantharides plaster over the affected muscle. After one week had elapsed, an injection of $\frac{1}{120}$ of a grain of sulphate of atropine was made into the platysma. On each of

the following three days an injection of $\frac{1}{100}$ grain was given, when the exaggerated mechanical irritability of the facial muscles had markedly diminished, and there was an abatement in the frequency of the spasm. Sensation was also returning in the anæsthetic area. The dose of atropine was gradually increased until $\frac{1}{48}$ of a grain was given daily. At the end of two weeks the most energetic effort by pressure or otherwise failed to produce any spasmodic action in the platysma. The administration of the atropine was then discontinued. One month later the patient reported that there had been no return of the spasm. The solution used was sulphate of atropine 1 grain to distilled water 1 ounce. One minim of this solution represented $\frac{1}{480}$ of a grain of atropine. The speaker's method was to give 4 minims at the first injection and to be on the alert for constitutional effects. Upon discovering that there was no idiosyncrasy in regard to the drug, it was administered once daily, and the quantity gradually increased from day to day until the desired effect was produced or intolerance was established. The production of severe constitutional symptoms is not an essential feature in this plan of treatment. One of the physiological effects of the drug, when given in sufficient quantity, is to paralyze the motor nerves, first affecting their trunks.

Dr. V. P. GIBNEY, on being asked for his views on the subject of the paper, said that he did not know whether the author had included in his earlier reports cases of hysterical torticollis, rotary spasm, and similar affections. He doubted whether it was the intention to include that class of cases known as spastic paraplegias. The cases which came under his personal observation were only those of functional disturbance or deformity.

Mouth-wash for Fœtid Breath.—

℞.—Water . . . . . 2 pints.
Alcohol . . . . . ½ drachm.
Borax . . . . . 15 grains.
Thymic acid . . . . 7 "

Or,

℞.—Decoction of chamomile . 10 ounces.
Glycerin . . . . 2½ "
Chlorine water . . . 6 drachms.

Or,

℞.—Peppermint water . . . 1 pint.
Aqua lauro-cerasi . . . 2 ounces.
Borax . . . . . 6 drachms.
Essence of peppermint, a sufficient quantity.

All of these mixtures may be used as gargles where the decomposition of particles of food in the crypts of the tonsils or the buccal cavities produces fœtid breath.

Treatment of Chronic Alcoholism.—ERGOLSKI reports ten cases of chronic alcoholism successfully treated by means of hypodermic injections of the nitrate of strychnine in the dose of $\frac{1}{20}$ of a grain. The amelioration in the patient's condition after these injections was constant. The dyspeptic symptoms disappeared and the patient did not desire alcohol. So complete was the action of the remedy that Ergolski regards it as almost a specific. A great advantage to be gained by the subcutaneous administration of the drug is that no irritation of the gastro-intestinal canal is produced at a time when it is apt to be affected by catarrh.—*Journal de Médecine de Paris.*

Treatment of Goitre.—According to the *Journal de Médecine de Paris*, AUERBACH has obtained an incomplete cure of goitre by the interstitial injection of osmic acid combined with massage.

℞.—Osmic acid . . . . 1 grain.
Distilled water . . . 3 drachms.

The injection of this liquid is resorted to every two days, and massage is practised daily for fifteen minutes. Iodide of potassium was also given internally. After three weeks of this treatment the tumor diminishes very greatly in size and the subjective symptoms disappear.

Vomiting of Pregnancy.—POMBRAK has employed with success menthol with sugar of milk for the treatment of the vomiting of pregnancy. He has also used tincture of iodine for the same purpose. The case in which he employed menthol with advantage was that of a highly nervous young woman suffering with chlorosis.—*Journal de Médecine de Paris.*

Syphilitic Ulcers.—In *La Semaine Médicale*, the following prescriptions are given for the treatment of syphilitic ulcers.

℞.—Salicylate of mercury, Carbonate of potassium } of each 15 grains.
Distilled water . . . . 6 ounces.

Apply to the part by means of compresses, or if an ointment is preferred, the following may be used:

℞.—Salicylate of mercury . . 15 grains.
Vaseline . . . . . 1 ounce.

Mix and use externally.

Sulphate of Copper.—BOLTON recommends sulphate of copper in the dose of a twenty-fifth of a grain for the relief of the muscular cramps which sometimes affect pregnant women.—*La Semaine Médicale.*

Powder for Atrophic Rhinitis.—HALL is stated to recommend the following in the treatment of atrophic rhinitis:

℞.—Bicarbonate of sodium, Borate of sodium } of each 5 grains.
White sugar . . . . 12 grains.

This is to be dissolved in two ounces of hot water and snuffed up the nostril thoroughly. After this has been employed to loosen any secretion which may remain, intra-nasal instillations of weak solutions of alum, in the strength of 1 per cent., or in other cases sulphate of zinc, nitrate of silver, or powdered iodoform, or aristol, or salol, or boracic acid, are useful. After these applications have been made, it is well to apply to the mucous membrane of the nasal cavity a spray of eucalyptus as follows:

℞.—Vaseline . . . . . 1 ounce.
Essence of eucalyptus . . 1 drachm.

In other cases it is only necessary to spray the nostrils with liquid vaseline.

CURRENT LITERATURE.

SATURDAY, MAY 23, 1891.

EPIDEMIC RELATIONS OF DIPHTHERIA IN NORWAY.

Axel Johannessen, of Christiania, reviews the various epidemics of diphtheria which have occurred in Norway, and makes some remarks upon diphtheria and croup. He concludes that the largest part of the cases of croup which occur both before and after the great epidemics of diphtheria are of diphtheritic nature.

An interesting point is developed regarding the mode of invasion of the disease and the parts of the country affected. These, in different epidemics, have been to a certain extent the same. Density of population and such means of conveyance as railways and streets do not appear to play any part in the spread of the disease. The coast districts have one-third more cases of diphtheria than the inland districts, and the fishing districts of the coast are the most affected. At Dorschfang from 25,000 to 30,000 men collect in 5000 huts, being huddled together under bad hygienic conditions. At Tromsö-Stift diphtheria generally shows the highest number of cases of the disease—as many as 105 per thousand of population. Moreover, statistics also show that those districts whence the fishermen are sent out and return again are invaded by the disease in proportion to the number of fishermen, a condition which is true of other epidemic diseases, especially typhoid fever.

In Norway and Sweden the morbidity in the cities is, on the whole, greater than that of the country; but usually epidemics in cities develop more slowly, and rarely reach an excessive height; whereas, it is much more frequent for an epidemic in the country to rise rapidly to a high ratio between disease and population. The mortality is absolutely greater in the cities; on the other hand, the percentage of dead of those medically treated in the country districts is considerably higher. This circumstance seems to be due to the fact that throat diphtheria is, in the country, more fatal than in the cities, where, on the other hand, a decidedly greater number of victims is furnished by diphtheria of the larynx.

The great variations in the disease curves are not primarily dependent upon meteorological influences. —*Deutsche med. Wochenschrift*, March 19, 1891.

DIAGNOSTIC VALUE OF THE PLASMODIUM OF MALARIA.

O. Hertel and C. von Noorden report, from Gerhardt's clinic, two cases which illustrate nicely the diagnostic value of the plasmodium of malaria. The first case was that of a woman, twenty-four years of age, with no hereditary tubercular or other taint. For the past few years she had drank beer to excess. To this excessive use of alcohol she attributed the pains in the stomach and vomiting from which she had suffered since May, 1890. On July 3, 1890, she was again taken sick with violent pains in the stomach, loss of appetite, and fever. On July 5th, at 12 M., she had a chill, followed by pains in both sides on taking a breath. On July 6th, 7th, and 8th, chills at the same time of day (12 M.). At 2 P. M., temperature 104.1°. Organs of throat and chest healthy. Some tenderness in epigastrium. Other organs of abdomen apparently healthy. Pains in stomach continued. Chills (followed by fever and sweat on the 10th) occurred July 9th, 10th, and 11th, from 11.30 A.M. to 2 P.M. No plasmodium could be found. On the 11th the spleen extended to the edge of the ribs. No chill occurred on July 12th, but one occurred July 13th. Quinine was then given; the chills did not cease, but returned at a later hour. The case was not clear. Continued absence of the plasmodium indicated that the disease was not malarial, and yet otherwise the disease appeared to be of that nature. On July 16th, the attacks of fever ceased quite suddenly, almost as though the quinine had had a delayed action upon them. In the next few days the spleen became swollen.

On July 24th the rise in temperature recurred, but in a moderate degree, without chill, and irregularly distributed over the day. Two days later a pleural effusion was discovered behind on the right side, and at the same time there were heard at the right apex fine crackling râles, which disappeared completely after a deep few breaths. There was, and had been, no sputum. After the lapse of eight days the percussion note over the right apex was higher, shorter, and softer, and the breathing not purely vesicular. The patient was then dismissed. In October following she was found to have marked infiltration of the right apex of the lung and pronounced tubercular ulceration of the larynx. Thus the case became clear.

In the second case, a man, twenty-eight years of age, was admitted June 28, 1890. He was, up to the time of his sickness, at work digging a trench, throwing up earth, and putting down water-pipe. About eight days before his admission he was taken sick with pains in the neighborhood of the navel and sacrum, and was in a condition of great stupor. On June 25th he was seized with a chill, which is said to have been repeated almost daily up to June 28th. He was generally unwell and was able to work only two hours a day. The chill, which occurred nearly every day early in the morning, was accompanied by a feeling of heat, headache, and stupor, disturbances which subsided gradually in the course of the afternoon after a pretty profuse sweat. The attacks are said, however, not to have been equally violent every day, but to have been more severe every second day. The liver was somewhat enlarged downward; the spleen was scarcely enlarged in breadth. Over the lung, in the neighborhood of the right nipple, there was a narrow zone having a tympanitic percussion note, and over this area were heard fine moist râles. There was no expectoration.

Up to this point the examination showed a febrile disease, the cause of which was obscure. On July 30th there was a violent chill. Plasmodia were found in the blood. Chills recurred until July 5th, when quinine was given. Plasmodia were found at the height of the disease. The patient was dismissed cured July 14th. The cause of the disease became clear as soon as the blood was examined.

Regarding the detection of the plasmodium, the authors say that fresh, unstained preparations, viewed through a good microscope with an immersion lens at the bedside of the patient, give the most beautiful pictures. If the blood cannot be examined in this way, cover-glass preparations can be made, heated over the flame or fixed with absolute alcohol, and stained with concentrated methyl-blue or malachite-green. When prepared in this way the plasmodia, frequently carrying pigment in the middle of their bodies, are stained pale blue or greenish and stand out sharply. They cannot be confounded with anything else, whether they are included in a red blood-corpuscle or free in the serum.—*Berliner klin. Wochenschrift*, March 23, 1891.

ETIOLOGY AND DIAGNOSIS OF PURPURA HÆMORRHAGICA.

LETZERICH believes the cause of purpura hæmorrhagica to be a special bacillus, which in its conditions of growth presents some similarity to the anthrax bacillus. Both form, in Koch's stick-cultures, more or less irregular colonies, the centre of which consists of reticular threads which, at the edge, pass over into sheaf-shaped little bundles, partly bent back. They differ essentially, however, in their size and in the form of the spores. Although in both a constriction of the rodlets is observed in bacilli of different lengths, those of purpura are shorter and narrower, and the spores are very small and absolutely round, not large and oval, as in anthrax bacilli. Moreover, the bacillus of purpura fluidifies gelatin only with great difficulty, at a high temperature (77° to 88° F.), and in the immediate neighborhood of the colonies.

In the petechiæ of men and of animals subjected to experiment, are found groups of microörganisms arranged in manifold sheaf-shapes, and part of them segmented; in these, often at uniform distances, are spores, frequently lying thickly under one another.

The surfaces of the points of inoculation in Koch's nutrient gelatin present smooth, crescent-shaped depressions, which are recognizable only upon attentive observation.

The bacillus of purpura forms no toxin, but only a weak ptomaine; this explains why there is only occasional slight evening fever.

Sections through petechiæ are best stained with simple methyl-violet solution, while for teazed and isolated preparations and for diluted blood carbol-fuchsin is preferable.

Letzerich describes an acute, or subacute, and a chronic form of purpura hæmorrhagica. They are occasioned by the different power of resistance of the infected individual. Recovery may occur in six, eight, or twelve weeks; or relapses at no precise intervals may occur and may drag on for years. The chronic relapsing form, however, seems to be rare. Four of Letzerich's cases belong to the acute, and two to the chronic, form.

Letzerich had his third attack of purpura in November, 1889. About three weeks before he had a feeling of weariness and heaviness in the limbs, with poor appetite and slight evening fever. There were at this time also hæmorrhages from the nose, throat, and gums. Diarrhœa then set in. The liver became much swollen and so did the spleen, while the skin assumed a pale-yellow color. It is noteworthy that with the occurrence of fresh petechiæ there was an itching sensation in those places where the petechiæ were about to form.

In the case of a boy, thirteen years old, the same symptoms occurred. The whole body, limbs, and trunk became strewed with petecheæ of various sizes. Upon the floor of the mouth, velum palati, and mucous membrane of the cheeks and throat were pretty large vibices. The liver dulness was more than double its normal dimensions. The spleen extended beyond the edge of the ribs and felt hard. There were slight evening fever and slight hæmorrhages from the bowel after the diarrhœa had lasted some days. The acute swelling of the spleen and liver subsided quickly.

In Letzerich's third attack, at the beginning, rodlets and bacilli of different lengths, some with spores, were found between numerous scattered blood-cells and some young epithelium and cells from the rete Malpighii. Free spores and single bacilli were to be found in large quantities in the field of the microscope. Three weeks later the fresh petechiæ were paler in color, smaller, and generally round in shape. The rodlets were much fewer, so also were the constricted bacili. Free spores could only be seen in scattered positions. After a further period of ten to fourteen days only a few rodlets were to be found, and they did not take the stain as well. Spores could be found only here and there. After a further interval of fourteen days rodlets had entirely disappeared, and only single groups of dull bacilli and individual spores were found. Letzerich thinks that the bacilli take the stain in its full intensity only when they are living, and hence this fact may be used to determine the vitality of the organisms.

As regards treatment, he speaks highly of a 4- or 5-per-cent. solution of antipyrine for local use to check hæmorrhage. The chief factor in recovery is the maintenance of absolute rest for a long time. Too early rising predisposes to relapses. The patient must be well nourished with eggs, broths, milk, and wine. Iron and quinine are valuable drugs. Letzerich expresses great confidence in the utility of benzoate of soda in all infectious diseases.—*Zeitschrift für klinische Medicin*, Bd. lxxx. Hefte 5, 6.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Forty-second Annual Meeting, held at Washington, D. C., May 5, 6, 7, 8, 1891.

[Continued from p. 567.]

Fourth Day—General Session.

Section of Surgery and Anatomy.

The first paper was read by Edmund Andrews, M.D., LL.D., Professor of Clinical Surgery in Chicago Medical College, on "Cadaver Studies on the Removal of the Semilunar Ganglion Through the Floor of the Cranium."

Dr. Andrews began by pointing out the severity and obstinacy of many of the cases of facial neuralgia, as well as the frequency of relapses following stretching and excision of the nerve. He has several times relieved this painful affection temporarily by simply loosening the old stump or cicatrix in a case which had previously had a neurectomy performed.

The author believes the origin of the neuralgia is a peripheral irritation, perhaps of a dental nerve; this causes a neuritis which travels upward until the semilunar ganglion is reached. Therefore, stretching or excision, without interfering with this ganglion, is usually not followed by permanent benefit. Following up this idea, about one year ago Dr. Andrews began an investigation upon the cadaver, looking toward a practical means of removing the semilunar ganglion in the human being for the relief of neuralgia of the trifacial nerve. While pursuing these studies he saw an account of this operation as having been performed by Dr. Rose, of London, in November of last year. This seems to be the first time this operation has been done. In this case all the pain seemed to be in the superior maxillary bone of one side, and, yielding to the request of the patient, this was removed, which gave ready access to the foramen ovale. A trephine was applied at this point, and the ganglion removed without difficulty. At the end of three or four months there had been no return of pain, but the eye on this side became inflamed, and was removed to avoid sympathetic inflammation of the other. It was thought that this was due to injury at the time of the operation.

In January of the present year Professor Rose did a second operation. This time an H-shaped incision was made over the zygomatic arch. The zygoma was sawed through at either end, and turned down with the lower flap. The coronoid process of the inferior maxillary bone was likewise sawed through and turned up with the upper flap. In this way the foramen ovale was again exposed, and the operation continued as before. After the operation is concluded, the coronoid process and the zygoma are wired in their places.

Professor Andrews has worked out four other methods for performing this operation, of which he considers the following the best: The H-shaped incision is made, and flaps, including the zygoma and coronoid process, as in Professor Rose's second operation. Some fibres of the masseter muscle are then snipped, and the origin of the internal pterygoid muscle is dissected off. The inferior dental and gustatory branches of the inferior maxillary nerve are thus reached, which guide the operator to the foramen ovale. The trephine is then applied to the edge of the foramen, and the ganglion which is on the anterior portion of the petrous portion of the temporal bone is reached. The dura mater and nerve are now peeled from the skull. Dissect to inner side with scalpel or scissors. The superior maxillary branch is now cut off, and the ganglion dissected from the dura lying between it and the convolutions. This is rather difficult, as it is very adherent to the dura. The dissection may be facilitated by making traction on the inferior dental and gustatory nerves. The wound is closed as advised by Professor Rose.

Dr. Lawrence Turnbull, of Philadelphia, then read a paper "On the Deaths from Chloroform and Ether since the Hyderabad Commission, with Conclusions Drawn from Them."

The whole number of deaths which he was able to collect was forty-three. Of these, thirty-nine were from chloroform, and four from ether. An analysis of the deaths due to chloroform showed that death occurred from syncope in five cases; in thirteen the heart stopped first; in ten the respiration failed first; in four the heart and respiration seemed to cease simultaneously; and in twelve cases the mode of death is not stated. The cases above alluded to, added to the three hundred and seventy-five cases collected by Wood, in a paper read at the Medical Congress held in Berlin last year, make four hundred and fourteen reported cases of death from chloroform to the present time.

Considering the fact that either anæsthetic does not always prove fatal in a uniform manner, Dr. Turnbull concludes that in the use of either chloroform or ether, the most careful attention to the pulse and respiration is necessary.

In the discussion Dr. Hunter Maguire said he did not consider chloroform more dangerous than ether, but thought that each anæsthetic had its uses, and one or the other should be selected according to the case. He believes chloroform the safer in organic heart disease, or if there is renal or bronchial trouble, and he does not hesitate to give it in these cases. On the other hand, he would give ether in cases of fatty heart. In over 14,000 administrations of chloroform he has known of but one death, and that was due to fright from rapid anæsthesia, owing to being in too great haste. He insists upon the necessity of administering chloroform slowly.

Dr. Hearn, of Philadelphia, believes that the secret in giving chloroform is to give it slowly.

Dr. W. W. Keen, of Philadelphia, read a very interesting paper on "Linear Craniotomy (miscalled Craniectomy) for Microcephalus."

He began by defining the operation, which is really a long incision in the skull, and objects to the term "craniectomy," as the termination *-ectomy* implies removal of the part.

In addition to his own cases, Dr. Keen has been able to collect eight cases in all, including two cases in which trephining was done for the same condition.

In Dr. Keen's operation an incision is begun in the scalp at the frontal eminence, and carried backward parallel with the sagittal suture, across the lambdoidal suture. By means of a trephine and specially adapted cutting forceps, a narrow strip of the skull is removed, corresponding with this incision.

Wyeth did two such linear craniotomies, one on either side of the sagittal suture, removing a strip of skull one-fourth of an inch in width, then by inserting the tips of the fingers against the outer edge of the wound thus made the skull is forcibly separated until the width of the incision in the skull measures one to one and a half inches.

Dr. Keen thinks that double craniotomy increases the risk in the operation considerably, and does not better attain the object of the operation.

Of the eight cases reported two died, one, one and one-half hours after the operation, of heart failure; the other, three and one-half hours after operation, of acute anæmia. In four of the cases the improvement in the mental as well as general condition, after operation, was very marked. One case was reported too soon to judge of the result. So far as the reports go, the result appears to be as good after trephining as after craniotomy, but the author thinks the latter the more logical operation.

DR. B. MERRILL RICKETTS, of Cincinnati, Ohio, followed with a paper on "Exploratory Incisions in Cases of Fracture of Bones, where Doubt Exists as to their Character, with Report of Observations on the Lower Animals."

After detailing some experiments on the lower animals, he advocated the replacing of all fragments of bone in cases of compound fracture, and believes that if the periosteum be made to overlie them, union will take place. He favors cutting down on fractures when doubt exists, and then wiring the fragments.

A paper on "Sprains of the Ankle" was then read by DR. W. R. TOWNSEND, of New York.

Attention was called to the unfortunate results so frequently following badly treated sprains of the ankle-joint; the most common of these being flat-foot. The author advises the Catterell dressing, which is applied as follows: The limb is elevated to reduce swelling; straps of adhesive plaster are then applied over the affected part, just as is advised in chronic ulcer of the leg, and a pressure bandage is then applied. The patient is allowed to use the foot as before. In cases of more severe sprain a plaster-of-Paris bandage is applied over this for a few days, being careful to remove the plaster-of-Paris dressing soon, to allow of motion. Massage is useful after the acute stage has passed.

DR. JOHN A. WYETH, of New York, then read a paper on "Supra-pubic Cystotomy."

He reported twenty-three operations performed by himself, all of which recovered. He considered the preparation for and the details of the operation. The abdominal wound is treated by the open method. If the bladder is perfectly healthy and has suffered no violence, the wound may be closed; otherwise, this is also allowed to close by granulations. Dr. Wyeth is deeply impressed with the safety and advantage of this operation, and believes it should succeed all other methods of cutting into the bladder.

In the discussion, Dr. McGuire said he had performed this operation twenty-nine times, and preferred it to any other method, where it was necessary to do cystotomy for any cause.

Dr. W. W. Keen, of Philadelphia, and Dr. W. E. B. Davis, of Birmingham, Alabama, also spoke very highly of this operation.

The last paper read was by DR. ROBERT NEWMAN, of New York, on "Platinum Needles for Electrolysis."

The theory of electrolysis was first considered, and then the essentials of a good needle. Platinum was found by all odds to be the best substance of which to make these needles, the only objection to it being its great ductility, which causes the needle to bend from the force necessary to introduce it into the tissues. Dr. Newman, therefore, devised a spear-pointed grooved needle, which was first thrust into the tissues, the platinum needle being inserted along the groove. The first needle was then withdrawn. This plan seemed to him to leave nothing to be desired.

Owing to a misunderstanding a session had been arranged for Friday afternoon, May 8th, but as the delegates were anxious to return to their homes, the papers on the list for that day were read by title, and referred to the Committee on Publication.

The following officers were elected for the next year:

Chairman.—J. McF. Gaston, M.D., Atlanta, Ga.

Vice-Chairman.—Mordecai Price, M.D., Philadelphia.

Secretary.—F. W. Mann, M.D., Detroit, Mich.

The section then adjourned.

FIFTH FRENCH CONGRESS OF SURGERY.[1]

(Continued from page 505.)

THE second question which had been placed before the members of the Congress for discussion was: "What are the After-results of the Extirpation of the Uterine Appendages in the Non-neoplasmic Affections of these Organs?"

SIR SPENCER WELLS, of London, opened the subject by saying that he continued to be very favorable to the operation, which had proven to be of great service to many suffering women, still he thought that oöphorectomy was too easily resorted to; and he thinks that if indications are very frequent for neoplasms, they are and ought to be rare for non-neoplasmic affections of the ovaries. Certain kinds of salpingitis can be cured without an operation, and certain women operated upon for metrorrhagia very often, if they do not die as a result of the operation, keep on suffering and even have menorrhagia.

MR. LAWSON TAIT next spoke, saying that extirpation of the uterine appendages gives excellent operative results, his death-rate being only 3 per cent. To be able to study the after-effects of extirpation of the uterine appendages, Mr. Lawson Tait divides his patients into three classes: The first one contains ovarian castrations for uterine diseases, especially for fibro-myoma; in the second are placed castrations for inflammatory lesions of the appendages; finally, a third class, in which enter extirpation of the appendages for nervous symptoms having a relation to uterine or menstrual troubles.

He has performed 271 ovarian castrations for fibro-myoma, and finds that these give him the best results. Out of 265 operations, 8 have not given satisfactory results, and the patients had to be subjected to a hysterectomy; while in 257 cases there was a complete cure, the tumor having either diminished or the pains having completely disappeared.

[1] Held in Paris from March 31 to April 4, 1891.

The influence of age in regard to results is important; before the age of forty 70 per cent. of the tumors disappear completely; between forty and fifty the tumors disappear less easily, but diminish from one-third to one-sixth their previous size. He does not think that the menopause cures those tumors or diminishes the bad symptoms produced.

He thinks that it is a wrong statement to say that 10 per cent. of the castrations for uterine fibroid tumors bring on insanity. Out of all his operations, Mr. Tait has only observed one case of insanity, while, on the contrary, he has seen three well-marked cases of insanity cured by castration performed for fibromata.

In his second class, which comprises all the cases of salpingitis Mr. Tait is less affirmative; he thinks the operation in those cases is a difficult one, yet he does not admit that one should stop in the middle of such an operation; he always goes on, and destroys adhesions, no matter how firm; intestinal and uterine fistulæ have been the consequence, but he has always succeeded in curing them. As to the after-results, they are simple if the operation has not been a difficult one. The menstruation may not altogether cease, but almost all the other symptoms disappear.

In regard to his third class, that of castration for nervous symptoms, Mr. Tait thinks he has not operated early enough, as he has always waited until pushed to the extreme point by the patient, her physician, and family.

He thinks that in the future we ought to operate in those cases more often than is now done. He operated in 1881 on a young idiotic lady, who had been so afflicted since her birth; at each menstrual period she suffered from severe epileptic fits. Since the operation, the menstruation has disappeared and the fits have greatly diminished and her general health (not her idiotic condition, however) has been most favorably influenced.

Another interesting case was that of a young woman who became pregnant fifteen months after her marriage; one year later she presented well-pronounced signs of mania which appeared to be related to menstrual troubles; no treatment did any good; she was prevented in time, one day, from killing her child. He was asked to operate, but refused; finally, eight months later, she was operated upon, which resulted in her complete recovery.

DR. JACOBS, of Brussels, from 1888 to this time has operated on 58 patients, 9 of which operations were for unilateral disease of the appendages, and he has collected 54 operative cases. Out of 7 operations for bilateral suppurative salpingitis all are now in excellent health, although 3 of them complain of occasional abdominal pains every month. One of the two unilateral suppurative salpingitis cases became pregnant since the operation and had a normal pregnancy; 23 were operated upon for catarrhal salpingitis, 19 being bilateral. These are all cured or greatly relieved except one, who suffers more to-day than she did before the operation. Three cases of hæmato-salpingitis gave him excellent results. His conclusions as regard distant results are: 1st. That they are very favorable in cases of suppuration of the appendages. 2d. In catarrhal affections, especially those of small volume, they are less favorable; while in nervous women castration is rarely of any benefit.

PROF. LE DENTU, of Paris, operated 34 times with one death from septic peritonitis, the ligature of the uterine stump having ruptured. Three cases showed unfavorable results; in one, one of the ovaries removed being tuberculous, the lesion has become generalized; in one there remains a fistula, while in a third there was a stercoral abscess.

As to the nature of the after-effects, some patients are completely cured, while others suffer for a limited time and others for an indefinite period. The causes of these variations are numerous. Nervous patients suffer much longer than others; again, adhesions which had been destroyed during the operation, reform, or a continuous metritis plays an important *rôle*. One of his patients, upon whom he had performed two laparotomies and one curetting, was only cured after an abdominal hysterectomy.

Dr. Le Dentu called attention to a peculiar after-result of extirpation of the appendages. A woman, operated upon in 1888, returned in 1890 suffering from violent pains of the left side, extending on that side up to the face; on digital examination a small tumor was found in the left vaginal cul-de-sac. Uterine dilatation was performed, and on the twelfth day she evacuated a large quantity of black liquid; since then the tumor and pain have disappeared. In another case, after removal of the appendages, the patient did not seem to recover as desired, and only did so after an extensive effusion of liquid through the vagina. He found in another patient operated on some time ago, two small cysts, one on the right, the other on the left side. These secondary cysts are probably, according to the speaker, the remains of a small portion of the tube which was not well removed.

DR. TERRILLON has performed 140 operations for removal of the uterine appendages: 82 for catarrhal parenchymatous salpingitis; 36 for purulent salpingitis (ovarian or tubal); 10 for hæmo-salpingitis; 8 for tubercular lesions, and 4 for hydrosalpinx, but he only presents the after-results of his first 90 cases, the series of which ended last August. Of these 90 operations he has had 4 deaths, 74 absolute cures, and 12 cures with a few disagreeable symptoms, such as painful menstruation or vesical pain. Out of his 50 operations performed since August, he has had five deaths.

Dr. Terrillon has also observed a peculiar complication in three cases: In the first, a woman was operated upon for double catarrhal salpingitis; she returned three months after the operation suffering severely from abdominal pain. Her temperature was 40° C., and she presented on the left side of the abdomen a painful tumor; by aspiration 324 grammes of a yellowish serous liquid were evacuated, the analysis of which indicated the presence of albumin and fibrin, but no pus or microbes.

In December last, a second patient, operated upon for double salpingitis, returned to the hospital, two weeks after having left it, with the same phenomena as the preceding case; aspiration gave 300 grammes of liquid of the same color as in the previous case.

Finally, last week, a patient, operated upon by Péan's method presented in a vaginal cul-de-sac 575 grammes of the same liquid.

PROF. BOUILLY, of Paris, said that the after-results are favorable when one has to deal with salpingitis, or

painful ovaritis; but such is not the case with interstitial catarrhal salpingitis, which demands a long and tedious operation. As to interference for nervous phenomena, he does not advise it. He has a series of 90 cases, and divides the unsuccessful into three groups: 1st, recurring pelvi-peritonitis; 2d, painful cases; 3d, secreting fistula. Out of his 70 patients he has had 9 more or less deferred troubles, twice severe peritonitis and abscess, with recovery; 3 cases of persistent pain; 3 cases of muco-purulent discharges, which, however, disappeared after curetting the uterus; and in one case persistent metrorrhagia.

Dr. L. P. Richelot, of Paris, has performed a total of 240 laparotomies since January, 1880, and has operated 170 times for removal of the uterine appendages for non-neoplasmic affections. Of this number, about 150 have been kept under observation. He divides his cases into eight groups, the first one comprising simple salpingo-ovaritis or parovaritis; in these cases, of course, the after-results will certainly be favorable, but one must be careful not to remove the uterine appendages uselessly.

In the second group he places ovaries with small cysts. The author had thirty patients, out of which the majority were rapidly cured, while about ten had a period of "therapeutical hesitancy," during which they did not admit they were well.

In the third group is chronic parenchymatous and adherent salpingitis and hydrosalpinx; patients of this group, who have suffered so much, all improve.

In a fourth group he places salpingo-ovaritis which is complicated by a movable or adherent retroversion.

In these cases he has always seen the uterus return to its normal situation by the pediculization of the appendages of the uterus.

The fifth group comprises hæmato-salpingitis and the hæmatoceles. Out of twelve patients, with the exception of two cases of hæmato-salpingitis complicated with strong and solid adhesions, all improved rapidly.

In a sixth group he places pyosalpingitis and suppurative ovaritis; this group gives the most satisfactory results. Out of 27 cases 15 were cured absolutely; of the remaining patients, there are several nervous patients who have complained of pains and menstrual troubles, although the pelvic organs became normal.

In the seventh group are the cases of uterine fibroma; the results have been very satisfactory, suppression of the pains and menstruation and sometimes atrophy of the tumor resulting.

In the eighth group we have neuralgia and true hysteria, and in this group he only includes fixed and violent neuralgias having their seat in perfectly normal organs. The cases referred to were as follows: A patient had a fixed, persistent, and very acute pain on the left side, which encouraged the author to perform unilateral castration, which was immediately followed by a disappearance of the neuralgia. Another patient had been suffering for five years with violent pains localized in the left side; removal of the corresponding ovary brought on an immediate cure. A third patient had been curretted, and the round ligaments had been shortened, yet, as she continued to suffer, the uterus and appendages, which were all normal, were removed and found perfectly healthy. Finally, a case of true hysteria, without any pain or ovarian lesions, was modified by castration.

Dr. Ségond, of Paris, was opposed to the distant results obtained by extirpation of the appendages through laparotomy. The results arrived at immediately by vaginal hysterectomy, applied to these same troubles. During the past two years he has performed 18 laparotomies for diseases of the appendages, and has had 17 operative cures and 1 failure; 5 radical cures, 2 for pyosalpingitis, 3 for non-suppurative lesions; 7 have been largely benefited by the operation but still suffer a little; finally, 5 have been operated upon, 4 for pyosalpingitis and 1 for a non-suppurating lesion, but all have suffered more or less since the operation; 2 of these patients present severe metrorrhagia, while 3 others present purulent discharges for which curretting and other treatment has proven fruitless. Moreover, 3 of these patients who had been carefully sutured have presented ventral hernias which are most troublesome.

On the other hand, Dr. Ségond has performed during that period 17 hysterectomies. All these patients are marvellously well, except one woman who had been operated upon by laparotomy before and who still continues to suffer.

Dr. Routier, of Paris, has removed, since 1887, the appendages 52 times: 27 were for pyosalpingitis; 4 tuberculous; 7 hydrosalpinx; 7 hæmato-salpinx; 11 interstitial salpingo-ovaritis. The results have been excellent in the great majority of these cases. Several of them have presented at the time of their first periods intense congestion of the face, dragging-down pains and felt miserable. As to the after-results, menstruation has been suppressed every time when the operation was not a complicated one, and, therefore, no danger was present of leaving fragments of the ovary in the abdomen. The abdomen is, as a rule, painless after the operation; still there are patients who have suffered from a heavy feeling in the abdomen, flushing, etc., at the menstrual periods; not more than half of those operated upon present these manifestations. Uterine atrophy is constant, the organ becoming infantile. In a word, removal of the appendages gives excellent results in cases of pyosalpingitis; in other cases, as of hydrosalpinx, hæmato-salpinx, interstitial salpingitis, ovarian cysts, the results are also good, but this surgeon finds that the suppression of menstruation in certain young people is followed by a state of uncertain health.

Dr. Bazy has also removed the appendages in two hysterical persons. In one case, the hysteria was a grave one, the patient suffering very much in the abdomen; all internal remedies having failed, the operation was resorted to and the surgeon found the ovaries and tubes fixed to the pelvic walls; the uterus was partly detached as well as the adhesions, and the immediate results proved to be very good, but later the pains recurred.

Dr. Doyen, of Rheims, has performed 56 operations for removal of the appendages for troubles other than ovarian cysts or cancer.

Thirty-two laparotomies have given 2 operative deaths and 3 negative results, one suffering from double fistulous purulent salpingitis, the other two being extreme cases of hysteria. Seven continued to suffer with abdominal dragging-down pains, neuralgia, and gastric

crisis; three of these last improved under appropriate treatment, a fourth was operated upon to obtain hysteropexia, two others required vaginal hysterectomy.

The 20 satisfactory results comprise 13 double-tube ovarian castrations and 7 incomplete operations, 4 of which were done to destroy pelvic adhesions and reduce the retroverted uterus.

Since 1887, he has performed 20 vaginal hysterectomies for non-neoplasmic diseases of the appendage, with only one death. The therapeutic results of these operations are most remarkable; only one of his cases had a temporary cure, as in this case after evacuation of the hæmato-salpinx the uterus was replaced in its former position. A simple laparotomy with destruction of the peri-uterine adhesions soon brought about a definite cure.

The later results of these 56 operations demonstrated that total castration, that is, vaginal hysterectomy followed by removal of the appendages, is the operation which gives the most satisfactory results. Dr. Doyen performs it whenever the uterus is painful and displaced and requires removal; but he finds that in a good many cases castration is excessive, and a simple laparotomy would be all that is necessary. Cases should be selected.

CORRESPONDENCE.

ST. LOUIS.

The objections to a Three-course requirement.—The advantages of the Examining Board.

To the Editor of THE MEDICAL NEWS,

SIR: The objections to a three-course requirement which was championed by Dr. Todd in THE MEDICAL NEWS of May 2d, 1891, are as follows:

1. It possesses an erroneous basis, viz.: the standard of time and not of knowledge.

2. It is unfair in that it takes no cognizance of the superior intellectuality and industry of students.

3. It allows no credit for previous work and study, no matter how extensive, unless pursued regularly in a recognized medical school.

4. It is unjust because it works hardship upon deserving young men who happen to be poor in worldly goods; the rich are thus given the advantage and preference.

5. It perhaps would encourage laxness amongst teachers and indifference amongst students.

6. The ends would not be accomplished, because second-class colleges would exist under its enforcement just as well as now, and they would be equally well patronized.

The advantages of the examining board are:

1. It possesses a just and rational basis, that of knowledge.

2. Every student would perforce depend upon his own efforts and zeal, and would not be indifferent to his studies unless he was not anxious to practise.

3. It is impartial—the rich have no advantage over the poor.

4. The licensing power being taken away from the medical colleges, their instruction, by the sheer force of competition, would be the drawing card, for students would go where they could learn most, rather than where they could most easily graduate.

5. Second-class colleges (and by this I mean those characterized by loose management and incompetent instruction) would be forced out of existence, because so many of their graduates would be rejected by the various State Boards.

In conclusion, let me re-state a remark that I have already made, to the effect that it will be easy to convince the legislators of the wisdom of this measure; it is so thoroughly in keeping with fairness and right that to the law-makers it so smacks of the very essence of all law, that they advocate it in preference to all other measures.

Then let the right prevail; relieve the boards of health of the annoying duty of censors of the medical profession, and dictators of medical colleges; let the State's money be expended—not for the compilation of statistics, their publication and circulation, articles of value to the doctors alone—but for the prime object of such a board—the hygiene of the State; let the impartial board of examiners pass on every new graduate who seeks the privilege of practising in the State.

In such a commonwealth the law of medicine will be the law of fairness, democracy and right, and the licensed doctor will lie more comfortably on the bed of roses nurtured by his own industry, while the incompetent one will seek some more congenial occupation.

Three results will obtain:

1. An ever-increasing number of good, competent, and worthy doctors.

2. An ever-decreasing number of unworthy, unprofessional, and incompetent physicians.

3. Medical colleges upon a higher, better, and more intelligent plane.

Yours truly, YOUNG J. BOND.

GRAND AND PAGE AVES.

NEWS ITEMS.

Beri-beri in a College.—At Rangoon, Burmah, there exists a theological training school or seminary for the native tribe called the Karens. The students of this institution have been for thirteen years seriously afflicted by beri-beri. The sickness has several times been so general as to threaten to break up the school. Various sanitary alterations in the buildings have been tried in the hope of ridding the place of the local causes of the disease, but without success. The measure about to be adopted will be the abandonment of the old buildings in Rangoon and the construction of new ones at a site where more space can be had, about nine miles above the city. The gradual removal of the college to that point is at present in progess. The attendance of students in 1890 was seventy-six; of these eighteen, or twenty-three per cent., were attacked by beri-beri, and were compelled temporarily or permanently to leave college.

A New Jersey Health Case.—A decision by the Recorder of Hudson County, New Jersey, in a certain Health Board prosecution is worthy of note. The complaint was in reference to noisy crowing roosters, alleged to be a detriment to the health of a neighborhood by

reason of the production of insomnia, a ground of complaint common to the experience of nearly all Boards of Health. After an attentive hearing of the counsel for both sides the Recorder gave his decision adversely to the Board of Health on the ground that "a rooster is not an animal in a legal sense." The counsel of the Board gave notice that he would appeal the case.

Outside Physicians to Admit Patients to the Philadelphia Polyclinic Hospital.—As an evidence of the liberal spirit with which the Philadelphia Polyclinic Hospital is managed, it has been decided that the full privileges of the wards, private rooms and suite of operating rooms may be extended by any member of the staff to physicians not connected with the institution.

Many physicians who are not attached to hospitals have frequently cases that they would like to have under the auspices of a hospital with its resident physicians, trained nurses, and sanitary *régime*, and yet wish them under their own observation.

Patients thus admitted to this hospital are attended by the physician for whom the case is admitted as fully as though he were a member of the staff. The admission blanks must invariably be signed by a member of the staff, who thereby assumes the responsibility for the acts of the physician, after which arrangements and terms may be made with the matron.

Visitors are cordially invited to visit and inspect the hospital, on Lombard Street west of Eighteenth, on Mondays from 3 to 4 P. M.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 5 TO MAY 18, 1891.

By direction of the Acting Secretary of War, Par. 5, S. O. 24, January 29, 1891, from this office, granting JULIUS H. PATZKI, *Major and Surgeon*, six months' leave of absence, is so amended as to grant said leave on surgeon's certificate of disability.—Par. 15, *S. O. 99, A. G. O.*, May 1, 1891.

KENDALL, WILLIAM P., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort D. A. Russell, Wyoming Territory, and will report in person to the commanding officer Fort Douglass, Utah Territory, for duty at that post.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

MCCAW, WALTER D., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort McPherson, Ga., and will report in person to the commanding officer Camp Pilot Butte, Wyoming Territory, for duty at that post, relieving George E. Bushnell, Captain and Assistant Surgeon. Captain Bushnell, on being relieved by Captain McCaw, will report in person to the commanding officer Fort McKinney, Wyoming Territory, for duty at that post.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

EDIE, GUY L., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Douglass, Utah Territory, and will report in person to the commanding officer Fort Niobrara, Nebraska, for duty at that post, relieving Timothy E. Wilcox, Major and Surgeon. Major Wilcox, on being relieved by Captain Edie, will report in person to the commanding officer Fort Huachuca, Arizona Territory, for duty at that post.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

GIRARD, JOSEPH B., *Major and Surgeon.*—Is relieved from duty at Alcatraz Island, Cal., and will report in person to the commanding officer Benicia Barracks, Cal., for duty as Post Surgeon at that post, and Attending Surgeon at Benicia Arsenal, Cal., relieving John H. Janeway, Major and Surgeon. Major Janeway, on being relieved by Major Girard, will repair to Philadelphia, Pa., and assume the duties of Attending Surgeon and of Examiner of Recruits in that city, and, in addition to his duties in Philadelphia, will perform the duties of Post Surgeon, Frankford Arsenal, Pa.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

CABELL, JULIAN M., *First Lieutenant and Assistant Surgeon.*—Is relieved from duty at Fort Niobrara, Nebraska, and will report in person to the commanding officer Fort Buford, North Dakota, for duty at that post, relieving Valery Havard, Major and Surgeon. Major Havard, on being relieved by Lieutenant Cabell, will report in person to the commanding officer Fort D. A. Russell, Wyoming Territory, for duty at that post.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

LA GARDE, LOUIS A., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Assinniboine, Montana, and will report in person to the commanding officer Fort McHenry, Md., for duty at that post, relieving Charles B. Byrne, Major and Surgeon. Major Byrne, on being relieved by Captain La Garde, will report in person to the commanding officer Fort Assinniboine, Montana, for duty at that post.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

CLARKE, JOSEPH T., *First Lieutenant and Assistant Surgeon.*—Is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer Camp Poplar River, Montana, for duty at that post, relieving Jefferson D. Poindexter, First Lieutenant and Assistant Surgeon. Lieutenant Poindexter, on being relieved by Lieutenant Clarke, will report in person to the commanding officer Fort Niobrara, Nebraska, for duty at that post.—Par. 14, *S. O. 102, A. G. O.*, May 5, 1891.

By direction of the Acting Secretary of War, DALLAS BACHE, *Lieutenant-Colonel and Surgeon*, is relieved from duty as a member of the Army Medical Examining Board, New York City, and will return to his proper station, Omaha, Neb., and resume his duties as Medical Director Department of the Platte.—Par. 5, *S. O. 108, A. G. O.*, May 12, 1891.

By direction of the Acting Secretary of War, the extension of the ordinary leave of absence granted HENRY P. BIRMINGHAM, *Captain and Assistant Surgeon*, in S. O. 81, A. G. O., April 10, 1891, from this office, is changed to leave of absence on account of sickness, to date from May 1, 1891.—Par. 4, *S. O. 108, A. G. O.*, May 12, 1891.

MCKEE, JAMES C., *Lieutenant-Colonel and Surgeon.*—Having been found incapacitated for active service by an Army Retiring Board, is, by direction of the Acting Secretary of War, granted leave of absence until further orders, on account of disability.—Par. 11, *S. O. 106, A. G. O., Washington, D. C.*, May 9, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 16, 1891.

RUSH, W. H., *Passed Assistant Surgeon.*—Detached from the "Saratoga," and prepare for sea.

ATLEE, S. W., *Passed Assistant Surgeon.*—Detached from Navy Yard, League Island, and ordered to the "Saratoga."

BRONNELL, C. DE W., *Assistant Surgeon.*—Ordered to Navy Yard, League Island, Pa.

STREETS, T. H., *Surgeon.*—Detached from Naval Examining Board, and prepare for sea.

MACKIE, B. S., *Surgeon.*—Ordered as member of Naval Examining Board.

CURTIS, L. W., *Passed Assistant Surgeon.*—Detached from Naval Academy, and ordered to the Practice-ship "Constellation."

LEACH, PHILIP, *Passed Assistant Surgeon.*—Orders to the U. S. Practice-ship "Constellation" revoked.

OPIATES IN ACUTE PERITONITIS.[1]

BY STEPHEN SMITH, A.M., M.D.,
OF NEW YORK.

PROF. ALONZO CLARK, in his article on "Peritonitis," in the *System of Practical Medicine*, makes the following statement:

"In 1840 there was a very fatal visitation of puerperal fever in this (Bellevue) hospital. . . . I was a daily visitor and took notes of all the cases. . . . The disease was fearfully fatal, although every known mode of treatment was tried in different cases . . . but, although with one or two exceptions, with the same result. At this time the opium plan was on its trial, and I had not acquired a confidence in it that authorized me to try it in these cases. The time for it came in 1851. Then a sudden, vigorous attack occurred. One woman was sent to me in whom the disease was well advanced; I instructed my house-physician not how much opium to give, but what effects to produce by it. I found this woman dying the next day, and that she had taken only three grains of opium in three doses. In three or four days seven cases were sent me from the lying-in wards. One was returned for error in diagnosis, and six put under treatment. Having found that prudence in my house-physician was so much more conspicuous than courage, another house-officer, who combined them both, was selected to be in almost constant attendance. The instruction was in these words: 'I want you to narcotize those women to within an inch of their lives.' He did it and saved every one of them. This gentleman is now known over the whole land as a learned and distinguished surgeon. I feel called upon to give his name in this connection that he may be a witness to the facts I state, and for the admiration with which his nerve and prudence impressed me."

It is an interesting fact that Prof. Clark failed to give the name of the gentleman whom he so highly complimented, and whom he thus publicly called to witness to the truth of his statement. As I was then a resident student in Bellevue Hospital and had the care of the six cases to which he alludes, I assume that I am the person referred to, and will take this occasion to bear witness to the facts which Prof. Clark brought forward in his paper.

At the period mentioned by Prof. Clark, Bellevue was a hospital only in name. The buildings were erected in the early part of the century, 1811–16, for prison and almshouse purposes. They were chiefly built on grounds reclaimed from the river, and without under-drainage or adequate sewerage. The buildings were very massive in construction and, in the prison style of that day, without a pretence of ventilation. For a quarter of a century, Bellevue was little else than a prison and a pest-house. All forms of contagious and infectious diseases were received into its crowded and illy ventilated wards. At various times, yellow fever, typhus and typhoid fevers, smallpox and cholera have been the prevailing diseases of its inmates.

The evolution of this establishment into a hospital was a very slow process. The prisoners were first removed to the Island, and gradually all of the able-bodied paupers were provided with quarters in the new almshouse. In time, only the sick poor were detained at Bellevue, and the institution assumed the general character of a hospital.

In 1840, the date to which Prof. Clark first alludes, the hospital had a resident physician, who was the sole responsible authority in managing its general and medical affairs. The appointment was purely political and the government was of the same character. In 1846–7 there came a complete change in the administration of the institution by the selection of a competent medical board and the final retirement of resident physicians. From this latter date, Bellevue as an organized hospital dates its origin. There was, however, comparatively little improvement in the sanitary condition of the hospital buildings for many years. Gradually better ventilation was secured, and the general cleanliness of the wards and beds was improved. The maternity wards of Bellevue were at this early date in the same condition as the other wards. They were not specially separated from the others, except that they were situated at the extreme end of one of the wings. The number of confinements usually averaged one daily, though they occasionally reached the number of sixty in a month.

Puerperal fever was the great scourge of the hospital at that period. Whenever it appeared, nothing seemed to control its progress, and no treatment saved its victims from speedy death. These facts are confirmed by referring to the outbreak in 1840, attended to by Prof. Clark, and reported by Dr. Vaché, the resident physician. He states that the disease made its appearance on the 12th of January, 1840, and was quickly followed by two more cases, apparently so malignant that it was immediately determined to vacate the room, with a view to its purification. The inmates were accordingly re-

[1] Address delivered at the annual meeting of the Fifth or Southern District Medical Association, held in Brooklyn, New York, May 26, 1891.

moved and the apartment whitewashed, ventilated and scrubbed; the bedsteads were cleansed, new beds and bedding introduced, and at the expiration of about a week it was considered sufficiently disinfected to return to it in safety; but the disease immediately reappeared, equally as violent and irremediable as before, and it was concluded most judicious to abandon the building. As promptly as it could be accomplished, another, some distance from the almshouse and appropriated for a nursery, was put in the most perfect order; the bedsteads were cleansed and painted, new beds and bedding were furnished; the physician and nurse were changed; the pregnant women were directed to cleanse their persons by bathing; new clothes, even shoes, were given to them, immediately prior to transferring them to their new habitation, and all intercourse with the inmates of the surrounding premises arrested. Notwithstanding these precautions, the first woman confined, and subsequently four others in succession out of five labors were attacked with the disease, which in every case was fatal. As a further effort in the cause of human life, and as the only rational means of arresting this terrible scourge, came the total abandonment of the lying-in establishment at Bellevue.

To the earlier resident medical students of Bellevue Hospital this sketch presents a graphic but familiar picture of an outbreak of puerperal fever in that institution in the years 1840–57. Cleanliness and isolation of patient and physician were the chief preventive measures employed, but they were powerless to control the spread of the disease. The mortality reported by Vaché was appalling. Of twenty-one cases, nineteen, or over 90 per cent., proved fatal. Nor was this death-rate unusual, as we learn from other sources.

It is important to notice the pathological conditions which were found to exist in the fatal cases. Careful autopsies were made in seventeen of these. The records of these autopsies, as published by Dr. Vaché, were made by Prof. Clark, for he states that he was a daily visitor and took notes of all the cases, and that it was from these notes that Vaché compiled his report of the epidemic. In sixteen of the seventeen cases examined post-mortem, there was, according to these notes, peritonitis. In these cases, there was effusion into the peritoneal cavity which is variously described as "sero-purulent" and "sero-lymphatic." In all seventeen, the uterus was examined and the pathological changes reported. In two cases this organ appeared to be without any special change. In the remaining cases, the alterations were those due apparently to metritis. In several, there were putrefactive changes of matters within the cavity, as the remains of the placenta and the natural discharges after child-birth. The following is an example: The cavity of the uterus was covered, from the fundus down to the cervix, with a dark-chocolate, stringy, fœtid substance, which was easily scraped off with the knife, showing the surface beneath injected; the cervix was covered with a firmly-adherent substance, of a greenish-gray color, with spots of white; the os uteri was of a dark-purple color; beneath the peritoneal surface of the uterus there was much lymph deposited. In several instances pus was found in the ovaries and Fallopian tubes. Pus was also found collected in considerable quantity between the uterus and bladder. In one case, many peritoneal bands had formed, binding the viscera together; an abscess, four inches in diameter, separated the peritoneum from the walls of the abdomen; the sub-peritoneal cellular tissue of the pelvis, extending nearly to the kidney, resembled lint soaked in pus; numerous deposits of pus were found under the peritoneal covering of the uterus, in the broad ligaments, ovaries and Fallopian tubes; the left internal iliac vein was occluded by a firm clot, which extended into the gluteal, ischiatic and obturator branches; in the clot were found collections of pus. The records of these autopsies were more or less accurately reported on every recurrence of puerperal fever at Bellevue Hospital between the years 1840 and 1851. They may undoubtedly be taken as illustrating the ordinary form of puerperal peritonitis when that disease prevailed in this hospital.

It is important also to notice the treatment of these cases, which is given in considerable detail. Of the two cases which recovered, in one the principal treatment was saline cathartics, wet cups to the abdomen, and opiates; and in the other, venesection and leeches to the abdomen. Of the fatal cases, four were treated with saline cathartics and venesection chiefly; in eight, calomel in scruple doses was given, combined with venesection and leeches; in ten, venesection was the more important element in treatment, combined in five cases with leeches; in five cases, turpentine as a cathartic was largely employed. In one, large doses of cinchona bark were used, as recommended by Dr. Burns, and later, turpentine as a purgative. It will be seen that the treatment was so mixed that it would be difficult to draw any conclusions as to the efficacy of any one remedy. Still it is noticeable that purgatives were actively and efficiently employed in seventeen of the twenty-one cases, and that in five cases the cathartic was salts. In the other cases, calomel and turpentine, two approved antiseptic remedies, were administered freely. Opiates, in the form of opium and Dover's powder, were given in most cases, but in small and occasional quantities.

This review of the outbreak of puerperal fever in

1840 may be regarded as fairly illustrating the average features of the recurring appearances of that scourge in the lying-in wards of Bellevue Hospital prior to the year 1851. Prof. Clark truly says: "Up to the time when the opium treatment was adopted, peritonitis was a fearful word; a large proportion of those attacked by it died of it." I was one of the resident staff of surgeons of Bellevue Hospital in 1851, and well remember the excitement created when the first case of puerperal fever was announced. To the visiting staff it meant a hopeless struggle with a virulent pestilence; and to the resident staff, the loss of the obstetric service, which was highly prized. Prof. Clark had already, in his lectures, and especially in the Pathological Society, advanced the opinion that opium might prove to be a successful remedy in peritonitis. He related his experience in cases which he saw in consultation with physicians in Vermont, where he lectured during the autumn months. He says in regard to this experience:

"I found that they were treating the disease on the Armstrong plan; that is, bleeding freely and then administering a full dose of opium, as they said, 'to prolong the effects of the bleeding.' In most cases there was a second bleeding and a second administration of opium. . . . I found they were getting better results than we were in New York, and I studied their cases as closely as I could, and reached the conclusion that opium was the curative agent and that it would be safe to omit the abstraction of blood. This conviction grew in strength with every new case, and I saw, with different physicians, several cases. . . . The idea then formed was that to establish the narcotic effects of opium within safe limits, and continue them by repeated administrations of the drug, would cure uncomplicated peritonitis—that a kind of saturation of the system with opium would be inconsistent with the progress of the inflammation and would subdue it. There was no theory to build the treatment on and no explanation of the action of the drug in my mind. What I saw of the action of two full doses of opium was the only foundation for the idea."

The first case of puerperal fever in the outbreak of 1851, in Bellevue, resembled in all of its peculiarities those of previous epidemics. The onset was violent, the symptoms characteristic, and the termination rapidly fatal. The patient was early transferred to Dr. Clark's wards, and there were great anticipations of the success of the opium treatment. The uninterrupted progress of the disease to its fatal termination, in spite of the opium administered, produced a very unfavorable impression upon the visiting physicians as to the alleged value of this remedy. Dr. Clark, however, declared that the opium had not been fairly tested, for it was found that the drug had been given in such very small quantities that no such effects could have been obtained as he intended and desired. Prof. Clark says:

"The drug symptoms to be produced are subsidence or marked diminution of the pain; some or considerable tendency to sleep; contraction of the pupils; reduction of the breathing to twelve respirations in the minute; in the favorable cases a considerable reduction in the frequency of the pulse; a gentle perspiration; an itchy state of skin, or oftener of the nose; absolute inactivity of the bowels, and after a time a subsidence of the tremor and tenderness in them; some suffusion of the eyes."

Three new cases were soon after transferred to Dr. Clark's care, then two more, and then one, making six in all. They occupied a separate ward, and Dr. Clark determined to make a thorough test of the opium treatment. Special nurses were provided, and I was selected as the immediate medical attendant. His instructions were very explicit. He required that I should aim to see the patients every hour; should closely watch the pulse and respiration, and personally see that the medicine was regularly given. In regard to the opium, he stated that I must not be governed at all by the amount administered, but by the effects. The condition of the patient to be secured was that of semi-narcotism; this was to be determined by the degree of stupor and the respiration; the patient must require to be shaken to arouse her to consciousness, and the respirations might fall to twelve per minute, but not below that figure. In concluding his instructions, he inquired if I had ever heard the schoolmaster say, "I will whip you to within an inch of your life?" On being assured that I was familiar with the expression, he said, "I wish you to give these patients opium to within an inch of their lives." Prof. Clark thus describes the method of medication:

"The plan is to begin with a dose that is safe—say two or three grains of opium or its equivalent of sulphate of morphia, and in two hours notice its effects. If any of the opium symptoms have appeared, repeat the dose; if none, increase by one grain, and so on at intervals of two hours till the degree of tolerance in the patient is ascertained. After that the case can be treated by a diminished occupation of the physician's time—two or three visits a day. The dose is to be increased if the opium symptoms diminish before the disease yields, but always to be diminished or discontinued if narcotism is approaching. The duration of the treatment will be sometimes no more than two or three days; it may be a week, or even a fortnight, and in one case the symptoms persisted mildly for forty days, and then yielded. In this case the medicine used was the sulphate of morphia, and the enormous dose reached by steady and graduated increase was one grain and a quarter every forty minutes in a boy ten years old."

The treatment was immediately begun. The opiates were given in the form of morphine, solid opium and laudanum, but the quantity of each was accurately determined by the apothecary and estimated in grains of opium. At the outset, each patient received one grain of opium every hour, for three doses. No effect being perceptible, the dose was increased to two grains every hour and con-

tinued for three doses. Failing with this dosage, the opium was increased to three grains every hour. In four cases, this amount of opium had the desired effect, and it was continued at that rate. In the remaining cases it had to be increased to four grains every hour. One of these remaining cases yielded to this amount and the opiate was continued at that rate. The other, or sixth case, was much more obstinate, and the opium was steadily increased until the dose reached twelve grains every hour. This amount simply secured a light but continuous sleep, from which she readily awoke on placing the hand upon her wrist to examine her pulse. The first four cases continued to receive three grains of opium every hour for some two or three days, when the pulse fell to its normal standard, the tympanites subsided, the tenderness of the abdomen disappeared, and the patients were evidently convalescent. The opium was discontinued; they rapidly recovered, and remained well. In the fifth case, an episode occurred which Dr. Clark mentions, but not accurately. The patient was a tall, young woman, having a pale and somewhat cadaverous face. On the fourth night, while the four-grain doses of opium were being given, the nurse failed to call me at the usual hour and I overslept two hours. On awakening and noticing the time that had elapsed I hastened to the ward. The nurse was sleeping soundly in her chair. The patients were all sleeping quietly, and were apparently doing well, except the fifth. On approaching her bedside, I was struck with her death-like pallor, heightened by the feeble light of a candle on an opposite shelf, her half-opened eyes, her fallen jaw, and absence of pulse. I stood a moment, quite paralyzed at the thought of my neglect and that of the nurse, when I noticed that she gasped. There was an interval, and then another gasp. I counted those efforts at respiration, and found that the fourth occurred just after the minute had expired. I at once aroused the nurse and took active measures to recover the patient from her profound narcotism. After several hours' continuous effort, she was regarded as securely restored. All the symptoms of peritonitis had meantime subsided; the pulse had fallen from 112 to 92 per minute, the tympanites and tenderness had disappeared, and she expressed herself as feeling well. Within twenty-four hours all the symptoms of peritonitis recurred, and the treatment was renewed, three grains of opium being given instead of four. Semi-narcotism was readily produced, and after a very brief period the symptoms again subsided; the treatment was suspended, and she remained permanently cured.

The following notes of one of these cases, contributed by Dr. Clark to Keating's edition of *Ramsbotham's System of Obstetrics*, illustrates the symptoms and progress of the disease while under treatment:

A. N., aged twenty years, married, delivered of her first child October 1, 1851. The labor was natural and of usual duration. Convalescence was not attended by any untoward symptom except a slight diarrhœa. . . . On the tenth day after confinement she was seized with a chill at 10 o'clock A.M.; chill lasted an hour; the abdomen was markedly tympanitic, extremely tender, and the seat of lancinating pains which caused sobbing; pulse 120; respiration thoracic; tongue clean. Ordered solution sulph. morph. (seventeen grains to one ounce of water), ten minims every hour. She slept most of the day and succeeding night quietly, but not profoundly.

Second day; 10 o'clock. Tympanites increased; tenderness somewhat diminished; extreme thirst; occasional vomiting of a bright-green fluid; bowels quiet; lochia had ceased previous to attack; pulse 120. Other symptoms as before. It was obvious that not much impression had been made on the disease in the first twenty-four hours, and the solution was given (ten minims) every half-hour. This produced sleep, and by evening the pulse had fallen to 90.

Third day. Tympanites and thirst continue; retention of urine; intellect rather obtuse. Other symptoms as before. The morphine solution was now increased to thirty minims every hour. These doses were continued from noon till six or seven o'clock in the evening, when the signs of narcotism became rather alarming. She slept heavily; was roused with difficulty; would not reply to qustions; pupil contracted almost to a point; pulse 68 and respiration seven in the minute. The opiate was suspended, and tablespoonful doses of strong coffee administered. The narcotism continued for six or seven hours, and gradually subsided.

Fourth day. Tympanites diminished; tenderness markedly less; features composed; intellect rather dull; pulse 78; tongue dry in the centre; green vomiting occasionally; slight hysterical symptoms; respiration 15. Morph. sol. resumed, ten minims every half-hour. Narcotism recurred at about the same hour as last evening, in which the sleep was very profound and the respiration only five in the minute. Treatment as on the previous evening. Toward morning these unpleasant effects of the medicine passed off.

Fifth day. The tongue was dry and slightly brown, but patient declares that she feels quite well; tympanites has nearly disappeared; no pain nor tenderness; pulse 80 and respiration 15; some appetite. . . . At 11 A.M. morph. sol. resumed, ten minims every two hours. At night, wakefulness and pain in the abdomen; three grains of opium every hour, under the influence of which she slept quietly.

Sixth day. Sleeps most of the time; easily roused, but answers questions slowly and with an effort; tongue moist, and not furred; tenderness that recurred last night less; pulse 80; still vomits green fluid; treatment continued.

Seventh day. Symptoms all improved; one grain of opium every hour.

Eighth day. Abdomen soft and free from pain or tenderness; thirst slight; says, "I feel so much better;" was decidedly convalescent. From this time the opium was continued in gradually diminished doses. The bowels were not opened until the thirteenth day; after this, treatment was discontinued, and she was discharged in a few days in her usual health.

The sixth case proved to be an anomaly in the tolerance of opiates. During ten days the treatment was persevered in, the pulse remaining at about 120, the respirations 34 to 36, the abdomen greatly

distended and tender to the touch, with lancinating pains, the features pinched, perspiration at intervals, etc. During these twelve days, this patient took the equivalent of 1950 grains of opium, and she neither vomited during that time nor did she have an evacuation of her bowels. No effort was made to secure an evacuation of the bowels during the opium treatment.

"Purgatives are entirely inadmissible. The bowels should be left entirely at rest till they recover their muscular tone; then they will expel first the gas and then the fæces; or if, after the inflammation is subdued, they do not move of their own accord, injections are admissible. I have often left the bowels absolutely inactive for fourteen days without any recognizable consequences."—PROF. CLARK.

At no time was the patient so narcotized that she did not awaken when anyone placed a hand on her wrist. She remained in the hospital as an assistant in the laundry for six months after her recovery, and during that time she was in excellent health. The following extract from the records shows the course of treatment of this patient:

"The treatment was commenced at 10 A.M. with two grains of opium hourly; at 2 P.M. dose increased to four grains; at 3, four grains; at 4, five grains; at 5, five grains; at 6, eight grains; at 8, ten grains; at 9, twelve grains; at 11, sol. morph. sulph. one and a half drachms; at 12, one drachm; at 1.30 A.M. respirations 6; at 6 A.M. respirations 12, twelve grains of opium; at 10, sol. one drachm; at 12 M., opium, twelve grains; at 1.30 P.M., sol. two drachms; at 2.30, two drachms; at 3.30, opium, twenty-four grains; at 5, twelve grains; at 6.30, sol. two and a half drachms; at 7.30, two drachms; at 9, opium, fourteen grains; at 10, sixteen grains; at 11, seventeen grains; at 1 A.M., sol. two and a half drachms; at 2, sol. four drachms; at 3.30, opium, twenty grains; at 4, sol. two and a half drachms; at 5, three drachms; at 6, three and a half; at 6.30, opium, ten grains; at 7, sol. three and a half drachms; at 8, opium, twenty-two grains; at 9.30 sol., four drachms; at 10, sol. three drachms; at 11.30, three drachms. On one day she took the equivalent of 472 grains of opium."

Such is my testimony to the facts which Prof. Clark gives in his articles. Subsequently I had abundant opportunities to witness the opium treatment of peritonitis, both puerperal, traumatic and idiopathic. The recovery of these six consecutive cases very naturally produced a profound impression upon the resident and visiting physicians of Bellevue. As the cases were all typical of those ordinarily occurring at that hospital, and as opiates were the sole remedies employed in their treatment, it was apparent that a new era in the therapeutics of this scourge had begun. From this time forward opium continued for twenty years to be the chief remedy employed in peritonitis in Bellevue Hospital, and with satisfactory results. Opium in peritonitis came into general use in the city. Prof. Clark states that "in private practice the drug has been perhaps more curative than in the hospital." He adds: "I have seen many cases in consultation, and a decided majority have recovered."

It is apparent from the preceding review that previously to the introduction of the opium treatment, puerperal peritonitis was a most destructive disease in Bellevue Hospital when treated by the methods employed prior to 1851. With the introduction of opium, employed as the chief remedy, and in the manner directed by Dr. Clark, the same disease, occurring under the same circumstances, became so manageable that a mortality of 90 per cent. was reduced certainly 50 per cent. These facts lead inevitably to the conclusion that the opium treatment of peritonitis has a place in the therapeutics of that affection of no small importance. Precisely what that position is, it is, perhaps, still impossible to state. Prof. Clark remarks that he cannot explain the curative action of opium in peritonitis. Prof. Barker, who has had a large and varied experience in the treatment of puerperal peritonitis in Bellevue, speaking of the same question, says:

"The most important of all agents in controlling and arresting this disease is opium in some form. Let us see what we gain by its use. The peristaltic movements are retarded or arrested, and thus the inflamed tissues have absolute rest; pain is annulled; emotional excitement is allayed; the nervous system is tranquillized; sleep is secured; and thus the depression of the vital forces resulting from the shock of the attack is lessened."

Prof. Clark regarded opium as valuable chiefly in simple, uncomplicated peritonitis. He says:

"When the inflammation of the uterus is the dominant lesion, and is purulent, opium has little or perhaps no control over its fatality; but in the cases in which peritonitis is the ruling lesion, if begun early, it will show its power."

And yet the preceding history of the six puerperal cases which recovered resembled in all their essential peculiarities the fatal cases reported by Vaché, in many of which the inflammation of the uterus and its appendages was the dominant lesion. Of course, we cannot positively assert that the cases which recovered had other lesions than those of the peritoneum, but six consecutive cases of peritonitis in the lying-in wards of Bellevue Hospital without any inflammatory changes of the uterus and its appendages would, at the period under review, have been regarded as impossible. Especially would this be true in an outbreak the first case in which rapidly proved fatal with such complications. We would seem, therefore, to be justified in the conclusion that several cases made a satisfactory recovery at that time in which the inflammation of the uterus and appendages was the dominant lesion.

Happily, in these latter days antisepticism has greatly diminished the frequency of this formidable disease, especially the puerperal form, and in the

meantime the remedial measures have been markedly increased. This improvement is due to a more accurate knowledge of the functions of the peritoneum and of the existence and action of pyogenic organisms. The researches of Wegner, Grawitz and Pawlowsky have determined that the peritoneum is quite tolerant of simple wounds which heal readily. As a lymph-sac, the stomata in its walls opening into the surrounding lymphatics, the peritoneum is almost directly connected with the spleen, pleura and other organs, thus admitting of rapid general infection by peritonitic microbes when they exist in large quantities. The healthy peritoneum is not sensitive to injected fluids, provided they do not contain putrefactive bacteria, but even these organisms may be injected in small quantities, without harm, as they are quickly absorbed and destroyed or excreted; but if the peritoneum has been previously irritated or otherwise injured, pathogenic microbes are far more effective. It appears also that chemical irritants cause inflammation with hæmorrhagic effusion, but without lesion of the intestinal walls or the penetration of microbes into the peritoneal cavity. Peritonitis, therefore, not due to putrefactive organisms, is local, while peritonitis produced by such pathogenic microbes as the staphylococcus aureus is rapidly fatal by general infection. Nearly coincident with our more intimate knowledge of the causes of infective peritonitis was the discovery of the means by which these pathogenic organisms can be destroyed. As these destructive agents must be applied directly to the microbes, the surgeon was brought into this field of therapeutics, and has here won some of his most brilliant victories, by boldly opening the peritoneal cavity and cleansing it with antiseptic solutions; but as there are many types of peritonitis, having their causation in different conditions, some being of a microbic and others of a non-microbic origin, it is as yet by no means certain where the line is to be drawn between the medical and surgical treatment of this disease. It is probable that the physician and surgeon will more nearly meet the multiform types which this affection presents by acting in concert, and discreetly employing the measures which each possesses according as they may jointly interpret the indications. Whatever may be the possibilities of the art of surgery in the treatment of peritonitis, and they are by no means inconsiderable, the question may pertinently be asked, Has any remedy, or combination of remedies, in the hands of the physician given results equal to or better than opium in a series of cases similar to those recorded in this paper? Prof. Fordyce Barker, who was for many years one of the obstetric physicians to the maternity wards of Bellevue, remarks, in his work on *Puerperal Diseases*:

"In this hospital, for more than twenty years, the opiate treatment . . . has been chiefly relied upon in peritonitis . . . and I do not hesitate to say that the records of this hospital will demonstrate a success in the treatment of this disease far beyond that which has ever been secured by any other method."

Is not this declaration as unimpeachable to-day as when it was first published, in 1874?

FURTHER STUDIES IN MALARIAL DISEASE.[1]

The Parasites and the Forms of Disease as Found in Texas.

BY GEORGE DOCK, M.D.,
OF GALVESTON, TEXAS.

SINCE Macculloch (in 1827) applied the Italian colloquialism *mal' aria* to the hypothetical marsh miasm, the convenience of the term, in the absence of any accurate knowledge of the nature of that poison, has been universally recognized. By a familiar figure of speech, the term has come to be used as expressing the morbid processes set up in the human organism by the paludal virus. The reasons for uniting processes which differ so much in their clinical phenomena as, *e. g.*, common intermittent, comatose and hæmaturic fever, have been so frequently and so well stated that repetition is unnecessary. Since we have learned to know the *contagium animatum* of the disease in the organism most commonly known as the *plasmodium malariæ*, it seems expedient to drop the use of the word malaria as expressing the cause, but to use it as synonymous with the process itself. This is, in fact, done by leading writers in Italy and Germany, and to some extent in this country, and, though it may be deprecated by linguistic purists, will outlast the objections of the latter.

On account of the technical difficulties in the determination of the precise biological nature and life history of the parasites, the study of malaria must be followed on a number of distinct lines having a common goal. All the diseases classed as malarial—not considering the illegitimate use of the word at the hands of careless diagnosticians—in all parts of the world, must be re-studied, with the object of determining the presence or absence of the parasites. The organisms themselves must be studied at the same time, in order to fill out the gaps in our knowledge of their nature and mode of growth.

In order to obtain an accurate knowledge of the malarial parasites, it is necessary to observe them for a long period, in various kinds of cases, and during all the stages of the disease. In this way one learns in time how to explain some of the discordant views of various observers, and acquires a toleration for those he cannot reconcile with his own experience.

[1] Read, in abstract, before the Section of Practice of Medicine and Physiology of the American Medical Association, at Washington, May 7, 1891.

For some time I have worked on the lines indicated, and the results seem important enough to warrant their publication now.[1]

The studies now under consideration include a period of one year since the publication of some earlier observations. In this period I have examined, in the manner to be described, the blood of seventy-six persons. In order to have the greatest objectivity, in almost all cases the blood was examined before ascertaining the clinical peculiarities of the cases, and the nature (if malarial) and course of the disease predicted from that. If the examination be made at a favorable time a demonstration can be made more brilliant than in any other field of medical diagnosis. Naturally, I was most frequently called to examine cases of malaria, but a history of chills, of suddenly developing fever, of paroxysmal course of symptoms, or cachexia, sufficed to call forth a microscopical examination of the blood.

In 41 of the cases the parasites were observed. The other 35 cases included dysentery, influenza, phthisis, sepsis, enteric fever (four cases, with two autopsies, one of each having been diagnosed as malarial fever), intermittent neuralgia, and miscellaneous cases, one of which had been considered as malarial costal periostitis. The subsequent histories confirmed the exclusion of malaria. Owing to the occasional admission of a number of cases of malarial fever at the same time, some were missed, but no selection was made at such times. On the other hand, a number of cases were encountered which the blood-examination showed to be malarial, but in which the diagnosis would not have been made without it, or the verdict of time and the therapeutic test.

Such control observations are, therefore, of great value. Through them we may widen, and shall certainly deepen, our knowledge of malarial disease.

In my investigations I examined the blood from the finger-tip, at once after withdrawal, by a Zeiss one-twelfth inch homogeneous immersion lens, Oc. iv. In case the result was negative, another examination was made before the administration of remedies. This was done to meet the theoretical objection that if the examination is made just after the segmentation of the plasmodium, the small forms (spores) may be overlooked.

In 30 cases in which parasites were found the patients were put to bed and the temperature taken at intervals of two or three hours. No specific medication was given until the first paroxysm had passed, except in cases which seemed to threaten life. Observations were made at frequent intervals on the fresh blood, and cover-glass preparations made in special cases.

Origin of the Cases.—The diverse origin of the cases studied by me adds to the importance of the observations. Six cases originated in Galveston, and, with one exception—a case of severe remittent fever—include all of local origin admitted to hospital during the year. This indicates a peculiarly favorable locality for investigating the etiology of malaria, to which I hope to give special attention.

Seven patients came from various parts of tropical America, and were seen within a short time after leaving the place of infection. Six of these I have already reported;[1] the seventh, from the northern side of the Isthmus of Tehuantepec, was one of malarial cachexia with crescents only. Negative observations, probably at the hands of inexperienced investigators, have led to the statement that the tropical malarial fevers differ essentially from those of temperate zones—a statement so at variance with the views of judicious clinicians familiar with the disease as to require more than ordinary proof.

The rest of the cases originated in various parts of the interior of Texas, and in that notoriously malarial part of Louisiana, on the Gulf of Mexico, between the Sabine and Mississippi rivers.

Influence of Season.—Malaria exists in my field of observation all the year round, but there is a spring maximum of intermittent, some of considerable severity, and an autumn maximum, with remittent fevers and atypical cases of all kinds, from the mildest to those which kill in a few paroxysms.

In the season now reported, the long dry period in the late spring and the almost continuous rains in the beginning of this year, coincided with a decrease or total absence of cases. In June, there were two cases; in August, one; September, two; October, eleven; November, twelve; December, four; February, two; March, three; April, four.

On a Large Plasmodium, the parasite of tertian fever of Golgi.—In thirteen cases of the present series a large plasmodium was met with. In ten cases it was the only form; in three, crescents and a smaller plasmodium were found.

These forms begin as amœboid bodies about the size of the blood-plates, and when at rest slightly resemble the latter, but can be demonstrated to be within the red blood-corpuscles. Throwing out

[1] Notwithstanding the efforts of clinicians and biologists, no unanimity has been reached in regard to the zoölogical classification of the plasmodium malariæ. That it belongs to the protozoa is certain, with close affinities to the nomads or the sporozoa. The difficulties in the determination of its proper place are due as well to our limited knowledge of the other classes as to that of the form in which we are now interested. For this reason it is advisable to work up the life history of the organisms in the blood as completely as possible—not neglecting, of course, attempts at cultivating them—and at the discovery of the form in which they exist outside of the body. For this two things are necessary: a full knowledge of the characteristics of the blood in health and disease, as seen under high powers, and some acquaintance, even if at second hand, with the morphology and physiology of the protozoa.

[1] Fortschritte der Med., No. 5, 1891.

pseudo-podial processes they gradually increase in size. This is accompanied by the formation of pigment, usually in yellowish-red to reddish-black rodlets. As they grow larger the invaded red corpuscle flattens out and becomes paler. Finally, the corpuscle is almost or entirely destroyed, and the plasmodium enters on the stage of segmentation.

That, at least, is the usual, or, if we may use another term, normal sequence. But the plasmodium may escape from the corpuscle at any stage, and, at any time, either in the corpuscle or free in the plasma, can undergo segmentation. In an earlier communication[1] I described the peculiarities of some of these forms, and many times in the present series have been able to confirm those observations.[2]

In seven of the ten unmixed cases I was able to study the typical segmentation of the organisms. In none of these did I encounter the precise form described as the usual one by Golgi, and which I had seen in previous seasons.

Most of the segmenting bodies of this series resembled those described by Golgi as having the second mode of division.[3] In this the pigment is gathered in one or several small heaps, while the whole body of the plasmodium becomes separated into small round or oval bodies, which are ultimately liberated.

On account of their minuteness these spore-like bodies are very difficult to study. Whether they are supplied with flagella, as seems probable, or whether flagellate amœba forms issue from them cannot yet be said. Certain it is, that in one way or the other, in a comparatively short time they infect in turn red corpuscles, and so continue their species for another generation. With the ordinary solutions of methylene-blue the spores stain on the periphery, leaving a clear, round, central space.

Occasionally I have seen the forms of segmentation described and figured by Celli and Guarnieri,[4] Councilman,[5] Dolega,[6] and Plehn,[7] and which, on account of technical difficulties, cannot be reproduced here. Sometimes a number of segmenting bodies, differing slightly in shape of spore and arrangement of pigment, were met with in a single case and in a single preparation.

The conclusion has been forced on me that the differences in the details of the segmentation are of minor importance. Similar variations in the appearances and details of the reproductive phase, depending on slight changes in the environment, are not uncommon among other protozoa.

The more regularly segmenting forms of these parasites require about forty-eight hours to complete their development. In only one case have I had to do with a pure tertian, but in six cases of quotidian type I have been able to recognize the existence of generations in different states of development. Predictions based on this fact were verified by the result of segmentation of the larger forms in the next paroxysm, and afterward by the gradual development of the smaller forms.

The tertian case gave the most striking example of the time of development and succession of generations. The diagnosis of tertian was made at noon on the day of apyrexia, being the day after the first chill in the attack, and so, from the anamnesis alone, it being impossible to determine whether it was to be tertian or quotidian. All the many plasmodia found measured from one-half to five-eighths of the diameter of a red cell, so the acme of the next paroxysm was predicted for twenty-four hours later. The temperature rose slowly from midnight to 10 A.M., when it was 101°. Half an hour later there was a slight chill, and the temperature rose rapidly to 105°, which point it reached between 2 and 3 P.M. At the time of the chill all the forms were large—as large as, or larger, than a normal red corpuscle. Some were beginning to divide after the manner of Golgi's second form. Segmenting forms were present in all specimens for more than two hours, when—though some of the plasmodia had not quite reached that stage—the smallest amœboid unpigmented forms, the results of the segmentation first seen, began to appear in the blood corpuscles.

It is almost needless to say that I recognize a close connection between the reproduction of the plasmodium and the febrile paroxysm. In making this statement we must clearly understand what a paroxysm in malaria really is. It is unnecessary to discuss that now. But in regard to the chill, it must be remembered that even in vernal intermittents, in which it almost always appears, it has no fixed place in the temperature curve. It may take place early in the rise, or it may only occur near the acme. As the result of experience, I have stopped predicting the probable time of a chill, but speak instead of paroxysms only, with some qualification as to

[1] THE MEDICAL NEWS, July 19, 1890.

[2] In one instance the peculiarities were more marked than in any I have seen before. This was in a case of tertian intermittent, in April. Near the acme of a paroxysm a plasmodium, which showed the characteristics of atypical segmentation, escaped from the remnant of a red corpuscle. Its diameter was equal to that of a normal red cell. At once the pigment in the outer zone began to circulate, forming many complete circuits in one direction, then reversing the direction. The pigment in the centre, which outlined three round spaces, was all this time in the "ebullition" motion. Gradually, the spaces became more distinct, and in them appeared the small spherical highly refracting bodies. A few minutes later a long and distinct flagellum appeared at one side, with pigment moving in it. At the end of half an hour all motion had ceased.

the probable time of the acme. I find the plasmodia reach the maximum size about the time the temperature begins to rise, and that segmentation begins within a period of not more than three to four hours later.

The period of forty-eight hours, though the normal one, so to speak, is by no means invariable, as we can easily see in cases with anticipating or postponing paroxysms. I have seen the time shortened by twelve hours. Causes ot which we have as yet no definite idea may so alter the rapidity of the development that there is no ground for denying that the development of single generations may produce quotidian or quartan paroxysms. Postponing paroxysms may be supposed to be caused by some delay in the development of the spores, though the opposite process cannot so easily be applied to anticipating paroxysms, which are probably due to the development of generations displaced, so to speak.

The severity of symptoms in my cases has been in relation to the number of organisms found. The severity, however, of these cases, aside from the anæmia in protracted cases, does not compare with that in the cases accompanied by small plasmodia, to be described later. The seven cases in which the large and typically segmenting plasmodia occurred were of intermittent type. In an eighth case in which this form was found the patient gave a history of (vernal) intermittent, but the case could not be followed up.

Two of the three cases in which this form was found with the small form were also intermittents. One of them, from Tehuantepec,[1] was a tertian with chills at 3 A.M. and acme at 7. The other, from Nicaragua,[2] quotidian without chills, with paroxysms in the afternoon. The third was a fatal case with subnormal temperature.

The two remaining cases belong to a class to which I have called attention before, and which I believe to be accompanied by the plasmodia of peculiarly atypical development. In these cases predictions based on the forms discovered were verified. The patients were kept under observation a week each, without quinine. The temperature was not measured, but there were no chills and no perceptible fever. The symptoms were only of the same vague character as those alleged by the patients as existing for some time, viz., pain in the bones, loss of appetite, headache, with anæmia.

Unfortunately, such patients will not remain in hospitals long enough to have careful observations made. They offer a very interesting field for observation, and the idea of their dependence on the atypical plasmodia, if confirmed, will give a scientific explanation of certain forms of malaria otherwise difficult to understand.

The Flagellate Bodies.—In the present series of cases I had abundant proof of the statements I made a year ago in regard to the origin of the flagellate organism. Out of the thirteen cases in which the large plasmodia were found, flagellate bodies were discovered in seven. Five of these were acute vernal intermittents—recurrent attacks which could be traced to infections in the last summer and autumn. Two were cases in which small plasmodia and crescents also occurred. Of the other six cases, three were seen only once. In one case the bodies were found in the third paroxysm of the season. In all cases I was able to observe their development from the atypical endoglobular plasmodia, after becoming free in the plasma, and within a short time after the exit from the corpuscle was observed.

The formation of the flagella while the body is still in the red blood-corpuscle, which I reported a year ago, had already been observed by Celli and Marchiafava, as I did not know at that time. It has since then been confirmed by Plehn.[1] It makes the parallel between these bodies and the *polymitus malariæ* of Danilewsky complete. From the observations of Plehn and myself, and of Antolisei,[2] we may assume as settled that the most perfect and characteristic of the flagellate bodies are closely related to, in fact derived from, the parasites of intermittents, not only in tropical and subtropical countries, but also in those temperate latitudes where the less severe but more typical forms of malaria occur. It is also beyond question that they appear very early in the course of malaria. It is evident, therefore, that when Golgi asserts that the flagellate bodies may represent a transition stage in the development of crescentic bodies, he must have conditions in his field of observation very different from those in many others. I have never seen crescents appear in the spring malarial fevers, and I shall show later that they are most frequent in cases in which flagellates are not to be found.

I have before this showed a comparatively greater resistance to specific remedies on the part of the atypically segmenting bodies and flagellates as compared with the more regularly segmenting forms, and suggested on that ground the probability of their being resting-stages of the organism. The facts have been confirmed by several observers, but I no longer, in the light of a wider experience, maintain the hypothesis. The reason why they, even when free in the plasma, resist the action of

[1] Fortschritte der Med., Bd. ix., No. 5, p. 191.
[2] Loc. cit., K. Sch.

[1] Loc. cit.
[2] Riforma Med., 1890, Nos. 26, 27; Centralb. f. Bakt., etc., Bd. ix., No. 12.

quinine is a question greatly in need of a scientific explanation.

It is unnecessary to consider in detail the clinical features of cases in which the large plasmodia are found. One or two points only may be mentioned.

The blood is characterized by the tendency of the invaded blood corpuscles to flatten out, sometimes becoming as much as one and a half to twice the diameter of a normal corpuscle. An increase of leucocytes—large lymphoid and eosinophile—can often be noted at the time of the acme of the paroxysm.

Leucocytes containing pigment are rare. In not a single case of the present series were they found.

So far as we can tell from our present methods of investigation the various forms of this large plasmodium represent a single species. It is a kind having the widest distribution, having been found in all parts of the world when looked for. I myself have found it with the same forms in Philadelphia, in cases from various parts of Texas and Louisiana, and from Tehuantepec, Nicaragua, and Panama.

It is also found in all seasons in which malaria prevails. It occurs not only in cases of primary infection, but in the vernal recurrences of mixed infection, to be mentioned later, it is the only form to be found.

These facts are especially interesting in connection with the conclusions reached by Hirsch, as the result of his monumental research in the literature of malaria:[1] "Intermittent malarial fever, by far the most frequent and widespread form of malarial disease, is met with everywhere, and at all times wherever the disease prevails endemically or epidemically."

This form also shows a remarkable ability to remain latent in the body. As I have said, all the vernal cases so far studied this year have been recurrences of fevers acquired last year. One, with the longest free interval, was in the case of K. Sch., reported as a tropical case.[2] The large plasmodium was found in his blood for the last time December 14, 1890. Crescents were last noted December 22. The patient was kept on large doses of arsenic, quinine, and iron until December 29. He had fully regained his strength and gained very much in weight, though still very anæmic. Treatment was stopped and the man assumed the position of porter in the hospital. Malaria never occurs in the part of the city in which the hospital is situated, and in the months of January and February the only other case I saw was one from the tropics.

The following shows the course of the recurrence:

"*February 26*, 3 P.M. The patient, K. Sch., complains of complete loss of appetite. Says that yesterday, about noon, he felt cold, without a rigor; later had fever, headache, pain in extremities. Temperature 99.4°. Many endoglobular plasmodia, not fully developed. Predicted paroxysm for next day. The temperature fell to 97.4° at 10 P.M.

"*27th*. Temperature rose from 98.8° at 6 A.M. to 104.8° at 10. At 10 a rigor lasting half an hour. The temperature remained at the maximum for two hours and then fell. During the rise and acme the blood examination showed the process of segmentation in the parasites. During defervescence the patient received 20 grains of quinine in solution, in four doses.

"*28th*. Patient feels well. In the blood a few free bodies."

After this no more organisms were found until March 13th. The patient was given tr. cinchona comp. ʒij and five drops of Fowler's solution daily; the temperature ranged from one to two degrees above normal.

"*March 13*. Felt chilly at noon. At 4 P.M. temperature 100°. In the blood a few plasmodia in early stages.

"*14th*. Temperature normal. In the blood plasmodia larger than yesterday. A few free flagellate bodies. Predicted paroxysm for following day, but gave 10 grains quinine hypodermically to abort it.

"*15th*. No chill, but temperature rose to 99.6° at noon. A few free bodies found in the blood. Quinine 20 grains."

After that there were no further symptoms, and the patient left the hospital, having obtained work outside.

In other cases there were intervals almost as long. They indicate the existence of a resting-stage of the organism, the precise nature of which and the causes determining its return to the active stage must be the task of future investigations.

(*To be concluded.*)

TURPENTINE AS A GERMICIDE AND ANTISEPTIC.

BY W. SCHLEPPEGRELL, A.M., M.D.,
NEW ORLEANS.

ALTHOUGH the oil of turpentine (*Oleum Terebinthinæ*, U. S. P.) is not unknown as an antiseptic and germicide, its insolubility in water and its irritating properties have hitherto made its use impracticable. That it has its special uses, however, in this connection I have had abundant testimony.

It is a well-known fact among naturalists, that, if the air of a cabinet be impregnated with the vapor of turpentine, the specimens are safe from the ravages of moths and other intruders so long as this condition of the air of the cabinet remains.

Having learned the advantage of turpentine in

preserving entomological specimens, I concluded to try its germicidal properties in the cases containing surgical instruments. A bacteriological examination of the cases, made four weeks afterward and compared with the examination of cases not provided with turpentine, convinced me of its efficiency, and I soon afterward applied the same principle to drawers containing towels, gauze, bandages, etc.

The method is simple. The turpentine is placed in flat, large-mouthed bottles at the bottom of each case or drawer, the volatility of the turpentine causing the vapor to impregnate the surrounding air.

Of late I have also placed my surgical instruments, the night preceding an operation, in a flat dish containing oil of turpentine. The instruments are completely sterilized, are not injured by the submersion, and are easily dried by a piece of sterilized gauze or towel. The characteristic odor of turpentine can be removed by ether.

The cheapness of turpentine and the ease with which it may always be obtained, added to its special adaptability in preserving the aseptic condition of instruments, bandages, etc., by its vapor, may make it a valuable addition to the list of our antiseptics and germicides.

I have also used benzole in the above manner. Its greater volatility gives it a more rapid germicidal action than turpentine, but its great inflammability admonishes caution in its use.

A REPORT OF TWO CASES OF EXTENSIVE COMPOUND DEPRESSED FRACTURE OF THE SKULL.[1]

BY THOMAS R. NEILSON, M.D.,

SURGEON TO THE EPISCOPAL HOSPITAL AND ST. CHRISTOPHER'S HOSPITAL FOR CHILDREN; ADJUNCT PROFESSOR OF GENITO-URINARY DISEASES IN THE PHILADELPHIA POLYCLINIC; INSTRUCTOR IN GENITO-URINARY DISEASES IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

FROM a number of cases of compound depressed fracture of the skull which have come under my care in my service at the Episcopal Hospital I have selected the two following to report at this time because of their exceptional gravity and as showing the results obtained by prompt operation, thorough drainage, and careful antisepsis:

CASE I.—A lad, Fred W., aged seventeen years, was admitted to the hospital on the afternoon of March 5, 1890. A few moments before admission, in attempting to jump from a descending elevator in a mill in which he was employed, he had missed his footing and fallen headlong from the fourth floor of the building down the elevator shaft, landing upon a stone pavement in the basement. While being conveyed to the hospital in the ambulance the boy had a convulsion, at the end of which his breathing almost ceased. Reaching the hospital he was taken to the receiving ward, where I was at the time with my resident physician, Dr. F. Rudderow. The patient was completely unconscious, had marked symptoms of compression — widely-dilated pupils, stertorous breathing, etc.—and, beside the head injury, he had a simple comminuted fracture of the left leg and a lacerated wound of the popliteal space.

A moment after he was placed on the bed in the ward he had a very severe clonic convulsion, ending in tonic spasm of the muscular system so long that he became asphyxiated and death seemed close at hand. I ordered a hypodermic injection of atropine to be given and instituted artificial respiration. The color and condition of the patient soon improved and respiration was reëstablished.

A superficial examination of the head showed an irregularly shaped scalp wound, communicating with a depressed fracture of the skull, at the right anterior part of the vertex. I had the patient taken at once to the operating room and placed upon the table, his head shaved, thoroughly scrubbed, washed with alcohol and then with bichloride solution, the ear of the injured side being also well cleansed with the last. Upon enlarging the scalp wound I disclosed a compound, comminuted, and depressed fracture, involving the frontal and parietal bones and extending downward toward the temple. The uppermost limit of the fracture was in the parietal bone, about one inch from the sagittal suture. The region of depression was about an inch outward from this and had an area of some two inches.

Applying the trephine near the posterior border of the latter, I had just got the instrument well set in the bone when the patient had another very violent convulsion. Remembering the respiratory embarrassment which had appeared at the end of the two previous seizures, I saw that everything probably depended upon the immediate relief of the compression, and, several assistants holding the patient as quiet as possible, I rapidly completed the trephining, and with the elevator dislodged the depressed and impacted fragment. Instantly the pupils contracted to the normal, and the patient gazed about him in amazement. In reply to questions he told me his name and where he lived, and realized that he was in a hospital, although he did not know why he was there—in other words, he had no recollection of the accident.

Proceeding with the operation, I found that at the place from which I had removed the depressed fragment of bone the dura mater was torn, and damaged brain substance protruded. Pressing the latter in, I saw beneath the dura, and close to the margin of the wound in it, the edge of a clot. Enlarging the dural opening with scissors, I removed the clot, which was not large, and irrigated the brain with 1:2000 bichloride solution. My attention was then attracted to a slow but constant welling up of blood through the line of fracture (which extended downward on the side of the skull), and, pressing the dura aside with a finger, I found that a quite noteworthy amount of hæmorrhage was taking place. Again using the trephine, I made an aperture in the parietal

[1] Read before the Philadelphia Academy of Surgery, April 6, 1891.

bone near its anterior inferior angle, and at the posterior edge of the line of fracture. Enlarging the opening with rongeur forceps, and pressing the brain aside with the finger, I made a careful search for the bleeding point, but failed to locate it. It seemed, however, that some of the bleeding was coming from the diploë of the broken bones. I traced the fracture into the squamous portion of the temporal bone in one direction, and in the other into the upper border of the greater wing of the sphenoid. Being unable to find any vessel to tie, I decided that under the circumstances the best thing to do was to provide, by drainage, against the accumulation of a basal clot, and accordingly inserted a horsehair drain into the middle fossa, pushing it into position with my finger. This done, the operation was completed by cutting away with the rongeur forceps some irregular projections at the upper end of the fracture and inserting into the brain at the seat of laceration a catgut drain, bringing it through the wound of the dura, which was then closed with a continuous catgut suture. At the situations in which, from the removal of the trephine buttons and the comminuted fragments, defect of bone remained, I placed upon the dura some small pieces of the portions removed, which had been cut up with bone forceps and kept in a hot bichloride solution during the operation. Before suturing the scalp wound, horsehair drains and rubber drainage-tubes were placed so as to drain the wound from each of the four ends of the crucial incisions. The ordinary antiseptic dressings were applied, and, after the wound in the popliteal space had been dressed and the leg placed in a fracture-box, the patient was put to bed. He was perfectly conscious and rational, and remained so throughout the subsequent history of the case. The treatment ordered was an eighth of a grain of calomel every three hours without opium, and the diet for the first three days consisted of a pint of milk in the twenty-four hours. From the fourth day the quantity was gradually increased, and later a more liberal soft diet was allowed.

Immediately after the operation the temperature was 99⅘°, and the respirations 36. Four hours later the former had risen to 100⅘°, while the latter had fallen to 26, afterward descending to the normal, and there remaining. On the morning of the next day the temperature was 99⅘°. At my visit I found that the dressing was quite saturated with blood and accordingly renewed it. On the morning of the third day the temperature was 99°, but it rose in the evening to 101°. An enema was then given and an intestinal evacuation secured, and by the next morning the temperature had again fallen to 99°. After that it remained practically normal, only once reaching as high as 99⅘°.

A fresh dressing was applied on the fourth and one on the eighth day, the rubber drainage-tubes being removed on the former and the intra-cranial and superficial horsehair drains on the latter, there being no discharge at that time.

The wound healed promptly, except at the spot where the brunt of the force of the fall had been received, and here, after a few dressings, the process of granulation was established and soon completed. When I went off duty at the end of March the patient was perfectly well, so far as the head injury was concerned; his broken leg, however, in the union of which there was some delay, kept him in the hospital until the end of May, at which time he was discharged, recovered.

Case II.—L. —, aged forty-two years; admitted to the hospital on the afternoon of January 23, 1891. While at work in a shipyard he was struck on the top of the head by the crank handle of a very heavy crane, which broke while he was standing beside it. He was taken at once to the hospital, and, happening to be there at the time, I saw him immediately after his admission.

On examination a scalp wound was seen on the vertex anteriorly, to the left of the median line and communicating with a comminuted and depressed fracture, from which a good deal of arterial blood persistently oozed. The left upper eyelid was swollen and discolored by effused blood. The patient was conscious and gave his consent intelligently to my proposition to operate. He complained only of soreness in his head and a sense of chilliness, his temperature being subnormal.

I had the head immediately shaved and cleansed, the wound irrigated with bichloride solution, a temporary wet bichloride gauze dressing applied, and hot-water cans placed about the patient, and waited a short time for reaction to set in.

In about an hour and a half, the patient's condition being more favorable, I had him etherized, the head again thoroughly cleansed, as well as the ear of the injured side, and then enlarged the scalp wound by a crucial incision and exposed the depressed part of the fracture. The line of fracture commenced in the frontal bone in the median line and extended downward and outward obliquely across the coronal suture into the parietal bone, seeming to go as far as its lower border. Cross lines of fracture made several comminutive fragments, and one of these, a large one, was driven firmly down at a point about two inches from the median line. I applied the trephine on the parietal bone at the posterior margin of the depressed fragment, and, enlarging the opening with the rongeur forceps, elevated the fragment, which came away together with some smaller pieces which were wedged in with it. One of the latter had penetrated the dura within half an inch of the superior longitudinal sinus, and from the irregular tear injured brain substance protruded. After irrigating the latter carefully with bichloride solution, I proceeded to inspect the rest of the injury, and, pressing the dura aside with my little finger, saw that arterial blood was welling up from the side of the cavity of the skull, and that a large clot was forming between the dura and the bone. Removing this I was startled by a free and rapid flow of arterial blood, and began to enlarge my opening in the skull with the rongeur forceps, but finding them rather slow I laid them aside and trephined at the anterior inferior angle of the parietal bone, having first extended my incisions in the scalp sufficiently to obtain free access to the locality. On removing the button I exposed directly in the centre of the opening a large branch of the middle menin-

geal artery, which had been torn across and was bleeding freely. The opening made by the trephine being too small to enable me to secure the vessel as I intended, by including it in a suture in the dura, I had to gain more room by using the rongeur forceps, in the meantime getting my resident physician, Dr. L. H. Adler, Jr., to pass a finger from the upper opening, between the dura and the bone, and to make pressure upon the bleeding point. While cutting with the rongeur forceps, I found that another line of fracture, extending from the lower part of the frontal into the squamous portion of the temporal bone, made another large comminuted fragment, which became loosened and was removed. Having gained sufficient space, I was about to secure the bleeding vessel in the manner alluded to, when it was discovered that the needle, which was the only one of appropriate size in the hospital, had been mislaid, and I was obliged to apply the ligature with the assistance of the hæmostatic forceps, which was successfully accomplished with a little care and gentleness. We then discovered that this had but partially controlled the hæmorrhage, and I made further search in the region of the spinous foramen of the sphenoid bone, thinking that perhaps the main trunk of the middle meningeal was injured, but, upon pushing the brain aside, I found that this was not the case. My patient being in a not very favorable condition, I decided to trust to pressure, by means of strips of iodoform gauze, for controlling the flow of blood. Taking several narrow strips, they were inserted one after another into the side of the middle fossa of the skull, the ends being left projecting from the temporal end of the wound. Before closing the latter I endeavored to suture with catgut thread the wound in the dura mater near the superior longitudinal sinus, but found that there was so little of the membrane left toward the side of the sinus that the stitches would not hold. Therefore, having inserted a catgut drain into the lacerated brain substance, I placed over the tear in the dura another compress of iodoform gauze, taking the ends of the strips out of the extremity of the wound at the median line. A rubber drain having been laid across the wound in both directions, and some fragments of bone thrown upon the dura at the position where the greatest deficiency of bone existed, the wound was hastily sutured and an antiseptic dressing applied, the ear being well dusted with iodoform and a dossil of bichloride cotton placed in the meatus.

The patient was put to bed, an ice-bag applied over the dressing; he was given one-fourth of a grain of calomel with one-eighth of a grain of opium every three hours, his diet consisting of one pint of milk daily. He remained conscious and manifested no observable paralytic symptom. For the first three days the temperature, at its highest, reached 101°, and only twice thereafter was it above 100°. The dressing was changed for the first time on the third day, when it was found saturated with a sanguinolent discharge. It was renewed again on the fifth day, being again soiled with bloody drainage. On the seventh day acute symptoms of ptyalism developed and the calomel was discontinued. That night and the following one the patient was somewhat delirious. On the fifth and eighth days the iodoform compresses were removed. The drainage-tubes were gradually shortened and at subsequent dressings finally removed. The wound healed quite promptly, and the patient was allowed to get out of bed for the first time on the 4th of March.

I asked my colleague, Dr. Albert G. Heyl, of the ophthalmic staff of the hospital, to examine the patient's eyes, as he has frequently done in other cases of cerebral injury in my wards. He reported finding no lesions of the fundus of either eye, but that there was diplopia due to paralysis of the external rectus muscle of the left, which he thought might have been due to orbital ecchymosis. This symptom, diplopia, is the only remaining inconvenience which the patient suffers. He was discharged from the hospital shortly before the end of March.

PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

LECTURE II.

Gentlemen: Last week we reviewed the valvular lesions implicating the left auriculo-ventricular orifice. To-day I propose to discuss those murmurs which are produced at the aorto-ventricular outlet. First of all, however, I desire to show you a patient who has three well-defined cardiac murmurs, and one that is less distinctly marked, that you may appreciate how easily these murmurs can be recognized and placed, by following the topographic scheme which I have arranged for locating the point of maximum intensity and the direction of transmission. Having settled these two points accurately, we are enabled to say just what the lesion is, and then to add all the other combinations that are commonly given in teaching the physical diagnosis of cardiac murmurs. As, for instance, having decided that a mitral regurgitation is present, we can say that there is a systolic murmur at the apex, that it occurs with or takes the place of the first sound of the heart, and that it is synchronous with the pulsation of the apex and radial pulse, etc.; but we are not compelled to confuse our mind with all these conditions before we decide as to the presence or absence of an abnormal cardiac sound. By studying these areas in routine order, and deciding as to whether abnormal sounds existed or not, and determining the direction in which they were transmitted, I have been able to verify my diagnosis at the post-mortem in almost every instance in which the opportunity has presented for an examination after death, until now I feel quite confident in regard to the diagnosis in this class of lesions. Without a large experience, however, in the post-mortem room, we have absolutely nothing upon which to rest

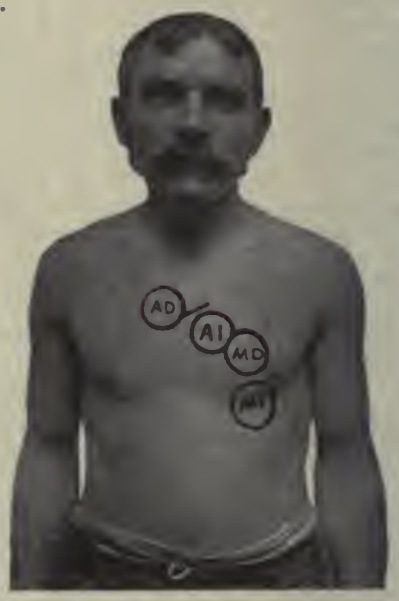
[1] A series of lectures delivered at the New York Post-Graduate Medical School and Hospital.

the certainty of the diagnosis that may be made. Unfortunately, too many of us are compelled to go through our whole medical career without ever having had the opportunity of personal and practical training in this most important branch of medical science—the combined clinical and post-mortem work. The more frequently we can place ourselves upon record as to the diagnosis, and have it confirmed or overthrown by the result of the necropsy, the greater will be the probability of obtaining skill in diagnosis.

Our patient, Mr. M. B., aged thirty-three, baker, first came under the observation of Dr. Adolph Zet, one of the instructors in my department, early in September last. At this time he stated that he had not been well for three years. During these years he has had several copious hæmorrhages from the bowels, each lasting about three days. In the intervals between the occurrence of the hæmorrhages the bowels have been fairly regular, but with a tendency to be constipated. He has also suffered a good deal from headache and vertigo, the latter especially after running up stairs. He has become very anæmic, and has developed considerable œdema of the lower extremities. Our patient has also suffered a little from dyspnœa, but has had no troublesome cough. His tongue is coated, pale and flabby. At one time, for a few days, he spat up some blood; aside from this, there is no evidence of hæmorrhage, either from the lungs or stomach. There is no history of scarlet fever, rheumatism, Bright's or any of the diseases commonly classed among the causative agents in producing endocardial lesions and valvular defects, with the exception of syphilis. The patient was placed upon laxatives and the heart tonic that we use for these cardiac affections, the formulæ of which will be given when we come to discuss the treatment of these lesions in general. Iron was also administered. The result of the treatment has been to improve his general condition and overcome in part the anæmia. The cardiac murmurs, however, have become more sharply defined, but the mechanical action of the heart has been very much improved. Physical examination, gives the following results: Inspection shows the patient to be somewhat anæmic; though in apparently full flesh, his tissues are soft and flabby. The apex impulse is not well defined or sharply limited. The subclavian arteries, however, are seen to pulsate very distinctly as they pass over the first rib. His respirations are shallow and hurried; the pulse is of the shot or bead-like character. Palpation and percussion yield a comparatively negative result. There is, however, without doubt, a moderate amount of cardiac enlargement, due to hypertrophy or dilatation, or both combined. We shall be able to determine this fact with greater accuracy after an auscultatory examination, for then we shall be able to decide what the exact mechanical defects are, to what degree they have advanced, and how much compensatory hypertrophy or cardiac dilatation has been developed. By percussion alone we may be led into gross mistakes, as I have frequently witnessed in making necropsy examinations. I recall one instance in which a number of gentlemen had examined the case and found, by percussion, a marked enlargement of the heart, but an absence of all other signs and symptoms that would warrant the opinion of cardiac hypertrophy or dilatation. At the post-mortem examination, the heart was found to be unusually small and weighed only six ounces, or one-half the normal maximum weight. Such results, frequently repeated at the deadhouse, have led me to be very sceptical in regard to the diagnosis of cardiac enlargement based upon percussion alone. There are so many conditions associated with the rise and fall of the diaphragm and the adjacent left lobe of the liver, and the expanded and contracted state of the lungs, that percussion at best is an uncertain sign, and very little reliance can be placed upon it in regard to cardiac enlargement. On the dead subject, as practised by the late Professor Alonzo Clark and Dr. Cammann, when everything is still and immovable, accurate results might be obtained, but not in the living subject, when everything is in motion and constantly changing position.

Upon auscultation of our patient, we find within the circle or mitral indirect area, which is lettered M I on our patient and in the chart, Fig. 1, instead of the normal first sound of the heart, an abnormal or blowing sound,

Fig. 1.



called a mitral indirect murmur. Further, we find that this sound is transmitted to the left along the sixth rib, that it is lost at the anterior axillary line, and that it is heard quite distinctly posteriorly, within the circle M I on our patient. Having ruled out the clear first sound of the heart, and heard in place of it at the anterior mitral indirect circle, and also posteriorly, the same sound within the ring M I, we are justified in saying that there is a leakage at the bicuspid valve orifice. As the murmur has not disappeared, although the general anæmia has improved under the treatment, we are confident that organic changes will be found in the left auriculo-ventricular valve if we have an opportunity to examine the patient after death. There is also a faint abnormal sound or mitral direct murmur, heard with greatest intensity within the limited area lettered M D on our patient and in the chart, see Fig. 1. This sound or murmur is of very short duration, and is not transmitted. You may find some difficulty in detecting this murmur, as it is

masked to a certain degree by the aortic and mitral indirect murmurs. But if you listen intently you will catch a decidedly abnormal sound, which is distinctly limited to the circle M D; if you move the chest piece of your stethoscope outside this area the murmur is entirely lost, and you will observe that its character is entirely different from the transmitted sound of the aortic or mitral murmur, with which it might be confounded. Thus we are enabled to decide that a certain amount of obstruction is offered to the current of blood from the left auricular cavity to that of the ventricle. In this particular case I believe the mitral direct murmur is due to the blood regurgitated at the aortic valve, falling into the ventricular cavity and floating up one of the segments of the bicuspid valve, as described in our last lecture. There is also a double murmur at the aortic valve, which you will fully understand after we have studied in detail all the lesions and murmurs that can be produced at the aorto-ventricular outlet. The abnormal sounds developed at this aorto-ventricular orifice are best divided into three general classes: *first*, those due to organic changes in the valve segments and the aorta, or in the substance of the ventricular wall as a whole; *second*, those due to congenital perforations in the segments of the aortic and pulmonary valves; *third*, the so-called hæmic murmurs.

In reference to the etiology of the first class of murmurs engendered at the aorto-ventricular outlet, they are, like those developed at the mitral orifice, due to congenital defects, seriously narrowing the aortic aperture or preventing juxtaposition of the three cusps of the valve, thus producing positive stenosis or incompetency. This form, or the congenital type, however, is exceedingly rare and in all my experience I do not remember to have seen a typical instance of the kind. The most frequent cause of valvular defects at the aortic outlet is secondary change in the segments due to an acute or chronic endocarditic lesion extending to and involving the valve, or the development of an acute or chronic endocarditic lesion on or near the valve, both of which ultimately involve the substance of the individual segments, causing vegetative outgrowths, stenosis, or thickening and retraction, with incomplete closure. Stenosis or incompetency may be developed independently of each other; but more frequently the two conditions are combined. If we comprehend the method by which these lesions in the aortic segments are brought about, it is easy to understand why a stenosis is most likely to be produced first, to be, later, followed by an incompetency of the aortic valve, causing the double murmur. Acute and chronic dilatation of the left ventricular cavity may result in a separation of the aortic segments to such an extent as to cause an incomplete closure of the aortic valve. From my experience of twelve years at the post-mortem table, I am fully convinced that acute dilatation is far more frequent on the printed pages of books than it is in the chest cavity of the individual, either during life or after death. Rupture of a segment of the aortic valve from its peripheral margin to its attached base will cause an insufficiency. Splitting of a segment in this manner is occasionally found at the post-mortem examination, in cases that have suffered from severe falls or crushing injuries implicating the thorax. I doubt the ability on the part of any human being to survive an injury of sufficient magnitude to lacerate the segment of a normal valve. As yet I have never seen any good evidence of such a case. I can recall one instance in which a rupture of an aortic segment was diagnosticated during the life of the patient, subsequently to a slight fall, by a most competent observer; when I made the necropsy, a few years later, the segments of the aortic valve were found to be normal and intact, and the true cause of the murmur proved to be a very small sacculated aneurism of the wall of the aorta just beyond the valve. In over two thousand necropsies, I have found only two cases of indisputable rupture of a cusp of the aortic valve and but one in which a mitral segment was lacerated; but in all three, death followed in a few hours after the reception of the injury supposed to be the cause of the rupture. At the aorto-ventricular aperture, we have an axial line upon which all murmurs are developed and transmitted. The direction of this axis is through the centre of the aorto-ventricular outlet from below upward, from left to right, and from before backward, following the natural course of the blood stream. All the murmurs, therefore, which originate at the aortic valve must necessarily be produced by the current of blood flowing through the now abnormal opening, either in the direct or in the indirect or inverse direction to the normal blood stream, or at right angles to a line drawn obliquely across the sternum opposite the third costal cartilages, as shown between the rings A D and A I in Fig. 1. The position of the aortic valve is behind the sternum, very nearly behind the oblique bar marked on the sternum in the chart, Fig. 1, and on the integument over the sternum of our patient. All abnormal sounds developed at this outlet will be due to an obstruction to the current of blood as it is thrown from the left auricular cavity through it into the aorta, or to the failure of the aortic valve to close tightly and prevent the leakage of blood back into the cavity of the left ventricle, which must of necessity follow incomplete closure.

Having developed the lesion, obeying the common law of production and transmission of cardiac sounds, we find that, if there is a stenosis or obstruction to the current of blood as it normally leaves the ventricle to reach the aorta, a murmur will be produced and heard just beyond the seat of its production, which is at the aortic aperture; or in the second intercostal space on the right side at the sternal margin, as indicated by the circle lettered A D in Figs. 1 and 2. This murmur will be produced by the blood passing in its natural course to the aorta and great vessels, and will be transmitted into them and heard with almost equal intensity over the subclavian arteries and the common carotids in the neck. When it is loud at the seat of development it will also be heard posteriorly where the aorta commences to impinge against the spinal column or over the fourth and fifth vertebræ. On the other hand if there is an incomplete closure of the aortic valve, the arterial tension forces some of the blood back into the ventricle and causes an aortic indirect or regurgitant murmur. This abnormal sound, according to the common law of development and transmission, is heard just below and to the left of the location of the aortic valve, or at the junction of the third intercostal space of the left side with the sternum, as indicated by the circle lettered A I in Fig. 1, and in our patient.

The natural course of the transmission of this murmur is primarily governed by the direction of the blood stream which caused its production and would be downward and forward toward the apex. This is true in part,

FIG. 2.

but, developed as it is, when the ventricle is expanding against the sternum, which is a dense structure, the common physical law of transmission of sound is obeyed, and the murmur is distinctly transmitted down the sternum and often heard with the same intensity over the xyphoid appendix as at the point of origin. In the second variety, or those due to congenital perforations in the cusps of the aortic and pulmonary valves, we often hear the same well-defined physical signs described in the case of an active and positive lesion producing incomplete closure of the aortic valve orifice. Having met with a large number of cases in the clinic in which positive evidence of aortic regurgitation was found, but in which the rational symptoms would not warrant the belief that a large leakage of blood from the aorta to the ventricle occurred, an attempt was made to find in the deadhouse a rational explanation for what at first appeared to be contradictory evidence. This resulted in finding a large percentage of cases that showed in the cusps of the aortic and pulmonary valves numerous little sharp-cut and distinct holes or perforations, located just behind the free margin. These openings varied in size from minute pin-point-like apertures to holes having a diameter of a quarter of an inch or more, and the number varied from one to a dozen. The clinical phenomena became at once perfectly clear; for any one who has attempted to make the valve of a mechanical suction and force-pump work perfectly tight knows how small an aperture will cause a leakage, and the same law unquestionably holds true here. Blood forced through these sharp-cut holes where the valve is tense and the edges in juxtaposition naturally causes a loud sound, while the volume of leakage back from the aorta into the left ventricle is too small to produce any dilating effect upon the ventricle or mechanical interference with the part acting as a pump.

That these apertures are congenital in origin appears to be true from the fact that they are sharply cut, as if punched out of the normal valve, and also from the absence of any of the common evidences of endarteritic or endocardial lesions implicating the valve segments, singly or as a whole. But for the presence of these holes the valve would be absolutely normal. They are also found from intra-uterine existence up to the advanced period of life, which also favors the congenital origin. These perforations have been observed by many, probably by all pathologists, but they are not generally recorded, from the fact that otherwise the valve was considered free from disease and also because they were regarded as of no particular account. I have often heard this remark, "A large per cent. of cases had them," and there it has ended. But when we note the facts that a large number of individuals present during life marked physical signs of aortic regurgitation, without the ordinary rational signs and in the absence of general discomfort; that many of these cases die from intercurrent diseases and the aortic valve is found to be thoroughly competent at the post-mortem with the exception of the leakage through these holes; that some of our most competent clinical teachers make the broad statement that individuals having well-marked physical signs of aortic regurgitation attain a good old age, when true aortic regurgitation is regarded as the most fatal valvular lesion; that some state that an aortic regurgitation gives the greatest expectation for life, and further that the statement is made that in a large percentage of instances the post-mortem examination does not sustain the diagnosis made during the life of the individual, it seems to me time to attach some importance to this lesion, and to place an interpretation upon our signs and symptoms which will enable us to have our diagnosis confirmed in the deadhouse in almost every instance—it may be asking too much to say in every case, but the error ought to be the exception to the rule and not the frequent result. Since taking this view of the subject and working upon its principles, my diagnosis has generally been confirmed at the autopsy. I have frequently diagnosticated these congenital perforations before the class in this room, and later have had the privilege of showing the same class the heart containing these perforations which they had previously listened to in life. Aortic regurgitation from incomplete closure of the aortic valve can be differentiated from regurgitation due to congenital perforations by observing the following differential points:

Aortic Regurgitation from	
Incomplete Closure.	*Congenital Perforations.*
Physical signs almost the same, except marked cardiac enlargement.	Physical signs almost the same. No uniform enlargement of heart.
Marked subclavian pulsation.	No subclavian pulsation.
Shot or bead-like pulse.	Pulse normal.
Marked dyspnœa.	No dyspnœa.
Cardiac interstitial pneumonia.	No brown induration of lung.
Cough, with bloody sputum.	No cough or sputum.
May have pulmonary hæmorrhage.	No pulmonary hæmorrhage.
Dropsy usually marked.	No dropsy.
Great general discomfort.	No general discomfort.
May be improved by treatment.	Not affected by treatment.

The comparative study of these two classes of murmurs shows conclusively that we must not be governed exclusively by the loudness and intensity of the abnormal sounds in the diagnosis and prognosis, but we must carefully consider all the evidences presented, before coming to a final conclusion. Above all things, never make a diagnosis or prognosis upon a single examination, but insist upon placing the patient upon suitable treatment and several examinations, and then a wonderful degree of accuracy in diagnosis can be obtained.

Hæmic murmurs, so-called, may be produced at the aortic and mitral orifices in very anæmic subjects. They may be of the direct or indirect variety. When due simply to changes in the blood which alter its density and render it more irritating to the poorly nourished valve-orifices through which it passes, they are usually of the direct type. A direct murmur may be produced both at the mitral and aortic orifices in every anæmic case, but, as a rule, they are not, unless the anæmia is very pronounced and of considerable duration. More frequently, however, the anæmic state of the system disturbs the nervous innervation of the heart or impairs the nutrition of its muscular wall, and causes an incomplete closure of the mitral valve and a mitral indirect murmur, as already described in the last lecture. In rare instances the left ventricular wall may become thin and its cavity dilated so as to prevent a complete closure of the aortic valve, and thus establish an aortic regurgitation. The diminished volume of blood in anæmia, however, will generally prevent any dilatation. The hæmic murmurs will be heard and transmitted in the same manner as the murmurs already described as occurring at the mitral and aortic orifices. They are differentiated from the other forms of murmurs by the anæmia, and the disappearance of the murmur with the removal of the anæmic condition.

You may have noticed in following me, that I have made no mention of the valves of the right side of the heart, except in my description of the pathological changes which are developed from a primary mitral incompetency. Neither had I intended to, but finding since my last lecture that much doubt existed in the minds of some as to the amount of value to be attached to the physical exploration of the right side of the heart, I have concluded to make a few remarks upon the subject in question. During a period of more than twelve years of continuous work in the deadhouse, in which time the number of post-mortems witnessed has reached thousands, I only saw one instance in the adult subject in which there was a primary lesion of the valves upon the right side of the heart, and that was a congenital incompetency of the pulmonary valve. During the life of this patient, although examined carefully by most competent observers, the primary lesion was regarded as an aortic insufficiency, with secondary changes at the pulmonary and tricuspid valves. The pulmonary and tricuspid leakage could not be overlooked, on account of the marked jugular pulsation which was synchronous with the systolic action of the ventricles, the general venous engorgement and the cyanotic state of the system. But none of the examiners detected or recognized a tricuspid regurgitant murmur; the chief cause of the murmur at the base was supposed to be due to incomplete closure of the aortic valve, followed by a similar defect at the ventriculo-pulmonary orifice. Neither have I ever heard a tricuspid indirect murmur, even in cases in which a large volume of blood was continually flowing back into the great veins, as is frequently observed when the pulmonary valve becomes incompetent, as described in the circle of pathological events which follow in order the mitral regurgitation described in my first lecture.

I have often heard a murmur over the "triangular præcordial space," described by some authors as the "tricuspid area," but the post-mortem examination in these cases always revealed numerous perforations in the cusps of the aortic and pulmonary valves, which defects, to my mind, most thoroughly explain the cause of the murmur heard during life, for in their absence the murmur is not heard, and the frequency of the perforations found post-mortem helps to explain a possible mistake. There are also anatomical and physiological reasons why tricuspid regurgitation cannot occur and give rise to a murmur, and especially if the pulmonary valve is competent. It is a well-known anatomical fact that the tricuspid valve is not capable of being closed perfectly at any time, and yet mechanical regurgitation does not occur to any extent. This fact is explained by the perfect closure of the pulmonary valve, which is rarely the seat of pathological lesions during adult life, together with the powerful aspiratory force of the respiratory act, which is constantly producing a large vacuum, as it were, in front of the right heart, so that normally the right ventricle is best described as pumping into a vacuum, which tends to suck the blood from the veins and keep up a constant flow of blood from the veins into the right auricle and ventricle. This reduces the possible chance of regurgitation from the right ventricle into the right auricle and veins, while the pulmonary valve is competent to an almost inappreciable minimum. It is far easier to suppose that the right heart will, and can, pump more easily into a vacuum than against the simple zero pressure of the great veins. Taking into consideration this powerful aspiratory force, and the fact that the venous capacity of the system is about three times as great as the total bulk of the blood, and then admitting that considerable tricuspid regurgitation does occur, it is even now hard to comprehend how the regurgitated blood from the auricle could cause disturbance enough in its backward flow to produce a murmur capable of being detected, because the pressure of the right ventricle is low and the resistance to the outflowing blood almost inappreciable. It is not logical to compare tricuspid insufficiency to the mitral lesion, in which the left ventricular pressure is very great, and being favorably influenced by a constantly increasing auricular and pulmonary tension, aided after a short time by that of the right ventricle. If the tricuspid regurgitation is secondary to profound lesions on the left side of the heart, and finally at the pulmonary valve, the murmur, if one is produced at the tricuspid valve, will be masked by murmurs of higher pitch and wider diffusion, which are already developed at the other valves where the mechanical strain is very much greater, and where the reversed or opposing blood-currents will produce more decided disturbances in the mechanism of the heart and its valves. Then, again, if we stop and consider for a moment the direction of the current of blood which is capable of pro-

ducing tricuspid regurgitation, and the laws which govern the production and local point of intensity of the murmurs and their transmission, we find another obstacle to the development of the sound of this murmur where it is commonly said to be found. The axial line for the right auriculo-ventricular orifice corresponds to a line drawn from left to right from before backward, and from below upward; or on an axis transfixing the body from before backward, from left to right, and from below upward, starting in front on the left side at the junction of the fifth costal cartilage with the sternum, passing through the chest, coming out posteriorly at the fourth intercostal space at the posterior axillary line. The tricuspid valve is situated on the line of this axis behind the right border of the sternum, opposite the junction of the fifth costal cartilage and the fourth intercostal space of the right side. The point, therefore, at which the tricuspid murmur could be heard with the greatest intensity would be just beyond the seat of the valve, or over the junction of the fifth costal cartilage and the fourth intercostal space, immediately beyond the right border of the sternum. Following the direction of the current of blood producing the murmur, it ought to be transmitted toward the centre of the right lung. In the transmission of the tricuspid regurgitant murmur, if it ever occurs, we cannot take advantage of the sternum as a medium by which the murmur could be transmitted in an opposite direction to the current of blood which is producing the abnormal sound, as is done in the mitral regurgitation. The reason for this assertion is that, at the time of the systole, the right heart is rolling backward under the cover of the right lung, and away from the sternum, and at the same time the lung on the right side, with each inspiration, is being crowded in between the heart and the anterior chest wall, all of which will tend to prevent the transmission of a tricuspid regurgitant murmur back against the current by which it is produced, and will tend to prevent its ever being heard in the immediate vicinity of or over the sternum. Viewed in this light, and in face of the opposing post-mortem facts, when we come to analyze the evidence candidly there is comparatively no ground for believing that a tricuspid murmur is produced and heard over the sternum. It seems, however, almost a waste of time to discuss at this length a condition which is considered by many of the best observers as out of the question.

At our next lecture, gentlemen, we will consider the treatment of these cardiac affections, the physiological and therapeutic action of the drugs classed as cardiac tonics and stimulants.

MEDICAL PROGRESS.

Remote Effects of Removal of the Uterine Appendages.—In a paper "On the Remote Effects of Removal of the Uterine Appendages," read at the French Surgical Congress, LAWSON TAIT (*Medical Record*, May 2, 1891) repudiated the statement that permanent evil results followed removal of the tubes and ovaries for disease of the uterus or its appendages, or for the relief of nervous disorders. He distinguishes between the sequelæ following removal of the ovaries or of the testicles before the period of puberty and those resulting from removal when the organism has attained maturity. He maintained that the changes immediate and remote which followed removal of the uterine appendages for disease were analogous to those which take place at the menopause. The scientific tenor of the paper is somewhat ruffled by an occasional outburst of virulence against those who differ with Tait.

Hæmocyne (the Serum of Dog's Blood) in the Treatment of Tuberculosis.—HÉRICOURT, LANGLOIS and ST. HILAIRE (*Gaz. Méd. de Paris*, 6, 1881) had made 150 injections of from one to three cubic centimeters (fifteen to forty-five minims) of the serum of dog's blood in the treatment of a number of cases of phthisis. The injections were made in the lumbar region at intervals of two or three days, and were, as a rule, unattended with local or general reaction. Of the four cases reported, two had both pulmonary and laryngeal phthisis. In these two the condition of the larynx improved and the voice became stronger. In all the appetite improved, the cough and expectoration diminished, the night-sweats ceased and the weight increased. The physical signs underwent little change.—*Centralbl. für klin. Medicin*, May 9, 1891.

Tachycardia at the Menopause.—KISCH (*Wiener med. Presse*, May 10, 1891) has observed twenty-eight cases of tachycardia in women at the climacteric period. At the time of the menopause, rarely after complete cessation of menstruation, such women suffer occasional attacks of palpitation, often on slight or no provocation. There may be, besides, a sense of anxiety and oppression, arterial pulsation, fulness of the head, flushing, headache, mist before the eyes, ringing in the ears, vertigo, and possibly loss of consciousness. The pulse is 120, 150 or more, strong, full, and regular. Tracings show a large wave, with a sudden, rapid ascent and a similarly sudden and abrupt descent, almost reaching the base line before the occurrence of the secondary elevation, which is increased. The heart-sounds are clear and voluminous. Fugacious redness of the face, neck, and chest sometimes appears, attended with a sense of burning. The paroxysms may occur several times daily or at intervals of a number of days, and last from several minutes to a quarter of an hour. There is usually a condition of bodily and mental restlessness. In the majority of cases observed by Kisch there were evidences of plethora; the blood was found to contain an excess of hæmoglobin. There was neither marked dyspnœa nor cardiac asthma; manifestations of stasis were rare; œdema of the lower extremities was exceptional; the urine contained no albumin. The patients felt an unwarranted fear of apoplexy. The disorder may last from a few weeks to two years or more. It was attended with no injurious sequelæ. Systematic, gentle purgation, associated with suitable dietetic regulations, exercised a beneficial influence. Mountain air, a bland diet, active exercise, and cold affusions were useful. Bromides, in small doses, may be used for their sedative effect. Kisch ascribes the etiology to the changes in the ovaries at the climacteric period: hyperplasia of the stroma at the expense of the parenchyma, with retrograde metamorphosis of ovisacs, giving rise to

nervous irritation. An analogous explanation has been given to the tachycardia observed in hysterical patients and in women from whom the ovaries have been removed during the period of maturity—the changes resulting from consecutive atrophy causing irritation of nerve fibres.

The Source and Function of Pus Corpuscles.—Before the Academy of Sciences, RANVIER (*La Médecine Moderne*, May 7, 1891) expressed the view that the phenomenon of diapedesis is not sufficient to explain the rapid formation of large quantities of pus. Twenty-four hours after injection of a solution of nitrate of silver (3 : 1000) into the peritoneal cavity of a mammiferous animal, the so-called clasmatocytes have almost entirely disappeared, being replaced by a large number of leucocytes. Intermediate forms between these two may be observed. The irritation has induced in the clasmatocytes a return to the embryonal state; they are transformed into leucocytes, which multiply by division. Of two rats, into the peritoneal cavity of each of which six drops of a solution of nitrate of silver (3 : 1000) were injected, in one, at the end of twenty-four hours, the cavity contained a large quantity of purulent fluid; in the other, at the end of three days, no pus had formed. In the first instance, the pus corpuscles contained débris of varied character, red cells, fat granules, grains of albuminate of silver, cellular fragments, etc. The interpretation is that the injection caused the necrosis of a considerable number of cellular elements, the products of the destruction of which it is the function of the pus cells to remove, in order that the processes of repair may be carried on.

Microcidin—a New Antiseptic.—POLAILLON (*La Médecine Moderne*, April 30, 1891) presented to the Academy of Sciences the results of an experimental and clinical study of the product obtained by heating β-naphthol to liquefaction and adding half as much soda. To the white powder which results Berlioz has given the name of microcidin. While possessing feeble toxic qualities, the product is said to be a good antiseptic, easily soluble in water, and without odor or taste. While its antiseptic power is lower than that of bichloride of mercury and of naphthol, it is ten times that of carbolic acid and twenty-eight times that of boric acid. It is less toxic than naphthol. It is soluble in water, in the proportion of one to three. The remedy is not caustic, in the proportions in which it is to be employed; it is not irritating to wounds; it does not corrode instruments or destroy linen. It lowers normal and febrile temperature in animals, and is eliminated by the urine, upon which it confers the property of not decomposing. It may be used in proportions of 3 or 5 to 1000 parts of water.

Terebene, Terpine and Terpinol.—Terebene is isomeric with the essence of turpentine and is obtained by the action of sulphuric acid upon turpentine with distillation. As an antiseptic and disinfectant it is agreeable in odor and vaporized acts as a sedative and antiseptic in phthisis. Internally it is employed in capsules for the purpose of producing intestinal antisepsis and for the cure of dysentery. It is also sedative and antiseptic to the walls of the bladder when eliminated by the urine. It may be administered by inhalation in the steam of boiling water, or by the stomach in the form of tablets as follows:

℞.—Terebene	. . . .	4 drachms.
Powdered gum arabic	. .	4 "
Water	. . . . .	2 ounces.
Pulverized sugar	. . .	6 "
Powdered gum tragacanth	.	2 drachms.

Make into 100 tablets and administer one every four hours.

℞.—Terebene	. . . .	4 drachms.
Pulverized gum arabic	. .	4 "
Water	. . . . .	2 ounces.
Syrup of ginger	. . .	1 ounce.

Divide into 100 capsules.

Terpine is the hydrated essence of crystalline turpentine. It is obtained by bringing together four parts of essence of turpentine, three parts of alcohol and one part of nitric acid. After several weeks it forms in beautiful crystals. Terpine may be transformed in the presence of sulphuric acid into an oily body, terpinol. The therapeutical actions of terpine and terpinol are precisely those of the balsams, and these are, therefore, particularly useful in the treatment of catarrhal affections of the respiratory tract.

LEPINE has employed terpine as a substitute for turpentine, as an expectorant and diuretic, giving it in doses of from three to six grains. The influence of terpinol in cases of chronic bronchitis with profuse expectoration is very useful but the odor is somewhat disagreeable. Terpine may be given in the following manner:

℞.—Terpine	. . . .	30 grains.
Glycerin	. . . .	2 ounces.
Alcohol	. . . .	2 "

Two teaspoonfuls each day.

Or it may be made into pills of which from four to five are given every twenty-four hours; or it may be placed in capsules in the dose of one to two grains. Terpinol may be given in capsules in the following manner:

℞.—Terpinol	. . . .	15 grains.
Benzoate of sodium	. .	15 "
Sugar, a sufficient quantity.		

—*Journal de Médecine de Paris.*

A Case of Poisoning by Aconitine.—In *La Médecine Moderne* a case is reported of a girl, aged twenty years, who had suffered from a violent attack of toothache, to relieve which aconitine in powder form was given. Immediately after its administration the patient was seized with violent colicky pains and in the course of a few hours died.

At the autopsy it was decided that the death was due to the aconitine, and after the testimony of Brouardel that the doses of the various aconitines is not known with certainty, the physician who prescribed the remedy was fined 100 francs. It was also pointed out that it is dangerous to prescribe aconitine without specifying the variety of aconitine which the physician wishes the druggist to dispense.

The Prophylaxis of Ophthalmia Neonatorum.—DEHENNE (*Journal de Médecine de Paris*, March 15, 1891) states that of one hundred blind persons forty-five have lost sight as a result of ophthalmia neonatorum. The gravity of this affection has been amply demonstrated. In hospitals in which rigorous antiseptic precautions are observed, before and during labor, ophthalmia of the newborn does not arise. Every purulent ophthalmia, carefully treated, ought to be cured. As a prophylactic measure, the eyes of the newborn infant should be washed with a 1:2000 solution of bichloride of mercury, or one drop of a 1:200 solution of nitrate of silver should be instilled into the eyes. If the lids are swollen, absorbent cotton saturated with ice-water should be applied. The cold can be maintained by placing bits of ice upon the cotton. The applications should be discontinued as soon as the swelling has disappeared. The lids should be washed about every hour with a 1:1000 solution of bichloride of mercury. Morning and evening, four or five drops of a solution of 1 part of neutral sulphate of eserine in 200 of distilled water should be instilled into each eye. Once a day the conjunctival surface of the lid should be gently brushed with a solution of nitrate of silver, 1:50. It is useless to apply stronger solutions. The solid stick must not be used, because it produces an eschar which, desquamating, opens the portals for the entrance of streptococci and gonococci.

Exstrophy of the Bladder and Epispadias.—BERGER (*L'Union Médicale*, April 30, 1891) presented to the Academy of Medicine an old man with exstrophy of the bladder and epispadias, in the case of whom, autoplasty failing, a strip of tissue was brought down from the abdominal wall to the opening in the urethra, the margins of which had been freshened. A large area of tissue was removed from the scrotum and applied to the exposed portion of the bladder. After two minor supplementary operations, the result was successful.

Congenital Hypertrophy of the Hand.—RICHARDIÈRE (*L'Union Médicale*, April 23, 1891) presented to the French Society of Dermatology and Syphilography a case of so-called pseudo-hypertrophy of the hand and fingers, the increase in size being due to an excessive development of the subcutaneous connective and adipose tissues. In true hypertrophy, the soft parts, the tendons, and the bones are all increased in size. In the false variety, the condition is perhaps one of diffuse lipomatosis.

Treatment of Nocturnal Incontinence of Urine in Children.—OLLIVIER (*L'Union Médicale*, April 21, 1891) recommends the introduction into the bladder of a small insulated sound tipped with a metallic button and connected with one pole of a battery, the other being applied to the pubes or the perineum. Weak currents are at first used. Twelve to fifteen applications are usually necessary to obtain a curative result. This treatment failing, belladonna or strychnine should be administered.

Treatment of Tuberculous Endometritis.—JOUIN recommends dilatation of the cavity of the uterus by means of a laminaria tent which has been placed for at least twelve hours in iodoform-ether, and, at intervals of several days, packing the uterus with iodoform gauze. Internally, creasote is administered. Sexual intercourse is interdicted until recovery is complete.—*L'Union Méd.*, April 28, 1891.

For Hay Asthma.—

℞.—Cocainæ hydrochlor. . . 1½ drachms.
Glycerini . . . . 3 fl. drachms.
Aquæ destil. . . . 5 "

Sig.—At the onset of the attack make two applications, with an interval of five minutes, by means of a brush, to the accessible nasal mucous membrane.

℞.—Cocainæ hydrochlor. . . ½ drachm.
Benzoini, pulv. . . . 1½ drachms.
Sacchari, pulv. . . . ½ drachm.

Sig.—Use as a snuff.
—*L'Union Méd.*, April 18, 1891.

For Herpes Genitalia.—(BESNIER.)

℞.—Acidi tannici . . ½ drachm.
Bismuthi subnitratis . 6 grains.
Pulvis amyli . . 12 drachms.

Sig.—Dust locally the region the seat of the herpes, after washing with dilute carbolized water. If ulceration exists, astringent dressings should be used. If the skin is dry, inunctions of vaseline should be used.—*L'Union Méd.*, April 25, 1891.

Cyanide of Gold.—Cyanide of gold is a yellowish, crystalline powder, without taste, insoluble in water, alcohol and ether. It has been given for the cure of scrofula, phthisis and amenorrhœa, in the following formula, by OESTERLEN. The dose is from $\frac{1}{60}$ to $\frac{1}{10}$ of a grain.

℞.—Cyanide of gold . . . 2 grains.
Chocolate . . . . 1½ ounces.

Make into twenty-five powders, and give from two to four each day.—*La Médecine Moderne.*

Treatment of Coryza.—

℞.—Salicylate of sodium } of each . ½ ounce.
Syrup of orange }
Peppermint water . . . 4 ounces.

At the onset of the attack a teaspoonful to a dessertspoonful should be given every three or four hours.—*Journ. de Méd. de Paris.*

Pilocarpine in Œdema of the Glottis.—MENDOZA (*La Semaine Médicale*, May 6, 1891) reported to the French Society of Otology and Laryngology the case of a young man with œdema of the glottis, in which two colleagues advised surgical interference. Detecting with the laryngoscope a small aperture in the midst of the swollen structures, Mendoza proposed the subcutaneous administration of pilocarpine. Accordingly, somewhat more than a third of a grain of the alkaloid was given in three doses, in the course of twenty minutes, with the happiest result. In the course of a week the patient had completely recovered.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

AN EDITORIAL CHANGE.

WITH the issue of THE MEDICAL NEWS for June 6th, the editorial management will pass into the hands of Dr. George M. Gould, of Philadelphia. In succeeding to the editorial chair Dr. Gould brings not merely a well-won reputation for both literary and medical training, but also an experience which amply guarantees that THE NEWS will well maintain its character as a periodical devoted to the highest interest of practical medicine.

The retiring editor desires to thank those who have contributed to the columns of THE MEDICAL NEWS, not only for their valuable articles, but also for the kindly courtesy which they have invariably shown him—a courtesy which he is confident will be extended to his successor.

THE UNIVERSITY OF PENNSYLVANIA AND HIGHER MEDICAL EDUCATION.

ON May 21st Dr. Pepper submitted to the Board of Trustees and the Medical Faculty of the University of Pennsylvania a proposition to subscribe on his part the sum of $50,000 toward a permanent endowment fund of $250,000, and also for five years the sum of $1000 annually toward a guarantee fund of $20,000 per annum. These propositions were conditioned upon the completion of the subscription to the endowment and guarantee funds before January 1, 1893, and upon other minor matters of detail, but principally upon the decision and announcement of the University before June 1, 1891, that a four-year obligatory course of medical study should be established on or before September 1, 1893.

There can be but one opinion concerning this generous and vigorous action of Dr. Pepper. The movement deserves the most unqualified support of all, and it is to be hoped that the necessary amounts may be subscribed in a short time. We understand it was reported at the meeting that the Medical Faculty had contributed about $10,000 of the entire guarantee fund, and that the conditions would in time be fulfilled.

The principal object aimed at—the four-year obligatory graded course—is one that deserves the sympathy of all. It has of late become more and more evident that two, and even three, years of preliminary study are insufficient to worthily and adequately equip young men for the best work in the medical profession. The multiplication of post-graduate courses of study, the efforts to raise the standard of admission, the painful unfitness of many graduates for the duties of their work, have served to bring the want more plainly before the mind. Why not do the preparatory work before, rather than after, graduation? Experience and learning are far more readily acquired under the eye of trained teachers than when the physician is placed in charge of those whose lives depend on his ability to deal with disease.

The generosity of Dr. Pepper and his associates will again advance the University in her proud office of leader in scientific and progressive medicine in the United States. It is in this spirit that men work who are conscious of the high import of the interests confided to their care and of the profound rôle scientific medicine has to play in modern life.

There is the greatest difference between being driven by an aroused public sentiment, or drawn by a shrewd self-interest, into taking a hazardous stride forward, and this other way of bravely placing the standard in advance, and with determination bracing oneself to a purpose of realization of one's own ideal whilst calling upon the laggard world to "come up higher." Provost Pepper and his fellow-workers have chosen the latter plan, and our profession has the best reason to congratulate itself and to pray for its speedy realization. But such

an actualization depends upon each of us—in part, even upon the humblest—and everyone should take to himself the admonition to give—if not money, what is often of greater value—his word of encouragement and his lift of helpfulness. Toward this end THE MEDICAL NEWS would most heartily signify its good-will by calling the attention of its many readers to this proof of noble enthusiasm, and by asking everyone to contribute his mite, each in his chosen way.

REVIEWS.

MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D. Third edition. Philadelphia: P. Blakiston & Son, 1891.

WE are glad to find that Dr. Reese has seen fit to enlarge and add to the already valuable material in this work the latest decisions and advances in medico-legal matters. The interest of the public at large, as well as of physicians, in medical expert testimony has been stirred to its depths lately by the numerous criminal trials in which prominent practitioners have been engaged. Unfortunately in many of our medical schools this important subject is too often given a very secondary position in the curriculum, so that such a standard text-book as the volume in question is an absolute necessity to the physician. The author explains thoroughly, in the opening chapters, the duties of the physician in medico-legal cases. He describes the observations he should make, the proper method of arranging and preserving such information, and to what, and how, a physician should testify in court. He points out the difference between the position occupied by the physician who is a witness merely as to facts, and his who is called to give expert testimony. Of the two, very different questions are to be asked, and Dr. Reese denounces the methods of cross-examination now so much in vogue.

Then follow chapters upon the signs of death and the detection of the immediate cause, and directions to be followed in making a post-mortem. Chapters on poisoning, feigned disease, pregnancy, criminal abortion, rape, insanity, and malpractice bring the book to a conclusion.

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY FOR 1890. Edited by HENRY C. COE, M.D. Philadelphia: Wm. J. Dornan, 1891.

THE volume before us contains the minutes and papers read at the fifteenth annual meeting of the Society, which was held at Buffalo, N. Y., in September last. A careful perusal of the many papers read, with the accompanying discussions, cannot fail to be of interest to all physicians, whether they be gynecologists or not. The elaborate research exhibited in the paper upon "Subpericranial Blood-tumor of the Newborn," by Dr. H. A. Kelly, is instructive in the highest degree. Dr. J. M. Baldy makes a most welcome contribution to our knowledge of the "Diagnosis and Treatment of Early Ectopic Gestation," in a paper which places clearly before one the various symptoms of extra-uterine pregnancy, and urges forcibly the necessity of prompt operative interference. Other papers are contributed by such well-known authorities as Drs. Skeene, Coe, H. T. Byford, Jenks, and Reynolds.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Forty-second Annual Meeting, held at Washington, D. C., May 5, 6, 7, 8, 1891.

[Continued from page 592]

THIRD DAY.—SECTION OF GYNECOLOGY AND OBSTETRICS.

The important subject of the "Comparative Merits of the Electrical and Surgical Treatment in Cases of Uterine Myomata" formed the topic for discussion in the Section of Obstetrics and Gynecology on Thursday morning, May 7th.

DR. MASSEY, of Philadelphia, opened the discussion with a paper narrating his results in the treatment of thirty-nine cases by electricity. His methods were those employed by Apostoli, with the exception that he seldom made deep punctures, but confined the insertion of his needle to a distance of about one-third of an inch. He reported five cases as cured, twenty-three cases of smaller tumors lessened in size, eight cases in which symptoms were relieved, two cases in which nothing was accomplished, and one case made worse by the treatment. His percentage of cures was 12.8; about three-fourths of the cases had their symptoms relieved; and in the two cases in which he failed to produce any effect, the tumors were inaccessible without danger to the patient. The case in which the failure of electrical treatment was followed by which injury was done was that of a fibro-cystic tumor, in an attempt to remove the tumor piecemeal, which ended in septic infection and death. His method of making punctures is that known as buried punctures, the needle being insulated with rubber to a point one inch from its extremity. The tissues, after such puncture, healed rapidly and without reaction. He exhibited electrodes tipped with platinum, some of them elastic and coated with shellac, which allowed disinfection with the alcohol lamp; he also presented a current-controller. It is his custom to allow five or seven days to elapse between intra-uterine applications. He had found benefit also from vagino-abdominal applications. In conclusion, he urged that a better knowledge of the successes of surgical operation in these cases is demanded before a fair comparison can be made between surgical and electrical treatment.

As a criticism upon the claims made by electricians, DR. WERNER, of Philadelphia, read a statistical paper, claiming a superiority for surgical over electrical treatment, and narrated the case of a patient having a multinodular tumor from whom she removed the ovaries to check hæmorrhage; this persisting, however, owing to the presence of submucous growths, these were removed, when the hæmorrhage ceased.

Electricity was also championed by DR. MARTIN, of Chicago, who confined himself to assertions based upon

an experience with two hundred and fifty cases, from which he claimed that 75 per cent. of fibroid tumors of the uterus can be cured or improved by electricity, while 25 per cent. demanded operations. He had found that surgical treatment was necessary in cases in which he could not insert an electrode within the uterus without danger to the patient. (Dr. Martin was upon the programme for a paper upon electrical treatment, but made brief remarks instead.)

Another advocate of electricity, Dr. Bigelow, of Philadelphia, failed to put in an appearance, hence that side of the argument was represented largely by Dr. Massey. The surgical aspect of the question was opened by DR. EASTMAN, of Indianapolis, who described and illustrated his method of performing supra-pubic hysterectomy. After abdominal section he compresses the uterus and tumor by an elastic bandage secured by large pins put through the capsule; the uterus is then opened and the tumor enucleated. A large staff, devised by him, being passed from below to serve as a guide, the peritoneum is then stitched over the stump, the actual cautery having been used to sear the interior of the uterus to prevent its contents from escaping into the peritoneal cavity. He had performed these operations successfully in nineteen cases, and had met three cases in which the relations of the tissues were such that no pedicle could be formed. In his method of performing vaginal extirpation of the uterus, Dr. Eastman places the patient in Sims's position, securing the uterine arteries by a ligature passed with a large curved needle. He prefers the ligature to the application of compressing forceps, and brings the stumps of the broad ligaments, as far as possible, outside the peritoneum. He also exhibited vulsella forceps of large size, devised by him for grasping large tumors.

Three hysterectomies were reported by DR. OPIE, of Baltimore. Clamps were used to secure the pedicle. Two of the cases recovered and one, having a fibro-cystic tumor, died. Dr. Opie had given electricity a faithful trial for several years, but had observed no other result than an occasional cessation of hæmorrhage and an improvement in general health. He advised operation in all cases in which fluctuation is present.

DR. JOSEPH PRICE, of Philadephila, read a paper giving the details of fifty-three cases of hysterectomy, with three deaths. This paper will soon appear in full in THE MEDICAL NEWS.

DR. FLORIAN KRUG, of New York, did not believe that large fibroids could be successfully treated by electricity. He believed the best operative procedure to be total extirpation of the uterus and tumor, leaving no stump. He had found Trendelenburg's posture an aid in all abdominal operations; in feeble patients it did much to prevent anæmia of the brain. He requires for such operations only scissors, scalpel, aneurism-needle with ligature-needle, and ligature ordinarily employed. The finger of an assistant takes the place of the staff employed by Dr. Eastman; he often performed operations in thirty minutes—a difficult case requiring an hour. The ligatures and iodoform gauze used as dressing are brought out through the vagina. The gauze is left in for a week without danger; the bowels are moved on the day following operation. Dr. Krug considers the ligature much better than the clamp for checking bleeding.

From the standpoint of surgery, DR. BALDY argued that most cases of uterine fibroids need no treatment. Several agencies will relieve pain caused by such tumors, among these being various drugs and electricity. When a patient will not consent to a radical cure by operation, he advises palliative treatment, and in operating he much prefers the extra-peritoneal method of treating stumps.

An interesting case, showing an unusual result of electrical treatment, was narrated by DR. FRY, of Washington. After the use of the galvanic current, the current strength ranging from 85 to 200 milliampères, severe uterine contractions caused the expulsion of a piece of the tumor, eight inches in length; this was followed by septic infection.

The question under discussion was ably summarized by DR. SKENE, of Brooklyn, who pointed out the fact that the remedy should be chosen with reference to each individual case, whether that remedy be electricity or surgical operation. What is most needed is careful study in diagnosis, that proper discrimination may be exercised in the choice of remedies for different cases. We have not yet sufficient information to decide positively as to the comparative merits of the two agents; electricity will control many cases, especially if applied early, and operation can thus be avoided. The dangers attending the use of electricity are constantly becoming less; punctures can probably be avoided, thus eliminating one of the greatest sources of danger. It is a very significant fact that at present the death-rate from surgical operation in these cases is higher than the death-rate of cases which are not treated at all.

The most interesting contributions of the afternoon session on May 7th were the papers of Dr. Polk, of New York, describing "Operations for the Preservation of the Uterine Appendages;" an interesting paper by Dr. Skene on the "Treatment of Chronic Ovaritis;" and a study by Dr. J. W. Williams, of Baltimore, upon the "Structure of the Fallopian Tube." For the full text of Dr. Skene's paper the reader is referred to a later issue of THE MEDICAL NEWS.

DR. POLK reported forty-nine cases of disease involving the uterine appendages in which an effort was made to avoid their removal. In the majority of these cases the operations resulted in benefit. In fourteen cases in which the tubes were very adherent, the adhesions were broken up much to the patients' advantage. In three cases, after abdominal section, an exploratory incision into the ovary was made, and the patient subsequently improved in health. In four cases in which the ovaries were found very highly congested and displaced, they were suspended by sutures in their proper positions, and the congestion was relieved. In five cases small cysts in the ovaries were incised and emptied; an improvement in the patient's health followed. Four cases of resection of the tubes were described. Dr. Polk believes that if the ovary is sound and the tube is affected, it is advisable to resect the diseased portion of the tube, stitching the extremity in the vicinity of the ovary. In two such cases pregnancy and labor had occurred after the operation, and a good result had been obtained.

The paper of DR. WILLIAMS was illustrated by drawings of the microscopic anatomy of the tubes, demonstrating that the mucous lining contains but one layer of epithelial cells arranged in longitudinal folds. Three layers of muscular tissue exist, and at some points in the tube diverticula are found in which an ovum may lodge, favoring the development of ectopic gestation. Dr. Williams also showed that during fœtal life the tubes are twisted upon themselves, and that this condition in adult life may account for sterility and favor pyosalpinx.

As an interesting contribution to our knowledge of ectopic gestation, DR. FORMAD, of Philadelphia, exhibited photographs, and stated the result of 3500 post-mortem examinations, in which he had found thirty-five cases of ectopic pregnancy. The women were multiparæ, between twenty and forty years of age; were conscious that they were pregnant; and in all cases chronic inflammation of the tubes was present. Thirty-one of the cases showed ruptured ectopic gestation-cysts in the abdominal cavity; three were cases of interstitial pregnancy, and one was ovarian. In every case, severe mental or physical disturbance was followed by shock, pain, and bleeding; the amount of blood found in the abdomen varied from a pint to two gallons. All of the women were in early pregnancy between the first and third month. Dr. Formad considers ruptured ectopic gestation to be the only cause of hæmatocele.

In the discussion of these papers, it was agreed that the diagnosis of chronic ovaritis is practically impossible, except by microscopic examination. A tube in which purulent inflammation exists can never be useful, and should be removed; operation, however, should be followed by thorough constitutional treatment, especially addressed to the nervous system. Pain after operation is sometimes relieved by hot douches and the use of electricity. The drift of general opinion was decidedly against the removal of the tubes and ovaries for neuroses only.

"Minor Gynecology" was the subject of a paper by DR. BALDY, of Philadelphia, in which it was shown that the modern pathology of pelvic disease rendered irrational many minor operations formerly often performed.

The merits of the vaginal tampon were discussed by DR. SELLMAN, of Baltimore. Many uses of the tampon the speaker discouraged as useless and harmful, especially urging that the duty of the physician is to remove the cause of hæmorrhage rather than to seek to dam up the blood in the uterus by a tampon. Tampons interfere with the functions of the bladder and rectum, and sometimes result in forcing secretions backward through the tubes into the peritoneal cavity. They are useful to limit an agent applied to the interior of the uterus from coming in contact with the external parts; they are useful also in cases of scanty secretion; they are unreliable in the treatment of displacements, although the three tampons suggested by Mundé are sometimes very effective.

In the discussion upon minor gynecology, Dr. Sutton, of Pittsburg, believed in operating upon lacerated cervices when they cause suffering, and when there is no disease of the appendages. He believed that a lacerated cervix predisposes to cancer; he favored also the use of the dull curette, and had seen nothing but benefit from the use of iodoform gauze as a tampon, which could remain from seven to ten days with safety.

The only paper bearing directly upon obstetric practice was one read by Dr. BERNARDY, of Philadelphia, in which he described his experience in the treatment of posterior positions in face presentations. The danger of impaction was demonstrated and explained, and the treatment suggested was version when the chin was still as high as the brim of the pelvis, or craniotomy as soon as impaction occurred.

In the closing session on Friday morning, May 8th, DR. HUMISTON, of Cleveland, read a paper upon "The Use of Cocaine in Gynecology." He first administers a half ounce of whiskey to his patients, and then injects the site of operation with from fifteen to forty minims of a 4 per cent. solution. He had recently performed an extensive plastic operation, lasting an hour, with the use of three grains of cocaine. His operations are done under strictly aseptic precautions. Union by first intention was the rule. In the discussion of this paper the prevalent opinion was adverse to the claims of cocaine as a reliable anæsthetic, there being danger of constitutional poisoning, interference with union by first intention, and failure to control the pain.

A paper of value, describing studies in the infection of drainage-tubes carried on at the Johns Hopkins Hospital, was read by DR. ROBB. Sixteen cases were studied by inoculation of culture materials with fluid obtained from drainage-tubes. In nine cases no infection resulted; in six cases bacteria of but feeble power were found, while in one case septic infection and the formation of pus occurred. The principle of treatment advised consists in carefully guarding the orifice of the drainage-tube and excluding every source of external contagion. The tube is emptied, not by a syringe, but by bits of baked cotton handled by a slender sterilized forceps.

A simple and remarkably efficient tube devised for drainage was shown by DR. R. T. MORRIS, of New York. It consisted of a narrow strip of gauze covered by a band of protective material, in which many holes had been cut, and rolled to form a long wicking. When it is necessary to inject antiseptic fluids through the drainage-tube, a soft rubber tube is placed in the centre, and the other is rolled about it. Both varieties of tube were not likely to leave fistulæ, and had been found very efficient.

The remainder of the morning was occupied by papers upon "Peritonitis after Operation," by DR. SHIMWELL, of Philadelphia, and by DR. C. R. READ, of Ohio, upon "The Palliative Treatment of Cancer of the Uterus."

A general discussion upon the question of Antisepsis *versus* Cleanliness, showed that operators relied upon both, recognizing fully the importance of such studies as those of Dr. Robb.

The opinion was also expressed that operations of magnitude should be confined to specialists, and not entrusted to incompetent practitioners.

As a matter of business, it was said that seventy papers had been presented to the Chairman and Secretary of the Section, of which twenty had been excluded as manifestly unfit to be read; a resolution was therefore offered by Dr. Opie, that in future papers be limited to forty, and that the Chairman be empowered to make

such selection of papers as he deemed most advantageous for the Section. The Chairman was congratulated upon the programme which he had offered to the Section, and, in return, thanked its members for the courtesy and kind assistance which they had shown him; after which the Section adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 7, 1891.

ALFRED L. LOOMIS, M.D., IN THE CHAIR.

OBSERVATIONS ON THE USE OF KOCH'S TUBERCULIN IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

THE discussion was opened by Dr. Francis P. Kinnicutt with a report of his observations at St. Luke's Hospital. Forty-two patients were under his personal supervision in connection with this treatment, 13 of which were cases of pulmonary tuberculosis; in 6 of these there was tuberculosis of the larynx, of greater or less severity. The only point in the technique to which he specially called attention was the necessity of employing fresh solutions of Koch's fluid, as experience had shown that the carbolic acid solutions deteriorated by keeping. The initial dose for adults did not exceed one milligramme; at first the severity and duration of the general and local reaction was taken as the guide to the frequency of the re-inoculations, but later on it was found better to await the subsidence of the physical reactions and to study more closely the idiosyncrasies which presented themselves. Gradual destruction, separation and elimination, or encapsulation were the steps of Nature's process of repair, and it was reasonable to expect that imitation of this process would give the best results.

Dr. Kinnicutt divided his cases into three groups, viz.: (1) those showing a notable improvement in the pulmonary and general condition; (2) those showing no improvement, or improvement in certain respects only; (3) those cases in which there was either a distinct deterioration in the patient's condition, or in which the progress of the disease continued unchecked. The first group consisted of five cases. In one of these, the daily quantity of sputum was only half an ounce; a careful examination by Dr. Prudden failed to detect the bacilli *before* the inoculations were begun, but during the treatment they were found. In all the cases, the bacilli gradually diminished in number and finally disappeared. The examinations of the sputa were made by Dr. T. M. Prudden, who mixed the whole quantity for the twenty-four hours with a saturated solution of borax, and allowed it to stand for twenty-four hours, with occasional vigorous shakings. One cubic centimetre was taken as the unit of measure. In the records of the number of bacilli found in the various cases, it should be remembered that a very large number of bacilli to one cubic centimetre does not mean very many to a cover-glass; thus: 400,000 bacilli to one cubic centimetre represents only 80 bacilli under a cover-glass, or in forty fields, and 500 bacilli in one cubic centimetre represents only one bacillus under a cover-glass. Three of the five cases were discharged after eleven, thirteen, and sixteen weeks of treatment respectively. Two of them had gained four pounds, and one eleven pounds, the sputa and cough being practically absent, and the temperature normal. The two remaining cases are still under treatment in the hospital. None of these cases had hæmoptysis, although two had had copious hæmorrhages just before admission. The diminution in the degree of dulness, and a more nearly normal character of the respiratory murmur may result from the disappearance of the intra-alveolar exudation, and not from destruction of the intra-alveolar tubercular tissue—the two prominent factors in pulmonary tuberculosis. The improvement in these five cases was more marked than in the other cases. These patients received cod-liver oil and creasote, or both, during the greater part of the treatment, but this medication had been used previously to the inoculations without benefit, one of the cases having been under this treatment for a year.

The second group comprised four cases. One of these for many weeks showed the least constitutional tolerance to the fluid inoculations which were usually accompanied by much constitutional disturbance. After the first two weeks, the cough was markedly diminished and the sputum was reduced from two ounces to one or two drachms in the twenty-four hours, and the bacilli from 650 to 120 in a cover-glass, or forty fields. The afternoon rise of temperature was much smaller, and the patient gained in flesh, but the physical signs in the lungs and in the larynx remained unchanged. When the report was made, the disease in the larynx had made notable progress, the sputum and bacilli were increased, the patient was losing weight, and his fever had returned.

In the third group of four cases, one of cardiac and renal disease, with infiltration at one apex, is interesting. Reaction followed the second inoculation of two milligrammes, but the albumin in the urine was at once increased, and red blood-corpuscles and hyaline and granular casts appeared in the urine. After the fourth inoculation of two and one-half milligrammes there was headache and obstinate vomiting, with the physical signs of pleuro-pericarditis. After stopping the inoculations, the symptoms and signs gradually declined to the point found on admission. In a second case in which there was infiltration at both apices, and also infiltration of the inter-arytenoid commissure, the first injection of one-half a milligramme caused general reaction and slight epistaxis, and after the second, of two milligrammes, there was slight tenderness and pain in the right iliac region. On Feb. 8th, an injection of four milligrammes produced all the signs of an appendicitis. Under the free use of morphine and poultices the symptoms gradually abated. Within the past few days, there had been a slight recurrence of the appendicitis. The pulmonary signs remained almost unchanged. In a third case in this group, the physical signs on admission pointed to slight infiltration at the left apex, and the existence of laryngeal disease was doubtful. There was a slight evening rise of temperature for the three days preceding the inoculations that the patient was under observation; bacilli were present. Reaction followed injection of one milligramme, and there was abundant moist crepitation over the first and second interspaces and inter-clavicular region, and distinctly diminished resonance over the same areas. Similar phenomena were noticed in many other cases, and were thought to be due to a transitory local hyperæmia, though in the case in question these

signs did not disappear, but rubbing and creaking sounds were heard, indicating the involvement of the pleura, and there was also a small area of fine moist crepitation over the scapular region of the opposite side. In view of this, and the patient's low vitality, no inoculations were given after the maximum dose of two milligrammes had been reached. Subsequently there were signs of two small cavities in the inter-clavicular region. Either a massive catarrhal or caseous hepatization, Dr. Kinnicutt thought, followed the inoculations, and it was the only case in his series in which such lesions occurred.

After a five months' experience with tuberculin, Dr. Kinnicutt concludes that the diagnostic value of this remedy is only relative, that small doses at long intervals should be advised, and that the beneficial effects are restricted to pulmonary disease in its early stages. Local reactions may be developed in the entire absence of constitutional effects as indicated by the temperature. Tuberculin is apparently capable of exciting pneumonic processes of varying degrees of intensity. He was of the opinion that tuberculin is capable in the early stages of pulmonary tuberculosis of effecting greater improvement in the physical condition than has been observed under any other method of purely medical treatment, but he thought its best effects would only be found when it is used in conjunction with the other methods of treatment.

The discussion was continued by the President, Dr. A. L. Loomis, with a summary of the results obtained by him at Bellevue Hospital. Thirteen cases of pulmonary tuberculosis were treated by this method, eight being in the stage of consolidation, two in the stage of consolidation with softening, and three in the stage of softening with excavation. The average dose was 1.9 milligrammes, and the largest number of injections was seventy-seven. The condition of every one of these patients was improved, and the average gain in weight was eight and one-half pounds. In every case the first injection was followed by evidences of increased activity of the process in the lungs, but at the end of the third week the affected areas would usually present an arrest of the disease. In the third class, the average duration of the treatment was eleven weeks, the average dose 0.7 milligramme, and the average gain in weight nine pounds. In all of these cases, the pathological process became much more active, and in one there was an extension of the disease. His experience had taught him that tuberculin was an agent which was capable of exciting active changes in the tubercular areas, the nature and extent of which depended upon the dose and the frequency of the injections. He knew of no method which so effectually maintained the nutritive processes in these patients as the treatment with the pneumatic cabinet, as advocated by Dr. Quimby. The number of bacilli diminished but never disappeared, yet this was not important, as he had known cases which had been cured by the climatic treatment for many years to have bacilli in their sputa, although they appeared to be in perfect health.

DR. H. N. HEINEMAN reported the results of his observations on twenty-two cases of pulmonary phthisis at Mt. Sinai Hospital. In one case of chronic fibroid phthisis, after the treatment had been discontinued for several weeks, the patient had for the first time a pulmonary hæmorrhage, and in two other cases hæmorrhages were brought on by small injections of tuberculin. In another case, having cavities and a tuberculous testicle, the tuberculous process in the testicle became so active that it was necessary to remove the organ in four weeks, when it was found to be the seat of extensive tubercular deposits. The presence of cardiac or renal disease should be considered a positive contra-indication to the use of tuberculin, for the albuminuria is always increased by such treatment, and in one fatal case he believed that the tuberculin had been the cause of the parenchymatous nephritis.

A paper by DR. E. L. TRUDEAU, containing the results of his observations on tuberculin in the Adirondack Sanitarium, was, in the absence of its author, read by Dr. Quimby. He had treated eight cases with this remedy in conjunction with the climatic, hygienic, and medicinal measures usually employed at his sanitarium. Six of these cases also received treatment in the pneumatic cabinet. The injections were given twice a week, and the dose was so adjusted as to produce very little reaction. One woman with miliary tuberculosis at both apices became much worse after the injections. Small doses excited such violent constitutional reaction that at one time the temperature reached 104.5° and the pulse 160. One case was apparently cured, four were greatly improved, two were unimproved, and one was apparently injured by the treatment. He thought that the changes in the physical signs supported Koch's assumption as to the specific action of the fluid upon the phthisical process, but that it was not likely that tuberculin could confer immunity against further infection.

DR. C. E. QUIMBY had treated six cases with tuberculin, combined with the use of the pneumatic cabinet. The cabinet secured expansion of the lungs and removal of catarrhal products; the tuberculin set up specific processes in the lungs, and then the pneumatic cabinet was employed to favor absorption during the stage of activity. In one case, each injection increased the inflammatory changes in the lungs, but these rapidly improved under treatment with the cabinet. Four out of the six cases had hæmorrhages. Strangely enough, none of his patients developed a tolerance for the tuberculin. He thought the remedy was chiefly indicated when the reparative processes were adynamic.

The general discussion was opened by DR. A. JACOBI, who said that he had already spoken upon this subject before the State Medical Society. He advocated the use of small doses, since the best therapeutic effects were obtained with these. As an instance of the impossibility of predicting the effect of the tuberculin in any given case, he related the following remarkable case: The patient, a lady about forty years of age, had had tuberculosis for at least ten years; she had had tubercular tumors in the abdominal cavity, had expectorated an unusual quantity of pus, and had suffered a long time from night-sweats. There were two large cavities in the lungs, and the sputum contained numerous bacilli. In the early part of the winter she had a pneumonia, from which she recovered; and about January 10th her husband, a physician, began to treat her with tuberculin. The first dose of one milligramme was followed by no reaction, and this was increased one milligramme each day until she received about forty milligrammes,

and still no reaction occurred. The dose was then increased by two or three milligrammes daily, until about ten days ago, she was receiving 350 milligrammes daily. Although the usual reaction was not produced, it was noticed that shortly after each injection her temperature fell, and remained low for eight or ten hours. Expectoration at first became more abundant, but it soon diminished and the number of bacilli grew less, the night-sweats and fever disappeared, and the patient began to gain flesh. At present the cavities are decidedly smaller than before the treatment. In general, the treatment of surgical tuberculosis had been disappointing. He thought that the best treatment hereafter for pulmonary tuberculosis would be a combination of the climatic treatment with the careful use of tuberculin.

Dr. E. C. Wendt had employed tuberculin in 38 cases —4 of surgical tuberculosis, 7 of phthisis, 22 of "strumous condition," chiefly children with adenitis, 4 of ordinary bronchitis, and in one healthy person. In *every* case a febrile reaction was obtained, which would seem to throw much doubt upon the correctness of Koch's claim as to its diagnostic value. There was but little improvement in the four surgical cases, and although the general condition of the phthisical patients was improved, the physical signs remained unchanged. In the "strumous" cases the anæmia improved, but there was no effect upon the glands or upon the harsh respiration. The initial dose was invariably one-fourth of a milligramme.

Dr. S. Baruch had employed this remedy in sixteen cases, and he detailed the histories of two which appeared to have been cured by this treatment. He thought tuberculin had some diagnostic value, and that when cavities existed it was undoubtedly beneficial.

Dr. H. S. Stearns continued the discussion by referring to the results of two autopsies upon cases in Bellevue Hospital which died while under his treatment. The lungs were filled with recent minute miliary tubercles, and there was also general tubercular infiltration of the abdominal viscera.

In answer to a question from one of the Fellows, who had noticed a marked acceleration of the pulse and a deepening of the respirations after the injections, Dr. Kinnicutt said that he had not noticed this peculiar feature in his cases.

The President said that he had seen one such case, and so marked was the susceptibility that a dose of one-tenth of a milligramme brought on symptoms of collapse. He added that the discussion seemed to show that in tuberculin we had an agent, powerful for good or evil, and one requiring more care and more experience than any other remedy which had been given to us for the treatment of tuberculosis, but he thought it would take a permanent place in the treatment of pulmonary tuberculosis and would enable us to save many lives.

CORRESPONDENCE.

BALTIMORE.

The Ninety-third Annual Convention of the Medical and Chirurgical Faculty of Maryland (the State Medical Society) has just come to a close. The convention was opened on Tuesday, April 28th, by an address from the President, Dr. Thomas A. Ashby, who has, in addition to his practical work in medicine, done excellent service to his profession as editor of the *Maryland Medical Journal* and, later, as one of the most ardent promoters of the extension of the faculty's influence in this State. His address, entitled "The Relation of the Medical and Chirurgical Faculty to Professional Organization in Maryland," was an able review of the struggles of the faculty against the obstacles which beset its pathway during its existence of nearly a century, and of the present attainments and future possibilities of this great and now active State medical organization. The attendance at the opening of the session was larger than usual, and those who had the faculty's interests at heart felt that there was unusual enthusiasm and interest in its affairs.

The Society met again in the evening, when the reports of "sections" were taken up. A paper was read by Dr. Joseph T. Smith on "The Treatment of Diphtheria," giving a summary of the methods and agents which may be most safely trusted in the battle with this dreaded scourge; and another by Dr. J. E. Michael on "Obstetrical Antisepsis" as employed in the lying-in hospital under his charge. The earnest discussions which followed the reading of these papers, and of others which were presented, were in pleasing contrast to the apathy which has characterized some of the previous conventions. Evening sessions are a new feature in the faculty's work, having been introduced at this time for the purpose of economizing the time of country practitioners who desire to stay in the city during the days of the convention. They have been quite a success, and are likely to take a permanent place on the programmes of future annual conventions.

The central point of interest in the morning session of Wednesday was the delivery, by Professor William Welch, of the Johns Hopkins Pathological Laboratory, of the annual oration, on "The Causation of Diphtheria," which was listened to with profound interest by a large audience, and appeared in The Medical News of May 16th.

The rest of the morning was spent in listening to reports of sections. The evening session was taken up by the election of officers for the ensuing year. The nomination of the orator of the morning for President was unexpected by many of those present, but it was at once apparent from its reception that the profession of the city appreciated most highly not only the services which Prof. Welch had rendered to medicine, but the uniform courtesy and modesty, and the interest in local medical affairs, which has made him among them the most popular of the corps of medical men attached to the Johns Hopkins Hospital. It is to be hoped that the election of Prof. Welch to this, the highest gift which the profession can confer, will strengthen the ties between the physicians of Baltimore and the Faculty of the Johns Hopkins medical foundation.

The third (and last) day of the convention was spent in the delivery of reports of different "sections," and in the reading of voluntary papers, a morning and evening session being held as before.

Two prominent members of the faculty have been removed by death since the last convention: Dr.

Richard Gundry, Superintendent of the Maryland State Asylum for the Insane, and Professor of Materia Medica, Therapeutics, and Mental Diseases in the College of Physicians and Surgeons of Baltimore, and Dr. John R. Quinan, author of the "Medical Annals of Baltimore." It is doubtful if the State has any available man to fill Dr. Gundry's position. Dr. Quinan belonged to a class of physicians rich in medical lore and devoted to literary research, which is never a large one in any community.

Taken as a whole, the convention just ended has been unusually successful. The only drawback has been the absence of many country members who might have honored it with their presence. The audience which assembled to hear Prof. Welch's "Annual Address" was the largest known to members who have served the faculty through middle life into old age, and it filled to overflowing the spacious hall of the faculty. Nor was the interest limited to this occasion, for the "President's Address" attracted a full audience, and all of the exercises have been unusually well attended.

The printing of carefully-arranged programmes of the convention, and the timely distribution of the same, was a very desirable improvement.

The outlook for medicine in Maryland is certainly encouraging, notwithstanding the dishonor which has been brought upon it in past years through the jealousy of factions and the rapacity of representatives in public offices.

The printed *Transactions* of the faculty for 1890–91, containing, in addition to the papers already mentioned, articles by Prof. Newell Martin on "The Changes Wrought in Nerve Ganglia by Prolonged Stimulation;" by Dr. Hiram Woods on "The Need of State Intervention for the Prevention of Blindness from Ophthalmia Neonatorum" (which led to the appointment of two oculists and two obstetricians as a committee of the faculty to report upon the subject); and by Dr. Chisolm on "Diseases of the Eye in the Fœtus;" together with many other communications read at the present meeting and at the semi-annual meeting in the past autumn, promise to be unusually full of interest to all practitioners.

NEWS ITEMS.

The Kashmir Medical Mission.—One of the most interesting of medical mission stations is that in the Vale of Kashmir, conducted by the two brothers, Drs. Arthur and Ernest F. Neve, both of them graduates since 1881, from Edinburgh. Their contributions are not infrequently seen in our American medical journals. Their report of last year's work shows a total of 2558 surgical cases, of which about 1000 involved eye operations. Most of these were minor cases, but often important as regards the future eyesight of the patients. Eight deaths followed surgical treatment; of these, three had no bearing upon the operation. A new block of wards has been added to the hospital for the accommodation of twenty additional patients, and is the best, as well as the newest. Its cost has been about $800. The location of this hospital is at Srinagar, the capital of Kashmir, with an altitude of 5235 feet above the sea, and in a section not yet approached by railroads.

Patients come to Srinagar from all parts of Central Asia, sometimes fifteen to twenty days' journey distant to the north and east, which sections are virtually unexplored by Europeans. A majority of the in-patients come from a distance, and the missionaries are taxed to find support for them, as well as to furnish them treatment and shelter in very many instances. A woman's hospital will be built at Srinagar, with room for thirty patients.

The Climatologist.—Under the name of *The Climatologist*, a monthly journal devoted to the study of climatology will be published in Colorado Springs, Colorado, under the editorial supervision of Dr. Keating, of Philadelphia, Dr. Gardiner, of Colorado Springs, and Dr. Griffith, of Philadelphia. A distinguished list of collaborateurs has been engaged, among whom may be mentioned Drs. J. M. Da Costa, A. L. Loomis, William Pepper, E. L. Trudeau, and W. A. Edwards.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 19 TO MAY 25, 1891.

By direction of the Secretary of War, the following assignments of recently-appointed Medical Officers were ordered:

LIPPITT, WILLIAM F., JR., *First Lieutenant and Assistant Surgeon.*—Will report in person, for duty, to the commanding officer Fort McPherson, Ga.

BROOKE, BENJAMIN, *First Lieutenant and Assistant Surgeon.*—Will report in person to the commanding officer Fort Riley, Kansas.

IRELAND, MERRITT W., *First Lieutenant and Assistant Surgeon.*—Will proceed from Columbia City, Ind., to Jefferson Barracks, Mo., and report in person, for duty, to commanding officer of that post.

WELLS, GEORGE M., *First Lieutenant and Assistant Surgeon.*—Will proceed from Paoli, Ind., to Columbus Barracks, Ohio, and report in person, for duty, to the commanding officer of that post.—Par. 7, *S. O. 115, A. G. O.*, May 20, 1891.

WOOD, MARSHALL W., *Captain and Assistant Surgeon.*—Is hereby granted leave of absence for one month, to commence on or about the 23d instant.—Par. 1, *S. O. 104, Division of the Atlantic*, May 20, 1891.

BANISTER, WILLIAM B., *Captain and Assistant Surgeon.*—Is assigned to duty as Medical Officer with Troop "B," Sixth Cavalry, while *en route* from Fort Myer, Va., to Fort Washakie, Wyoming Territory. On arrival of the Troop at its destination, Captain Banister will return to his station at Washington Barracks.—Par. 3, *S. O. 104, Division of the Atlantic*, May 20, 1891.

By direction of the Secretary of War, GEORGE MCCREERY, *Captain and Assistant Surgeon*, is relieved from duty at Fort Clark, Texas, and will report in person to the commanding officer Fort McIntosh, Texas, for duty at that post.—Par. 4, *S. O. 114, A. G. O.*, May 19, 1891.

SKINNER, JOHN O., *Captain and Assistant Surgeon* (Fort Davis, Texas).—Will proceed at once to Fort Clark, Texas, and report to the commanding officer, for temporary duty.—Par. 4, *S. O. 44, Department of Texas*, May 13, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 23, 1891.

BRIGHT, GEORGE A., *Surgeon.*—Detached from the U. S. S. "Omaha," and granted three months' leave of absence.

MEANS, V. C. B., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Omaha," and granted three months' leave of absence.

KEENEY, JAMES F., *Assistant Surgeon.*—Ordered for examination preliminary to promotion to Passed Assistant Surgeon.

AWAY WITH KOCH'S LYMPH!

BY N. SENN, M.D., PH.D., .

PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN RUSH MEDICAL COLLEGE; ATTENDING SURGEON, PRESBYTERIAN HOSPITAL, CHICAGO, ILL.

WHEN six months ago the telegraph operator at Berlin touched the key of his instrument and flashed to all parts of the civilized world the joyful tidings that a cure for tuberculosis had at last been discovered, the people and the profession felt that the millennium in medicine had come. For days and weeks the public press devoted a liberal space to telegraphic messages, to editorials and messages from medical men, relative to the new treatment. For months, the medical journals in all countries rivalled each other in presenting the latest reports from Berlin and other large medical centres, in the form of telegrams, correspondence, editorials and original contributions. The first announcement of the discovery brought thousands of patients and doctors to the German capital, the former to be cured of their tuberculous disease, the latter to receive instruction and to make themselves proficient in all the details of the new treatment. No other event in the world's history ever attracted so much attention and no discovery in medicine or surgery ever found such ready introduction and universal acceptation. The discoverer, the distinguished Koch, the father of bacteriology, had scored so many victories on this modern field of research that every word he uttered brought conviction. His views were promptly adopted by the most prominent physicians and surgeons in Germany and other countries, and the new treatment was applied everywhere by the best men in the profession, as fast as the precious remedy could be obtained. Within a few weeks, the most enthusiastic and encouraging reports came from scores of prominent clinics and large hospitals. Within a few months, volumes have been written on this subject, and several special works have left the press and have been translated into many languages. A new journal, devoted exclusively to the treatment of tuberculosis with Koch's lymph, has come into existence and has a good subscription-list to start with. It is true that some of the more conservative members of the profession were a little slow in accepting the new doctrine and practice, but the great majority followed the current set in motion by the great Koch and his many eminent admirers and devoted followers. It was not long, however, before the glowing accounts of the results of the new treatment of tuberculosis came at longer intervals and in a more moderate tone, and were interspersed with the reports of cases from different parts of the world in which it had proved a complete failure, and in a not inconsiderable number of cases it was charged with having caused a speedily fatal termination. Then came the timely warning of the veteran pathologist, Virchow, who showed, by numerous post-mortem examinations of patients who died while under this treatment, that death was caused by dissemination of the disease from a local focus acted upon by the lymph. The evidence proving this source of danger has been rapidly accumulating and has contributed largely toward subduing the first enthusiasm and limiting the scope of administration of the remedy. The disastrous consequences which followed the use of the lymph, perhaps often injudiciously and recklessly applied, induced a number of medical societies to condemn its use, and led some of the local governments by legal enactments, to restrain its further application. Time enough has now elapsed to judge of the merits of the treatment of tuberculosis by Koch's lymph, or, as it is now called, tuberculin. It has been put to test in the treatment of all forms of tuberculosis. Surgeons, physicians, gynecologists, obstetricians, dermatologists, otologists and ophthalmologists have given the new treatment a fair trial, and the accumulated experiences from all these sources have shown beyond all doubt that its indiscriminate use is attended with many immediate and remote dangers, and that most cases in which it at first appeared to prove beneficial have relapsed, and after weeks and months were no better or even worse than when the treatment was begun. Men who first regarded the lymph as a specific in all forms of tuberculosis no longer make this claim. Many who were enthusiastic in their praise of what they observed from the use of the remedy in the beginning have now suspended its use. Hospitals and wards set aside for the special treatment of patients suffering from tuberculosis are now deserted. The market is overstocked with a supply of Koch's lymph and Koch's syringes. Not only the profession, but also the public, has become aware that the claims made for the remedy only a few months ago are unfounded. It is left for Koch, or some future investigator, to discover a substance or agent which

will answer the expectations that were at first entertained from the lymph. Koch's lymph has been a deceptive bubble which for a short time commanded the attention and admiration of the whole world, but which has been ruthlessly pricked by the father of modern pathology. The treatment of tuberculosis with Koch's lymph and the numerous substitutes which have recently been forced on the attention of the profession will soon be only a matter of history.

My "Away with Koch's lymph!" is based upon my own observations made at the Milwaukee Hospital during the last four months' service in that institution prior to my removal to Chicago. The material is not large, but the careful observations made entitle me to enter my protest against any further experimentation with this remedy. The lymph first used I received through the courtesy of Dr. J. S. Billings, of Washington, and when this was exhausted I received an abundant supply directly from Dr. Libbertz, through the influence of my distinguished friend, Professor von Esmarch. The tuberculous nature of the lesions in all cases that came under my own care, if any doubt existed in this regard, was established by microscopical examination and search for the bacillus. As lupus of the face was mentioned in the first reports from Europe as having been cured with Koch's lymph, I was exceedingly anxious to commence treatment with this form of surgical tuberculosis.

In all of the cases treated, the local and general reactions were typical and corresponded with the descriptions given by von Bergmann, von Esmarch and others. As a rule, the injections were made every other day in order to ascertain the full extent of the local and general reaction following each dose of tuberculin. The first dose never exceeded one milligramme; in grave cases the treatment was commenced with one-half of this quantity. The dose was never increased if the temperature during the reaction following it rose above 101° F., and if this was reached, in many cases the dose was diminished or the interval between the injections increased. It is, therefore, probable that in the grave cases, the unfavorable symptoms following the injections were not so much due to the action of the tuberculin as to the intrinsic tendencies of the disease to aggravation. It is, however, an entirely different matter in the mild cases, in which, in spite of a careful increase of the dose, the local and general symptoms underwent a rapid change for the worse, because in such cases the unfavorable results must be attributed to the action of the tuberculin and not to the intrinsic tendencies of the disease. The whole number of cases treated by injections of tuberculin at the Milwaukee Hospital during the months of January, February, March and April was 43—32 males and 11 females. For the sake of convenience these can be divided into mild, medium and grave cases:

	Males.	Females.	Total.
Mild cases	8	4	12
Medium cases	11	2	13
Advanced cases	14	5	19
			44

Died in the hospital: 1 male and 1 female—2.

	Males	Females.	Total.
Aggravation of all the symptoms during treatment	14	8	22
No improvement	5	1	6
Improved	11	1	12
Apparently cured	2	...	2
Died	1	1	2
			44

Died soon after leaving the hospital: 4 males and 2 females—6.

	Males.	Females.	Total.
Of the mild cases unfavorably affected by the treatment	1	3	4
Of the mild cases improved	4	1	5
Of the mild cases apparently cured	2	...	2
			11

The two cases that were apparently cured belonged to the mild type of the disease; no such result was obtained in any of the thirty-one cases belonging to the medium or advanced form of the disease. In one of the cases that was apparently cured, the sputum contained no bacilli, and in the other there was no expectoration, consequently some doubt must remain as to the tuberculous nature of the pulmonary affection.

In the cases of medium gravity the result of the treatment was as follows:

Aggravated	5
Not improved	3
Improved	5
	13

In the grave cases the treatment was followed

By serious results in	12
By no improvement in	3
By temporary improvement in	2
By death in	2
	19

GENERAL REMARKS. *Diagnostic Value of Tuberculin.*—Great diversity of opinion prevails at the present time as to the diagnostic value of tuberculin. The first reports of the use of this substance were unanimous in attributing to it positive diagnostic value. It was claimed that reaction only occurred in tuberculous patients as a result of the specific action of the lymph on tuberculous tissue, and that the absence of increase of temperature after injection of the lymph decided the non-tuberculous nature of the affection. Leyden, Quincke, Ebstein, Weber and Biermer maintain that the absence or presence of reaction after the use of tuberculin must not in all

cases be regarded as absolute proof of the existence or non-existence of tuberculous disease. Schultze, Finkler, Guttmann, Schreiber, Lichtheim and Rumpf have great faith in the diagnostic value of the use of tuberculin in tuberculosis of the internal organs. The same discrepancy of opinion exists among surgeons as to the value of injections of tuberculin in the differential diagnosis of surgical tuberculous and non-tuberculous lesions. Bergmann relies on the reaction following the use of tuberculin in differentiating between tuberculosis on the one hand and syphilis and carcinoma on the other. Bardeleben and Kohler are reserved in their verdict as to the diagnostic value of the method. Trendelenberg regards the febrile reaction following an injection of tuberculin as an evidence of the tuberculous nature of the lesion, except in tuberculosis of the testicle. Esmarch is of the opinion that in doubtful cases the reaction following the use of the remedy is of great diagnostic value. Bramann and Mikulicz place great confidence in the presence or absence of reaction. König and Hildebrand have observed reactions in lesions resembling in appearance tuberculous affections, but which by other diagnostic aids were shown not to be of a tuberculous nature. Clinical experience has demonstrated that general reaction is produced by tuberculin in cases of actinomycosis and in certain forms of sarcomatous tumors, and that consequently this method of diagnosis cannot be relied upon in differentiating between tuberculous lesions and other affections. A number of the cases upon a study of which this paper is based furnishes conclusive proof that the susceptibility to general reaction varies greatly in different tuberculous individuals. In some, intense reaction followed the use of small doses, when the tuberculous lesion was limited; in others, suffering from extensive tuberculosis, large doses produced no rise in temperature. That in the latter class of cases the affection was of a tuberculous nature there could be no doubt from the history of the cases, the appearance and location of the lesions, the subsequent behavior of the affection; and in some of the cases the presence of tubercle bacilli in the affected tissues was demonstrated. I look upon the local reaction in affections of the lymphatic glands as a valuable diagnostic aid in differentiating, by the use of Koch's lymph, between tuberculous and non-tuberculous affections of these organs. If the enlargement of the lymphatic glands is due to a tuberculous affection, the existing swellings not only become larger, more painful and tender a few hours after the injection of a dose of the lymph, but other glands, that could not be felt before the injection, become enlarged and can be felt in the vicinity of those that were recognized before the use of the remedy; but even in such cases, I regard inoculation experiments of greater diagnostic value than injections of tuberculin, yielding more positive results without exposing the patient to the risks of local and metastatic dissemination of the disease incident to the latter procedure. If on the one hand patients suffering from non-tuberculous affections will occasionally only respond to the tuberculin test, and on the other hand, in exceptional cases, individuals suffering from well-marked typical tuberculous affections have proved refractory to the action of tuberculin, it must appear evident that the use of this substance cannot be relied upon in making a positive differential diagnosis between tuberculous and non-tuberculous affections. At the same time, if it can be shown that a single injection of tuberculin is not devoid of danger, and that implantation of the product of this disease in guinea-pigs will in the course of three or four weeks yield results which will enable us to make a reliable diagnosis between tuberculous and non-tuberculous affections, it is apparent that the use of Koch's lymph as a diagnostic resource should be discarded, or at least limited to exceptional cases.

Therapeutic Value of Tuberculin.—It is now generally conceded that many cases of tuberculosis reported as cured have since relapsed; some of these have died, and others have been subjected to different treatment. In many instances, of course, the original report has not been supplemented by subsequent communication. Since, even by the use of Koch's lymph, an absolute diagnosis is not always possible, it may be that some of the alleged cures rest on a faulty diagnosis. This applies with especial force to the two cases of pulmonary disease reported in this paper as cured. Again, it must not be forgotten that under favorable local or general conditions or improved dietetic, hygienic or climatic changes, tuberculous affections not infreqently undergo spontaneous cure, so that for nearly all methods of treatment so far suggested similar exceptional results can be claimed. Of the eleven cases of surgical tuberculosis that came under my own observation, in not a single instance did the treatment result in more than temporary improvement, and in several it was followed by local extension of the disease and serious impairment of the general health. The effect of tuberculin proved more serious in the treatment of the forty-three cases of pulmonary tuberculosis. There can be but little doubt that in a number of the fatal cases death was hastened by the treatment, and that in a number of the mild cases it contributed largely toward the rapid local extension of the lesion. While the tuberculin treatment of pulmonary tuberculosis can show no better results, it is difficult to ignore the fact that it has been productive of more harm than almost any other plan of treatment heretofore suggested, and on this score alone the verdict,

"Away with Koch's lymph!" is timely and imperative.

Dangers Attending the Use of Tuberculin.—Tuberculin when brought in contact with tuberculous tissue produces coagulation necrosis, and during this process a toxic chemical substance is produced, which, when it reaches the general circulation, causes the febrile action. The time necessary to reach this stage of its action is usually from three to six hours. The intensity of the reaction depends on the quantity of the toxic substance that is produced and finds its way into the general circulation. The general reaction is evidence of a septic condition of the organism produced by the toxic substance resulting from the action of the tuberculin on the tuberculous tissue. The evidence of temperature and the other general symptoms continue until this toxic substance is eliminated by one or more of the excretory organs. The immediate danger attending the tuberculin-treatment consists in the production and introduction into the circulation of a fatal quantity of this toxic substance. That the fear of fatal sepsis resulting from the action of Koch's lymph is not unfounded is shown by a number of such cases that have been reported. If the whole truth were known, this number would be greatly increased by unpublished cases. The more remote dangers attending the tuberculin treatment have been pointed out by Virchow. The destructive effect of the tuberculin on the granulation tissue breaks down the wall surrounding the infected area and liberates the bacilli and their spores—an event which can hardly fail to give rise to local and general dissemination. The granulation tissue, the specific primary product of tuberculous inflammation, is the wall of defence built up by the tissues to protect the adjacent parts and the organism against invasion. Any method of treatment interfering with this mode of defence clears the way for the enemy and secures victory for the invading army. If future research should lead to the discovery of a specific remedy for the cure of tuberculosis, it will be a microbe antagonistic to the bacillus of tuberculosis, or a substance which, when brought in contact with a tuberculous focus, will have an effect on the tissues opposite to that of Koch's lymph.

I have given Koch's lymph a fair trial and have carefully observed its effects, and I have become firmly convinced both of the danger attending its use and its utter inutility in curing any form of tuberculosis.

This paper has been written for the special purpose of placing myself on record as one who protests earnestly against further experimentation with this mysterious and dangerous fluid. A careful study of the voluminous literature on the use of Koch's lymph, and my own experience with it, have induced me to head this paper with the title it bears, "Away with Koch's Lymph!"

FURTHER STUDIES IN MALARIAL DISEASE.

The Parasites and the Forms of Disease as Found in Texas.

BY GEORGE DOCK, M.D.,
OF GALVESTON, TEXAS.

(Concluded from page 606.)

The Small Plasmodium.—During the season under consideration I have learned to recognize another form of the parasite of malaria, and one that is for many reasons the most important of all. Certainly from the point of view of pathogenesis and prognosis it cannot be overrated. As the description which follows makes clear, this is the form so thoroughly described by Marchiafava and Celli as the "small form" (*piccolo forme*), and which is found in the fevers which predominate in the summer and autumn in Rome.

Not having access to the proper literature I had ended my investigations on these bodies, when, through the kindness of the authors, for which I cannot sufficiently thank them, I received reprints of their articles, translations of which appeared still later in various German journals.

The reason I did not learn earlier about these bodies is that in previous seasons they occurred but seldom, and always with the large forms. In the unusually severe epidemic of the last autumn I encountered them in twenty-six cases, in only three of which the large forms were also found. In twenty-three cases only the small forms, and in some cases crescentic bodies, were found.

In eighteen of the twenty-three cases I was able to make observations at frequent intervals before, during, and after treatment, and in two cases *post-mortem*.

My attention was first called to these bodies by the peculiarities of their pigment, a matter to which I have long paid particular attention. I found a number of cases in which the plasmodia never became large, but beginning as small unpigmented bodies they grew, with characteristic amœboid movements, and formed pigment, usually in very fine granules. Becoming larger, though never more than one-third the diameter of a red corpuscle, the pigment became gathered in a roundish or irregular mass. This was the last seen of the bodies. Disappearing from the blood their place was taken in a short time by the smallest forms, and so the process was repeated.

I might have remained in ignorance of the later stage, had it not been for the occurrence of a fatal case in which only these forms occurred, and in which, owing to the short duration and severity of the disease, they could be studied alone and to great

advantage. I intend to publish the case in full, with histological studies at another time. It is sufficient for our present purpose to say that the patient, a man of twenty-three years, was sick for a few days, having been exposed in a very malarial locality. On admission the patient's condition did not seem alarming; the history pointed to a continued fever rather than to an ordinary malaria. At the first examination of the blood, however, the diagnosis of pernicious malaria was made, with a fatal prognosis, and in little more than a day the man was dead. The blood was examined for many hours, including two paroxysms, but no segmenting forms were seen. Death occurred as the forms were attaining the maximum size. At the autopsy segmenting forms were found in enormous numbers in the brain, spleen, kidneys, and some other internal organs. None were found in the peripheral blood. The segmenting forms were completely developed. In some cases they were still in the red corpuscles, in others free. They were of great regularity in appearance, having the pigment in or near the centre and from ten to fifteen or eighteen spores around it. They seemed in fact to be more regular in their arrangement than the large plasmodia. This may have been due to their small size preventing us from seeing variations such as have been described of the others.

So far as one can learn without actual comparison, this is the "small form" of Marchiafava and Celli. I did not, however, see all the varieties described by those observers—the one, for example, in which the hæmoglobin of the red corpuscle is gathered in a ring around the parasite,[1] I have never seen, nor have I been able to find plasmodia in the shrunken red corpuscles, so common in this infection.

I have never seen the larger stages without pigment. In many instances numbers of plasmodia without pigment were seen, but in such cases pigmented leucocytes or crescents showed the pigment-forming stages to be present somewhere in the body.

In the twenty-three unmixed cases typical flagellate bodies were never seen. Free bodies were frequently found, though not so often as with the large plasmodia. In one case a filament was seen on a free body, and in the spleen of the fatal case another was found, but neither had the sharply cut outlines and homogeneous appearance of the flagella found with the large forms. It may be believed that, after my statement in regard to the frequent occurrence of flagellates, I spared no pains in looking for them in these cases, but the conviction was forced on me that they were not present. On the other hand, I had opportunities for studying another form equally interesting—the crescentic body of Laveran.

The Crescents.—The origin, nature, and development of these bodies is still involved in obscurity. Much of this depends on a misconception of their actual appearance, as may be demonstrated by the statements still current that they are altered red blood-corpuscles, and from the descriptions and figures given by some writers.[1] Though I cannot hope to clear up the obscurity, I have certain facts to advance which may help to do so.

During the last season I have found crescentic bodies in twelve cases, as follows: In five cases with the small plasmodium only, in three with small and large forms, and in four (in the finger blood) alone.

The presence of the pigment shows that the crescents are derived from organisms which destroy the hæmoglobin. No one as yet has seen the complete cycle, owing to our imperfect methods of studying the organisms. The method of Plehn promises to be of value.

In all cases but four—and these I shall examine critically later—in which crescents were found in this series, the small plasmodium was found also. To believe the crescents are derived from bodies entirely similar in appearance, yet differing essentially from these in nature, as the alternative hypothesis assumes, seems quite unwarranted. Moreover, in two cases I have found the bodies held to be the intermediary forms by Marchiafava and Celli. These were as follows:

C. W., a laborer in a malarial part of Galveston, admitted to hospital October 22, 1890. Patient said he had fever, without chills, for two weeks in May, and has never been well since. For six days has had pain in back and fever without chills. Temperature at 9 A.M., 100.4°. Spleen enlarged; great anæmia.

The temperature rose in the next two hours to 106° without a rigor, and then fell, on the administration of antifebrin in one large dose, with copious perspiration.

1.30 P.M., temperature, 104°. In the blood many small amœboid endoglobular forms without pigment. A few pigmented leucocytes.

Later in the afternoon small pigment grains began to appear in the plasmodia. The temperature reached the normal at midnight and then rose slowly. The organisms in the blood were larger and contained more pigment. The approach of a paroxysm was predicted at 11 A.M. No sign of a rigor appeared, though the temperature rose to 102° and the larger of the plasmodia disappeared, to be followed in about three hours by the appearance of many small forms. Quinine was given in three doses of ten grains each during the night, but the temperature, instead of falling, rose slowly.

24th. Many plasmodia, pigmented, in the blood.

[1] Arch. per le Sci. Med., xiv., No. 8, Fig. 14; also, Fortschritte der Med., Bd. ix., No. 7.

[1] Cf. Dolega, l. c., Taf. v., Fig. 8.

In the afternoon they began to show the later stages of development, with the pigment in one large mass. About 2 P.M. these disappeared, and only small, unpigmented forms were found. At 5 P.M. the supposed developing crescents were found in considerable number. These were oval, or thick, spindle-shaped bodies, with pigment in short rods scattered through them. Usually they were in the middle of the affected corpuscles, with the ends reaching the opposite sides; but in some cases they were on one side, and then showed a curved shape corresponding to that of the corpuscle. The bodies had clear outlines, were more highly refracting than the plasmodia, and sometimes of finely granular structure, like that of the crescents. Changes in form were slight and took place slowly. Temperature, 105°.

25th. Patient had thirty grains of quinine during the night. Temperature at 10 A.M., 99°. In the blood a few small amœboid plasmodia and spindle-shaped bodies as before. The patient was by this time thoroughly cinchonized, and the temperature fell gradually to below the normal. No more spindle-shaped bodies appeared, though a few small amœboid forms could be found.

29th. The patient left the hospital, having taken three drachms of quinine.

November 27. Patient returned. States that he was well for two weeks after leaving, but that for the last twelve days he has had chills daily.

4 P.M., temperature, 102.4°, rising to 104.4° at 7, and remaining up until next morning at 10, when the blood was examined. This showed many small amœboid forms, such as are found after a paroxysm. Owing to the number of plasmodia and the prostration of the patient, quinine was given at once to the point of cinchonization.

29th. Temperature, 97°. In the blood a few pigmented leucocytes; no plasmodia.

The temperature rose for two days to 101°, then remained below normal, and the patient again left the hospital.

In the case of C. S.,[1] at the first examination a number of spindle-shaped or oval bodies similar to those described were found, in addition to the ordinary forms of plasmodium. In some instances the arrangement of the pigment in the former approached that common in the crescents, having a central position. Next day the patient was cinchonized; there was no paroxysm. The blood showed no plasmodia, but a few crescents, many of them remarkable for their slight curve and sharp ends, but almost all having the line or band on the concave side. In several the pigment was scattered along the whole length.

In the case of Th. C. (l. c.) crescents appeared on the third day, after the plasmodia had disappeared with cinchonization. They, too, were often peculiar in the arrangement of the pigment, often having it at one end.

A remarkable case in which crescents developed during the time of observation was the following:

"A. C., living in Galveston and working in the harbor, admitted November 26, 1890. Present illness began about November 1st, with constipation, loss of appetite and chill, and continued until admission. Chills were not regular, but usually came on when weather was bad, and generally about sunset. Has taken no medicine; spleen enlarged; anæmia.

"In the blood only unpigmented plasmodia were found, some of them as much as one-third the diameter of a blood corpuscle—that is, almost the full size of this form.

"The temperature rose to 101.6° at 10 P.M. without a chill.

"*27th.* Temperature at 11 A.M., 100.6°. Patient feels shivering sensations. In the blood are small amœboid plasmodia, pigmented leucocytes, and free crescents.

"The temperature remained at the point indicated until the morning of the third day, when it fell to normal within three hours, but at once rose to 100.4°. The organisms had persisted as before. Quinine was then given; the temperature fell after the administration of fifteen grains and did not rise again. Plasmodia disappeared in a short time, but crescents could be found until the patient left the hospital, a few days later."

The fact that crescents are sometimes found alone in the blood has led to the supposition that they represent a distinct species, capable of reproducing their like, though no direct proof has yet been advanced. One of my four cases with crescents only gave an opportunity for learning the possibility of a fallacy in the supposition stated. The case is as follows:

J. McG., of Galveston, express driver, admitted to hospital December 15, 1890. Patient stated he had had chills for two or three days, with fever and dull headache. Temperature at 3 P.M., 99.6°.

December 16, 6 A.M. Temperature, 100°. Soon after this a chill; patient became comatose; urine examination negative.

12 M. Patient cannot be roused; pupillary and corneal reflexes abolished; face flushed, with tinge of yellow; splenic dulness enlarged, but the organ cannot be felt.

Blood pale, watery; leucocytes increased, especially the large lymphoid corpuscles. Many crescents but no other forms.

12.45 P.M. Spleen aspirated by a hypodermic syringe below the eleventh rib, the needle pointing upward; needle moves with respiration. The blood withdrawn shows many amœboid bodies of all sizes, including some in the later stages, with a single large pigment mass; many crescents and pigmented leucocytes. The crescents nearly all show the membrane on the concave side, which those in the finger blood do not. The membrane is very easily seen; sometimes is wrinkled. The most remarkable feature about the crescents is their excessive curve. The width across the horns is not greater than that of a red blood-corpuscle, the arc being about two-thirds of a circle.

The subsequent history of the case can be condensed in a few words. Quinine was given in large

[1] Fortschritte der Med., No. 5, 1891.

doses—forty grains daily—hypodermatically. Strychnine was also used in the same way, and mustard foot-baths given. The temperature did not begin to fall until 7 P.M., five hours after thirty grains of quinine had been given. It then fell to normal. The pupils then reacted to light, but the patient could not be roused. Forty grains of quinine were given during the night, hypodermatically.

Next morning, 17th, at 10 o'clock, the temperature rose rapidly at first and by 4 o'clock reached 102.4°, when it began to fall. Up to this time the finger blood showed the same characteristics as at the first examination. During the night the patient had forty grains of quinine injected as before.

18th. The blood examination showed no change. The temperature rose from 97.4° to 98.8°. At night twenty grains of quinine.

19th. Patient still comatose, but reacts to pin-thrust. In the blood a few crescents; no pigmented leucocytes. Temperature rose from last night to 4 P.M., reaching 100.2°, then fell next day to sub-normal.

20th. Patient's mind was clear. Temperature normal. There was muscular weakness and anæmia. In a few days the man left the hospital, feeling quite well.

In this case none of the supposed transition forms of the crescent were seen. In all instances the affected blood corpuscle was entirely decolorized, though the complete membrane could not be looked upon as anything but its shell.

All the facts I have brought forward do not prove the origin of the crescents from the small plasmodium, but in view of the improbability of any other explanation of their origin that has been given up to this time, the suggested source seems very probable.

It has been asserted that the crescents undergo sporulation, giving rise to small amœboid bodies. This seems very probable, though proof is wanting. All my own efforts to observe such a process have been negative.

Equally negative have been my efforts to see another process often described—the formation of flagella on crescents or their degenerated bodies. In all of my many observations made with that object, the results have been almost identical. The crescents become oval, with double contours, then round, and finally break down into hyaline masses. Some of the common flagellate bodies have a distant resemblance to the rounded crescentic bodies.

In speculating on the nature of the crescents it seems to me we have allowed ourselves to be misled by two things—the form of the organisms and their resistance to quinine. In regard to the former, the name alone has been the cause of misconception with some, who have forced a parallel between these and the crescentic or sickle-shaped spores of the coccidia—certainly with very little reason.

As for quinine and its effects, we must bear these facts in mind: It has been demonstrated that the various forms of the plasmodium other than the crescents differ in their resistance. Thus the larger forms and those with flagella are more resistant than the smaller stages of the same kind.

Again, the small plasmodium, as shown by the researches of Celli and Marchiafava, and confirmed by me, is more resistant in all its stages than the large form. If now the crescents are derived from the small forms we have some ground for assuming their greater resistance. There is still another possibility to be considered. We have seen that there is a stage, even of the most easily affected form, which resists the action of quinine for long periods, and is then capable of giving rise to new generations. We must, therefore, consider the possibility of the similar stages of the small plasmodium, probably true spores, having a proportionately greater resistance, and we can easily see, from the last case quoted, how the intermediate stages of the development could be overlooked in the usual method of investigating.

The cause of the final disappearance of the crescents is unknown. They certainly are not often taken up by phagocytes in the peripheral blood. In the case of Th. C., after appearing in the course of the observations they soon disappeared. This would seem to show that their development had been checked at an early stage, a stage more easily influenced than the later ones or the spores.

For the present I feel justified in looking on the crescents as representing a phase in the development of the small plasmodium, and while accepting the possibility of their sporulation and producing flagella, I do not consider it a common or necessary part of their existence.

Clinical Features of Cases with the Small Plasmodia and Crescents.—The cases in which the small plasmodia occur have certain peculiarities which distinguish them from those accompanied by the large form. They are the cases described by authors as remittent or sub-continued, or even by some as continued, and a full description of which at this time would be superfluous.

Intermissions do take place. In six out of eighteen of my cases—before the administration of quinine—there were intermissions, but in these cases the apyrexia was of very short duration and the cold stage less distinct than in the paroxysms of the common intermittents.

In these cases there are also anomalies in the duration of the hot stage, which is sometimes unusually long, and not always followed or accompanied by copious sweating.

The fever curves in remittent cases present the greatest irregularity. The rise may be sudden, or may be slow and uncertain. In them rigors are absent. The patient may not feel cold at any time, or may complain of a feeling as if a soft breeze were blowing over some part of the body. The acme may be short or may last over a day (in one case at 104°). The fall may be rapid, but is usually slow. The difference between lowest and highest temperature varies from two to five (100°–105.5° in one case) degrees, but is usually between three and four.

Quotidians are the rule. In two cases a tertian curve was caused by remarkably slow fall and subsequent rise, the apyrexia or remission being of very short duration.

In two of the eighteen cases the curves were so atypical as not to give an intimation of their malarial nature. One was the case of A. C., already detailed. The other was that of a young man working on the wharves, who gave a history of diarrhœa, vomiting, headache, and dizziness for three weeks, without a chill, with fever for seven days. There was slight anæmia and the spleen was enlarged. The blood showed small plasmodia and crescents. The patient remained in the hospital four days, the temperature ranging between 98° and 100°, and the diarrhœa having been checked, he left, with the blood as before.

Symptoms, sometimes of great severity on the part of the stomach, brain, and other organs, have always been present in my cases. The cases are too few to serve as a basis for comparative diagnostic points. They agree closely with the descriptions, especially of those who have given us the best accounts of tropical malaria.[1]

In many cases, not only from the anamnesis, but also from the symptoms and the temperature curve, it would have been difficult to distinguish between malaria and some other infection—for example, enteric fever. It is important to note that in none of the cases in which such doubts could have arisen, and in which the microscopic diagnosis of malaria was made, did quinine fail to be followed by a fall of the temperature to normal or below, usually within two days, sometimes in three or four, with cessation of all symptoms except those due to anæmia, and with subsequent recovery.

I hold, therefore, that the ability to recognize the true nature of certain of our fevers by the microscope is of great practical advantage, and should be applied when possible, and that in the scientific study of these fevers, to ignore the plasmodium is to make our conclusions impotent.

In regard to the cases in which crescents occur, my experience agrees with that of Laveran and of Celli and Marchiafava. Though most constant in cases of advanced malarial anæmia, they also occur, as the foregoing pages indicate, in cases of comparatively short duration, and in which the term cachexia could hardly be applied.

The blood in cases showing the small plasmodium is in certain respects remarkable. In the first place, one does not see the large, pale, flattened corpuscles so common with the other forms, but the corpuscles are often smaller and darker. Poikilocytosis is very common, especially the internal alteration causing the so-called vacuoles. The latter, it may be observed, can never be a cause of confusion to the practised observer.

The most marked feature in the blood in these cases is the regularity of appearance and number of the pigmented leucocytes. Out of 26 cases with small plasmodium they were found 14 times, and of the other cases 5 were seen but once, and the rest were of short duration, in which the disease was soon jugulated. In most cases they were very numerous. The pigment was usually in roundish masses, and evidently derived from the matured segmenting bodies. Frequently one leucocyte could be seen with several such masses. The leucocytes that were so affected were almost all large ones, evidently endothelial in origin.

Decrease in the number of red corpuscles and increase of leucocytes, especially the large lymphoid corpuscles, is a common feature of the blood in these cases, and, in those showing pernicious features leucocytosis may be intense (1 : 5 in one of my fatal cases).

I have described the various organisms as they occurred in all but one of the 41 cases which came under observation last year. I preferred to speak of this case by itself, on account of its peculiarity. The clinical history has been given in the *Fortschritte der Medicin* (loc. cit., J. B.), and need not be repeated. It was a case of atypical malaria, with a history of continued fever, but the one paroxysm observed in the hospital was preceded by complete apyrexia. The organisms were very numerous. Examined in the acme, they were peculiar in that the segmenting forms were of great regularity. They were about two-thirds the diameter of a red corpuscle, with the pigment in the middle, and six or eight round or oval spores around it. Unfortunately, I could not get dried preparations, and, as it was necessary to cinchonize the patient, no further observations could be made.

The Relation of the Different Forms of Plasmodium to Each Other.—As has been shown by the foregoing, there are a number of forms of the organism which vary widely in appearance, mode of growth, and type of disease they accompany. Are we to look on

[1] See Schellong: "Die Malaria-krankheiten, etc.," for interesting remarks on this Protean disease.

these as being all members of a polymorphous species, or are there different species or genera?

Evidently this question cannot be definitely decided until we have more accurate methods of studying the parasites. The experiments of injecting blood from various kinds of cases, as practised by our Italian colleagues, have had contradictory results. This is all we could expect in view of the sources of error in such experiments. The disproportion between the amount of blood injected and even the largest quantity that one could examine is so great that certain forms might be overlooked. Or, it might be that the spores of one form could be circulating in the blood, but, on account of a temporary or permanent immunity, not be able to reach full development, and yet in another host rapidly perform their full cycle, with the result of impressing their peculiar features on the disease.

The reasons for believing in the existence of different species (genera?) are, in short, as follows:

1. The different forms may exist by themselves, or combined, but in the latter case no transition from one to the other can be seen, but both continue distinct.

2. Either form may accompany cases of malarial disease of atypical course and symptoms, but in cases which show pernicious features the small forms are always to be found.

The forms I have described explain all cases of malaria in which they occur. The large form with the tertian or quotidian intermittents and some mild atypical cases; the small form with usually quotidian cases, almost always atypical in symptoms, and often pernicious.

This does not exclude the possibility of a distinct form for quartan fevers. Never having seen a case of that kind, I cannot consider it particularly, but must look on it as a necessity. I also believe there may be other varieties. At the same time I think we must accept the view that the active life of any one generation is not in a fixed relation to the daily rotation of the earth, but liable to variations.

The belief in the existence of various species or genera of malarial parasites does not essentially alter the view usually held as to the unity of malarial disease, but gives scientific ground for explaining certain clinical facts which, under other suppositions, have always been difficult to understand. This applies to cases of pernicious malaria especially.

To conclude, then, the special object of this communication, we find in a certain number of malarial localities of wide geographical distribution a number of kinds of parasitic organisms. We find, also, that these agree, in appearance and mode of development, with the organisms found in similar classes of cases in other parts of the world, especially with those found in temperate climes, like Germany and the northern United States, and those with tropical temperatures, if not latitudes—Italy and Algiers.

It does not enter into the scope of this paper to consider the pathology of malaria, yet there are certain points in regard to it on which a word may be said. It has been stated that the discovery of the plasmodium malariæ does not clear up our knowledge of the disease. Such statements show an unfamiliarity with the subject. One of the most marked morbid changes in malaria, destruction of red blood-corpuscles, with formation of melanin, can be followed from beginning to end under the microscope. In a case of pernicious fever the extent of this is so great as hardly to be believed, unless one sees the fact. It is sometimes said that the segmentation of the parasites explains the paroxysms. Mechanically this is difficult to understand. Nor do the results of pathological investigations make this clearer. The formal occlusions of vessels by the parasites and the congestions of various internal organs explain certain symptoms; but in the cases with the most marked intermittent course we have no reason for believing that these are prominent factors. It is difficult to believe the remarkable symptoms in pernicious cases are due to the effects of the bodies acting mechanically on the nerve centres. Many of them point strongly to the action of chemical substances. There are certain facts known which lend strength to such a supposition. Many protozoa have the power of dissolving cellulose, woody fibre, and starch, and of coagulating albumin. Krukenberg has discovered a peptonizing ferment in *fuligo varians*. All the parasitic monads living in certain plants produce a substance, probably an acid, which alters the color of chlorophyl, and many produce substances which completely decolorize the pigments of their hosts.

Metchnikoff and his pupils have shown that though the protoplasm of protozoa gives an alkaline, the fluid in the vacuoles gives an acid reaction.

The rapid digestion of hæmoglobin and its transformation into the bodies of the plasmodium and melanin is evidence of powerful metabolism. Can we believe that no other substances result from this? On the contrary, it seems as if such processes must necessarily result in the production of chemical substances capable of powerfully affecting the organism in which they are formed. Such substances would be excreted by the usual organs, and it may even be that the vomiting so common in the paroxysms of malaria is due to an excretion by the stomach similar to that which we know occurs with morphia.

Chemical examinations of the blood and excretæ should throw a light on this subject. The only investigations of the kind I can find are those of

Roque and Lemoine.[1] They examined the urine of one case of tertian intermittent, and of two cases of malaria acquired in Algiers, in which albuminuria occurred in consequence of alcoholic excess, and recurrences of the malaria took place in France.

The authors' conclusions are as follows:

"Malaria produces a large quantity of poisonous products; these are excreted mostly by the urine, and the excretion reaches its maximum immediately after the paroxysm.

"Sulphate of quinine favors and increases this excretion.

"The severity of the paroxysm and certain pernicious forms stand in reverse proportion to the quantity of excreted toxine, and appear in consequence to depend on disturbances in the liver and kidneys.

"The disappearance of the paroxysm is probably dependent on the quantity excreted, in the sense that an energetic excretion appears to precede the end of the disease."

Nothing is said in regard to the nature of the toxic body or the mode of detecting it. I think, however, it is not claiming too much to say that such investigations will explain the pathology of malaria, in all the details not yet cleared up, by our knowledge of the pathological anatomy in connection with the development of the plasmodium.

A communication like the present one is of little value by itself. If, however, it lead to other investigations on the same or improved lines, our knowledge and control of one of the banes of our existence will be materially increased.

THE DIAGNOSIS OF TRAUMATIC LESIONS IN THE CEREBRO-SPINAL AXIS, AND THE DETECTION OF MALINGERING REFERRED TO THIS CENTRE.

BY B. A. WATSON, M.D.,
CONSULTING SURGEON TO THE BAYONNE HOSPITAL; SURGEON TO THE JERSEY CITY HOSPITAL, ETC.

THE counterfeit cannot be detected without an accurate knowledge of the genuine, and, in addition to this, an exact knowledge of the counterfeit, together with a definite knowledge of the difference between the genuine and the counterfeit, is still imperatively required.

It therefore follows that whoever would attempt the detection of malingering should always be able to diagnosticate concussion of the brain and spinal cord. The proper performance of this task requires a full knowledge of the etiology, semeiology and pathology of the morbid condition under consideration. Let us therefore direct our attention to these essential factors of diagnosis, carefully analyzing each in order that we may more thoroughly comprehend their relation and bearing on each other. It is universally admitted that concussion of the spinal cord most commonly follows falls upon the feet, the buttocks, and less frequently upon the hands when both arms are out-stretched; gunshot wounds involving portions of the spinal column; a stroke of lightning; heavy blows delivered over the bones of the pelvis or in the line of the spinal column.

The direct effect of these falls and blows is the production of contusions of the soft parts, etc., which are more or less disorganized by these traumatic agents. The force of these agents is not by any means entirely expended in the production of these contusions, but there will be carried along the bony structures a vibratory motion which will also be imparted in varying degrees to the adjacent soft parts. A very fair idea may be gained of these vibratory movements by placing the hand on the apex of a bell, suspended in the air, while its base is struck with a metallic hammer; or by the touch of a properly keyed string of a musical instrument when it has been put in motion. The same vibratory motion may also be very well illustrated by tapping gently with the finger on a glass jar or other vessel which is partially filled with jelly and then watching the tremulous movements imparted to the contents by the slight blows delivered on the vessel. The attention of the medical profession has been frequently called to the peculiarities of concussive or vibratory force by French authors, but its physiological and pathological action has never received that careful study to which it is entitled. A very important factor which presents itself for our consideration in connection with the study of this force is the fact that it is not transmitted equally well by the various organs and tissues of animal bodies; and, consequently, a direct blow delivered on one part of the body may be entirely negative, or result in the production of very little vibratory action, while on another part of the organism the results will be very marked. Thus a blow delivered directly on the nates will give rise to this concussive force and be transmitted along the spinal column to the bony walls of the skull, and from this structure to the brain itself, which is in such close contact with these bones. A portion of the same force will likewise be expended in varying degrees on those organs in intimate contact with this line traversed by the traumatic agent. The functional disturbances and the pathological changes in the various organs will depend on the physiological functions, weight, texture, etc., of the parts involved, and these need not be enumerated here.

A blow delivered on the feet, while the lower extremities are extended, will be transmitted to the

[1] Recherches sur la Toxicité Urinaire dans l'Impaludisme. Rev. de Méd., 1890. Centralbl. f. Bakt., etc., ix. p. 353.

bones of the pelvis and then along the spinal column. A somewhat similar result may possibly be produced by a fall on the hands when the arms are extended; though the force of this blow will be much diminished by reason of the anatomical differences in the parts, particularly the less intimate connection between the bones of the arms and the spinal column than exists between the bones of the lower extremities and this important highway for the transmission of concussive force. It should likewise be remembered that the more concentrated the direct traumatic force, *i. e.*, the smaller the area to which it is applied, the greater will be the amount of concussive force generated, while the other factors remain unchanged. Thus a blow covering an area of four square inches delivered directly over any part of the spinal column will generate far more concussive force than it would if spread over the whole posterior region of the body. In fact, in the former case, if the blow was a severe one, functional derangements and pathological lesions might rationally be expected to follow from the concentrated nature of the concussive force, but in the latter they will be looked for in vain. There is a very marked difference between the concussion in the case of gunshot wounds produced by musket or rifle balls and that which follows heavy blows or falls; in the former the pathological changes are more circumscribed, while in the latter they may be considered general. Thus, a musket ball having found lodgement in the vertebral column, and in some degree having impaired its outer surface without producing any lesion of the osseous tissues within the canal, the spinal cord will frequently be found in an ecchymotic state at a point near the lesion in the spinal column. In connection with this subject, it may be stated that no single blow, however great its momentum, delivered on the anterior surface of the thorax or abdomen could rationally be expected to produce concussion of the spinal cord, since its force would be expended almost entirely on the visceral organs within these cavities. The study of the effects of lightning, and likewise those of electrical currents of both high and low degree of potency, possesses very great interest for the surgeon in connection with the consideration of concussive force.

The vibratory character of electrical currents is apparently identical with the other forms of concussive force; and it is readily demonstrable that the physiological action, functional disturbances and pathological changes possess essentially the same characteristics. The fact has long been recognized by the ablest authorities that concussion is physiologically indicated by a nervous and circulatory excitation or depression. In accordance with this opinion Verneuil has given the following definition of concussion: "A series of phenomena more or less sudden followed by a mechanical disturbance of the anatomical elements, tissues, and organs, characterized by a temporary excitation or a depression of the functions of the parts disturbed, and likewise producing anatomical changes, are generally observed in cases of functional activity or repose." Mechanical concussive force, like lightning strokes and electrical currents, may produce every possible degree of concussion, varying from the slightest functional disturbances which pass off within a few seconds, to instantaneous death. Further similarity in the effects of these agents is shown by the fact that concussion and even death may be produced by rapidly repeated mechanical blows or a rapid succession of electrical strokes, while a single impulse would be scarcely sufficient to cause even temporary functional disturbance. The pugilist knows that to render his antagonist unconscious the blows should be delivered upon the head. He therefore seeks to deliver in rapid succession blow after blow until his object is accomplished. Experimentation on animals has shown that concussion of the brain may be caused by slight taps with a hammer delivered on the head in rapid succession.

In our consideration of the etiology of concussion of the cerebro-spinal axis we have said little in regard to its causation in the brain. It is probably understood, however, that those agencies which have already been mentioned are the important factors in its production in this organ as well as in the other organs of the body. The same general laws pertaining to the etiology of this morbid condition are as applicable here as elsewhere, consequently a blow delivered on the head will be more efficacious in the production of concussion of the brain than would be the concussive force had it been transmitted to this organ from some other part of the body. Furthermore, the weight of this organ and its other anatomical peculiarities must receive due consideration.

In the attempt to describe the symptoms of concussion in the cerebro-spinal axis we immediately encounter a difficulty arising from the fact that the functions of these organs are materially different, and consequently the symptoms observed in connection with a traumatism in the spinal cord will produce entirely different symptoms from those found when a similar lesion exists in the brain. The remedy for this difficulty is very simple and only requires that the symptoms be separately noted as they pertain to lesions in the different organs. A much more serious obstacle is found in the combination of all sorts of injuries with those of *pure* concussion, especially those having their origin in fractures, dislocations, sprains, rupture, and stretch-

ing of ligaments, particularly in the spinal column, and likewise with the concussion in one organ the symptoms of which are erroneously attributed to this morbid condition in another. In illustration of the above-mentioned error, I desire to call attention to the fact that hæmaturia is frequently mentioned as a symptom of concussion of the spine, while I have conclusively shown by my experiments on animals that it bears no constant relation to lesion of the cord, but, on the contrary, following concussive accidents, *indicates a concussion of the kidney.*

Furthermore, visual changes are frequently attributed to concussion of the spine, although as a matter of fact the lesions on which these changes depend are situated either in the brain or the eye. I am now prepared to assert that the greater part of the organs within the thorax and abdomen are equally as liable to suffer from concussive force as the brain itself; and likewise that concussive accidents are much more frequent in these visceral organs than in the spinal cord. This assertion is based on the fact that these lesions are entirely analogous to those observed in the brain, merely requiring that the proper allowance be made for differences in weight, texture, etc., factors which must be taken into consideration in connection with the study of the lesions of concussion in the brain and spinal cord. Furthermore, every true concussion takes its origin in the same peculiar force. Therefore, if it be desirable to speak of concussion of the brain, spinal cord, etc., why should it not be applied to the lungs, liver, kidneys, etc.? Would it not be absurd to speak of gunshot wounds of the brain and spinal cord, while the term is withheld from analogous lesions caused by the same peculiar force in other parts of the body? An attempt has recently been made to employ the term "nervous shock" instead of concussion; but this departure possesses no advantage and has already caused much confusion. No attempt is here made to deny that certain portions of the nervous system participate in the concussion; although it is self-evident that the functional disturbance and pathological lesions are primarily developed in connection with the *circulatory system.* These preliminary comments are made in preference to any attempt at the mere enumeration of symptoms, which, in order to possess real value, must be fully stated and explained. It should likewise be remembered that there are different degrees of concussion and these differences are indicated by a corresponding difference in symptoms.

It must now be apparent that the limits of this article compel me to economize space, so far as it can be done without defeating the object for which it was written. Permit me, therefore, once more to call attention to the fact that concussion always produces either excitation or depression, *i. e.*, functional activity or repose. The former condition possesses practically little interest, if observed immediately after the application of the concussive force, since it is commonly of short duration, and does not require any attempt at treatment. However, there is another form of excitation occasionally observed in severe cases of concussion of the brain which commonly makes its appearance from twelve to forty-eight hours after the receipt of the injury. This condition is indicated by a full pulse, flushed face, throbbing of the carotids, headache, hot and dry skin, photophobia, noises in the ears, and sometimes marked drowsiness. These symptoms point to the existence of cerebral hyperæmia, which is commonly of short duration; but in some cases it is the prelude to inflammation of the brain. In the severe cases of concussion of the brain or spinal cord the prompt appearance of *symptoms indicative of depression* commonly suggests the existence of organic lesions, rather than mere functional disturbances; while, as a general rule, the degree of danger is fairly expressed by the depression. It should, however, be remembered that the symptoms of depression, in order to possess any special value, must pertain especially to the functions which are known to be performed by these organs. Therefore, a diminished consciousness, although the patient may be aroused sufficiently to answer questions, the pupils contracted or dilated, relaxation of the sphincters, a feeble and irregular pulse, shallow and sighing respirations, a cold, pale, and clammy skin, are symptoms that point very clearly to the brain as the seat of the injury when the symptoms have followed promptly after the application of concussive force. The symptoms following those above recorded belong to the reactionary period; the object of this paper does not require their mention here. Concussion of the spinal cord is most commonly indicated by the appearance of paralytic symptoms, which frequently involve the lower extremities, especially the motor power and likewise in many cases also the sensory. Therefore in our experiments made on dogs our attention was promptly directed to the movements of these animals immediately after the application of the concussive force.

The following facts possess an important bearing on the subject now under consideration. From a recent summary made from my "Experimental Study of Lesions arising from Severe Concussion" I shall here venture to cite the following: "Paraplegia is a very important indication of a lesion of the spinal cord and may have its origin either in a disease or traumatism. This morbid condition may be either complete or incomplete, and when due to

disease it is commonly slowly progressive; but if due to traumatism it is rapidly manifested and soon reaches its fullest development. In support of this statement examine the following facts: The whole number of cases in which pathological changes were found in the cerebro-spinal axis was fifty; the whole number of cases in which any indications of these lesions were observed during the life of these animals was thirty-three, while our record shows that in the last-mentioned class there were twenty-three cases of paraplegia."

It will here be observed that there were ten cases in which there had been noted during the lifetime of these animals some indication of traumatism, but which did not exhibit during that period paraplegic symptoms. It is also worthy of notice that in every instance these paraplegic symptoms were observed immediately after the application of the concussive force; and, furthermore, that in all cases of complete paraplegia there was not a single case which subsequently improved. In the large majority of cases of incomplete paraplegia there was commonly some improvement observed during the first three days, but in a few instances the paraplegic symptoms became more marked during the first twenty-four hours; however, even these cases soon showed signs of improvement. It is not claimed that even the immediate appearance of paralytic symptoms after the application of concussive force establishes, in all cases, the existence of pathological lesions in the spinal cord. I am strongly impressed with the idea that an injury of the peripheral nerves may be followed by temporary, and commonly, local paralysis. A certain degree of importance should be attached to the existence of either anæsthesia or hyperæsthesia in all cases where lesions of the spinal cord are suspected. The existence or absence of pain in these cases possesses very little interest for the diagnostician. In fact, the existence of pain and soreness ought probably to be looked on as having their origin in a contusion, sprain, or wrench, involving the vertebral ligaments, muscles, etc., rather than indicating lesions of the cord. Having now presented a few of the characteristic symptoms of true concussion of the brain, and likewise of the spinal cord, I desire in this connection to add that it is certainly very unfortunate for the science of surgery that it has hitherto been the custom of nearly all authors, writing on what they have unfortunately designated *concussion*, to group together half a dozen or more traumatic conditions, differing radically from each other in their *etiology*, *semeiology*, and *pathology*. It requires no prophet to assert positively that so long as this grouping is continued there will be a want of clearness in all these articles; that theory will be frequently introduced in the place of scientific facts; that clinical observation will continue to mislead the profession; that good-natured authors, believing that all their predecessors in writing on this subject have told a little truth, will still further add to the existing confusion in their attempts at compounding these incompatible ideas. Let me ask what would be the inevitable result, if medical authors should group together under the unfortunate cognomen of "Smith's disease," scarlatina, diphtheria, rubeola, roseola, variola, typhus fever, etc.? But this combination is no more objectionable than that grouped under the name of "railway spine," which is so frequently employed by so many of our surgical authors even at the present time. However, the dawn of a new light may be approaching, since Dr. John A. Lidell, in writing on "Injuries of the Back, including those of the Spinal Column, Spinal Membranes, and the Spinal Cord," states that "The traumatic lesions of the back naturally arrange themselves in three groups, as follows:

"1. Injuries of the integuments and muscles, or soft parts generally.

"2. Injuries of the vertebral column.

"3. Injuries of the spinal membranes, spinal cord, and spinal nerves." [1]

It must be apparent that this classification presents many important advantages over that commonly employed. Another serious source of confusion has arisen from the fact that the term concussion was, in former times, restricted in its application to the brain, although analogous pathological lesions were produced by the same force in nearly all the organs of the body.

Furthermore, concussion was badly defined by the old authors; because the term was used to indicate a condition induced by a more or less violent shaking of the brain, whereby serious symptoms were produced without lesions of the structures. Recent experiments on animals and a careful study of this subject have entirely failed to support their statements in regard to the non-existence of lesions after concussive accidents in the brain and spinal cord. The results of my experiments were very conclusive in regard to the existence of these lesions. There were fifty cases in which pathological changes were observed in the cerebro-spinal axis, but only thirty-three of these cases showed any symptoms of injury of this centre during life; it will, therefore, be readily seen that in seventeen cases, although pathological lesions existed, they were not made apparent by symptoms which could be recognized in the animals. It is also noteworthy that there was not a single case in which the existence of concussion of the cerebro-spinal axis was even suspected,

[1] The International Encyclopædia of Surgery, vol. iv. p. 668. Edited by John Ashhurst, Jr., M.D. New York: Wm. Wood & Co., 1884.

wherein by our subsequent examination, we failed to discover pathological lesions, *post-mortem* or *microscopical.* These pathological lesions in true concussions are certainly unique in character and nearly or quite pathognomonic in significance. The only lesions that bear semblance to the pathological changes of concussion are those arising from contusions, and these are localized and not distributed generally throughout the organ, as is commonly the case in the former morbid condition. However, there is found an exception to these rules in the case of concussion following gunshot wounds, in which the injury is commonly localized and more or less closely resembles the ecchymotic appearance arising from contusions. The functional disturbances and the pathological lesions are clearly shown in my experiments to have had their origin in the vasomotor system. In order to illustrate the pathological changes in the spinal cord which have been observed to follow in a mixed or complicated case of concussion of this organ, I will here cite the report of an autopsy, etc.,[1] made on the body of a coal-porter, who had died thirty-four hours after the accident:

"*Autopsy*: There was no external trace of injury. The membranes of the cord were healthy. The substance of the cord was contused opposite the fourth and fifth cervical vertebræ. On section there was found ecchymosis of the posterior horns of gray matter on the left side, and of the adjacent part of the lateral and posterior columns. There were also limited spots of ecchymosis on the right side, one in the right posterior column and one in the right anterior horn of gray matter. The gray substance, generally, was hyperæmic. On removing the spinal cord and membranes nothing abnormal was discovered in the vertebræ until the posterior ligament had been dissected off, when it was seen that the body of the fourth was separated from that of the fifth, and the left articular process of the fourth had been chipped off."

Dr. John A. Lidell, who reports this autopsy, comments on it as follows: "The essential features of this instructive case are as follows: (1) The cord substance was injured by concussion and not by any displacement of the parts. (2) The injury was attended by a number of minute extravasations of blood (ecchymoses) in the gray substance. (3) There were anæsthesia and loss of motion in both lower extremities and in the left arm. (4) There was paralysis of the sphincter ani and sphincter vesicæ, which denoted that the reflex motor apparatus was also paralyzed. (5) The anæsthesia passed away in the course of some hours, the return of sensibility being noted first in the parts most distant from the injury. (6) Hyperæsthesia appeared synchronously with the reaction from 'shock,' and steadily increased in severity. (7) Hyperæmia of the gray substance was found as well as ecchymosis. It should be remarked that the hyperæsthesia was more severe in the right arm than elsewhere, and this part had not at any time been paralyzed." This case was reported by Dr. Lidell as a pure or uncomplicated one of spinal concussion, but I am compelled to qûestion the correctness of the report in this particular, and direct attention to the ruptured ligament which it seems to me may have permitted a partial dislocation to have taken place, with contusion of the cord, the vertebræ afterward having been restored to their proper position by the natural resilience of the parts. The symptoms of paralysis were certainly more marked than they are usually in cases of pure, uncomplicated concussion of the spinal cord. The following microscopical report conveys a very clear idea of the pathological lesions observed in our experiments on animals in the cerebro-spinal axis when there were no complications in this centre:[1] "Brain intensely hyperæmic, otherwise normal. Every portion of the cord intensely hyperæmic. There were punctate hæmorrhages in the dorsal and cervical regions of the spinal cord, in both the anterior and posterior horns, also in the middle commissure."

The striking analogy existing between the lesions in cases of death caused by electricity and the other cases of concussion may be probably better illustrated by citing the report of the autopsy made by Dr. Carlos F. McDonald on the body of William Kemmler after execution by electricity, since this examination has been more carefully detailed than any of the others. The others, however, entirely agree with McDonald's, so far as given. McDonald's report is as follows: "Rigor mortis marked. On incising the skin over the sternum the blood which escaped was unusually dark and fluid and remained so on exposure. Lungs: Tardieu spots were noticed on the posterior border of the lower lobe of the left lung, also in the middle lobe of the right lung. Heart: Valves and substance normal, ventricles empty. Liver: Blood from cut surface of dark-crimson hue. Gall Bladder: Distended with bile. Spleen: Normal. Kidneys: Both markedly congested. Brain: *Capillary hæmorrhages* were noted in the floor of the fourth ventricle, also in the third ventricle, and in the anterior portion of the lateral ventricle. The perivascular spaces seemed to be distended with serum and blood." Dr. Spitzka's report of the preliminary microscopical examination is as follows: "The brain,

[1] International Encyclopædia of Surgery, vol. iv. p. 790 et seq. Edited by John Ashhurst, Jr., M.D. New York: Wm. Wood & Co., 1884.

[1] An Experimental Study of Lesions arising from Severe Concussion, p. 22 et seq. By B. A. Watson, M.D. Philadelphia: P. Blakiston, Son & Co., 1890.

spinal cord, and peripheral nerves appeared strictly healthy in every part examined, except in the area corresponding to the discolored (anæmic through the contraction of the vascular channels) area of the Rolandic and pre-Rolandic regions, the ventricular surface, the pons and the medulla oblongata. The latter, which had been the seat of post-mortem preservation of temperature approaching that of the normal human body, were distinctly softer than the observer has ever been accustomed to find these parts in autopsies on persons of Kemmler's age, so soon after death. The hæmorrhagic spots in the fourth ventricle, which were strongly marked, were not accompanied by signs of parenchymatous rupture of large bloodvessels. Hence they may be regarded as having the same significance as the 'taches de Tardieu' found on the surfaces of the organs, notably the heart and lungs. The peculiar softened vesicular zone of tissue underlying the outermost layer of the cerebral cortex is noteworthy as 'the destruction line,' and runs parallel to the free surface of the brain without dipping with the sulci. Examination of the fresh specimen revealed the existence of vacuoles (probably gas bubbles) in the ganglion cells and in the parenchyma of the destruction line. From the fact that no hæmorrhages had occurred in this softened area, it is a just inference that it was produced after life had become entirely extinct, for the continuance of a blood circulation in a softened brain area is incompatible with the bloodless appearance already noted, and the absence of capillary hæmorrhages in this very district, while they were present in those remote from the site of the electrode."

In order to approach the consideration of *malingering* it is necessary to devote some attention to the traumatic conditions which frequently complicate concussion in the cerebro-spinal axis; since the majority of authors still include these morbid conditions under the head of "spinal concussion," "railway spine," etc. Fractures and dislocations of the vertebræ require little attention at the present time, since they are generally easily diagnosticated, the only exception to this rule being those cases where there is a complete absence of deformity, which may be the case where the fracture consists in chipping off a portion of the articular vertebral surface, etc., or in an incomplete dislocation of a vertebra in which the natural resiliency of the ligaments and muscles has restored the symmetry of the parts. In these cases, it is thought that the careful and observing surgeon will not be compelled to remain long in doubt as to whether the patient before him is a malingerer or suffering from a real traumatic injury—since the prompt appearance of objective symptoms will certainly be largely dependent on the locality of the injury, while their degree of severity will depend very much upon the extent and character of the traumatism.

There now remain for our consideration in this connection contusions, sprains, twists and wrenches of the back, which on account of their medico-legal bearings are entitled to a more thorough analysis than can be given them in this article. The study of these morbid conditions will be greatly simplified by bearing in mind that their symptoms, the primary and secondary effects, are entirely analogous to injuries of the same character in other parts of the body. It is claimed that the spinal column and the bones which connect directly with it are provided with ninety-nine articulations. The symptoms which characterize the morbid conditions now under consideration are pain, swelling, tenderness under pressure, and occasional ecchymoses. The existence of the symptoms will be limited to the area involved in the traumatism, while the degree of severity will depend on the intensity of the injuries. In some cases there may be constitutional disturbances which will aid in establishing the existence of a morbid condition. The ecchymoses and swelling are objective symptoms, and consequently entitled to due consideration, while the pain, stiffness, and tenderness under pressure may require confirmation. The verification of the patient's statements on these points, and frequently on others, especially questions involving the existence of paralysis, might be definitely put at rest by the proper use of an anæsthetic, which ought to be frequently employed in medico-legal cases. The general surgeon no longer hesitates to employ this agent in his private and public practice for diagnostic purposes; and why should it not be thus employed for the purpose of securing justice in our courts?

Drunkenness and syncope may make the diagnosis more difficult in certain cases of concussive accidents, whether it be pure or complicated concussion; but these factors are of short duration, and therefore cannot long continue to embarrass the surgeon.

It is unfortunately too frequently the case that a surgeon commences his examination in medico-legal contests after *having fully formed an opinion*, or at least a bias or prejudice. In many cases, in fact almost universally, this arises from the want of an analytical mind and of any carefully arranged system of examination. These are very serious defects in the expert witness, and when fully demonstrated should disqualify him from testifying. There is another serious defect frequently observed in the members of our profession, which sometimes has its origin in laziness, although occasionally in an inordinate greed, where the physician has been accustomed all his life to give an opinion to a patient without either

an examination or thought. It will be perceived that I have not yet reached the case of the malingerer; but I have thus far merely paid my respects to those who aid and assist the malingerer. The malingerer is certainly entitled to a careful and thorough examination, and each surgeon employed in the case ought to proceed in his examination with the same degree of care and caution that the most conscientious chemist would exercise when required to make a chemical analysis in the interest of justice. It therefore becomes highly important to learn the true history of the litigant, and likewise that of his father, mother, brothers, and sisters. All these matters have a special bearing on the case. It will be readily admitted that any person who has established a good character for truthfulness and honesty ought not to be classed with a mere adventurer. In the examination of all the factors involved in these cases of so-called "railway spine" the fact should never be lost sight of that *correct scientific opinions can only be reached by a systematic, methodical, and painstaking investigation.*

Let us here present a brief *résumé* of some of the points which have been more or less considered in this paper:

1. As used by those who first employed it, the term concussion was erroneously defined, and in its application, unfortunately restricted to the brain. These errors had their origin in a deficient knowledge of the pathological lesions engendered by concussive force.

2. Concussion is a more or less violent shaking or agitation of various organs in the body, producing functional derangements dependent on vasomotor changes and well-defined pathological lesions.

3. Concussion may be either general or special—general when several organs are involved at the same time, or special when the entire concussive force is expended on a single organ.

4. The symptoms arising from concussion will chiefly depend on the extent of the pathological lesions and the functions of the organs.

5. The frequency with which concussion will occur in any particular organ will depend on the point to which the concussive force is applied; the relative weight of the organ; the character of its texture; the protection afforded by its anatomical surroundings.

6. The fifth statement supplies the explanation of the comparatively frequent occurrence of concussion of the brain, lungs, liver, and kidneys, as compared with that of the spinal cord.

7. Concussion of the brain and spinal cord is always attended with immediate symptoms.

8. Concussion of the brain or spinal cord without immediate symptoms is a mere hypothesis, a myth, and has no real existence.

9. There is no pathognomonic symptom of concussion in any organ of the body, but a thorough, systematic, methodical examination by a skilled surgeon will secure a correct diagnosis.

Finally, I desire to reiterate the fifth conclusion, expressed by Dr. Henry Hollingsworth Smith in a paper which he read before the surgical section of the American Medical Association in 1889, and which is as follows: "No physician should go into court and swear that a plaintiff has had a concussion of the spinal cord, or of its nerves, unless he has proved the disturbance of the normal functions of the cord, as shown in sensation, or motion, or both, and that the symptoms appeared *soon* after the injury."

ORIGINAL LECTURES.

PLEURISY WITH EFFUSION—SIMPLE ENLARGEMENT OF THE THYROID GLAND.

BY JOSEPH M. PATTON, M.D.,
PROFESSOR OF INTERNAL MEDICINE IN THE CHICAGO POLYCLINIC, CHICAGO, ILL.

GENTLEMEN: I show you this afternoon this young man, who is fifteen years of age. He comes to us saying that about two or three weeks ago (he does not state the exact time, which is a point to be noted) he began to complain of some transient pains in the side, and that he felt languid and tired. A week or ten days since, he began to notice that there was some difference in the contour of the two sides of the chest, this difference being sufficiently marked to call his attention to the fact that there was something wrong with his chest, and to-day he comes for advice. We will examine him to see what we can find. The imperfect history is one point in this class of affections to which I desire to call your attention. His pulse is 100, and his temperature 101° F. You notice, as you look at the boy with chest stripped, that there is considerable difference between the two sides, the left being fuller and more prominent, especially in the mammary region, and not so flat as the other (right). This prominence in the mammary region on the left side is not important. In young people, before the cartilages have attained growth and firmness, some deformity in this region is often found as a result of pressure on the yielding cartilage, especially when there has been rhachitis; it is of no importance in this connection, so that we do not pay much attention to the prominence which you see in this case. You notice, also, that behind there is apparently some lateral curvature of the spine; the shoulder on the left side droops somewhat, and there is distinct bending of the spinal column. The reason for that you will see later on. There is an absence of pulsation in the cardiac region, but a marked pulsation to the right of the sternum, at about the third and fourth intercostal spaces; this is due to the displacement of the heart; hence there is an absence of pulsation in the natural cardiac area. This may be due to effusion into the pleural cavity; to extensive emphysema in one lung; to tumors in the mediastinum; or to extensive retraction of the lung, with pleuritic adhesions, so that the heart is displaced.

These causes are not factors in the displacement of this boy's heart. We must go farther to find the reason for it. So much for inspection. On palpation there is a loss of vocal fremitus on the left side, while the fremitus on the right side is exaggerated. The percussion note is flat on the left side, and a little more resonant on the right side. In regard to the percussion note being flat all the way up, you know your text-books tell you that in pleurisy with effusion you have flatness below the line of fluid, and above it you have resonance of a tympanitic quality, or increased resonance, which may be due to some compression of the upper lobe of the lung of that side, or to slight condensation. In cases with a moderate amount of effusion, the lung being pressed upward, you will get percussion resonance of a tympanitic quality if the upper lobe is not compressed; if the fluid nearly fills the pleural cavity, and the upper lobe is moderately compressed, the resonance is increased. In this case the left side is practically filled with fluid, so that the flatness is uniform up to the first rib. The vocal resonance is more or less distinct all over the left side, and the respiratory murmur can be heard all over the left side and at the angle of the left scapula distinctly, having a marked bronchial character. That is not in accord with the signs of palpation and percussion. The sounds we have elicited by palpation and percussion are those of pleurisy with effusion, yet we should not be able to get with pleurisy and effusion the vocal resonance or respiratory murmur. I want to call your attention to the fact that there are exceptions to all of these cases, and that you cannot go absolutely by the classical signs as laid down in your text-books. You will find cases of pleurisy with effusion in which you can get distinct vocal resonance below the level of the fluid, and you get distinct respiratory sounds. In those cases of pleurisy with effusion in which the chest is half full of fluid, as a rule you have the classical signs of pleurisy; you have absence of all signs below the level of the fluid. When the chest is almost or completely filled, and the lung is compressed against the spinal column and against the opposite side, you get a transmission of sound if the bronchi are still patent. Some of the books tell you that in some cases of pleurisy with effusion you get breathing of a bronchial character at the angle of the scapula. I want you to listen to see how distinct it is in this case. It is not vesicular in quality; it is bronchial in character, the same as is observed in croupous pneumonia, with the exception that it is further away. It is not quite so harsh, and it has the sensation of being produced at a greater distance, because of the indistinctness with which it is transmitted through the fluid. So that, taking the exceptions in this case into account, we would make a diagnosis of pleurisy with effusion, notwithstanding the fact that we get the sounds so plainly all over the left side of the chest. The scoliosis here, which is slight, is probably due to the weight of the fluid, and will probably disappear on removal of the pleural contents, as will also the displacement of the heart.

The most important point in the differential diagnosis of this affection pertains to croupous pneumonia. There are other diseases of the chest which will simulate it more or less, such, *e. g.*, as emphysema and those diseases of the chest which give you dilatation of the chest wall—chronic pleurisy, empyema, pneumothorax, etc. Any of these diseases will simulate pleurisy with effusion, from the fact that they will dilate one side of the chest. But the most important differential diagnosis is to be made between this disease and croupous pneumonia. Both may give loss of motion of the affected side of the chest; both give you compensation by the opposite lung; both are usually unilateral; both give you changes in the physical signs which may be very much alike. You get the dulness, with the exception that in croupous pneumonia the dulness is not so complete, and it does not approach the complete flatness that you may get in pleurisy with effusion. The vocal fremitus in croupous pneumonia is increased instead of diminished or absent. The voice-sounds in croupous pneumonia are increased; you get bronchial breathing and increased vocal fremitus. You get bronchial breathing on this (left) side at certain points, so that, although the classical signs of the two diseases are entirely different, the diagnosis is not so easy when you get a case of this kind, in which you have bronchial breathing at certain points in the lung; you have to be careful to distinguish it from pneumonic consolidation of the entire lung. Though the physical signs of the two diseases may be at times very similar, other symptoms are the more sudden onset in pneumonia; the character of the pain; the character of the dyspnœa; the temperature range; character of the sputa—rusty and sticky in pneumonia, frothy and white in pleurisy, etc. In differentiating this disease from emphysema, you can do so by the character of the respiration and the tympanitic character of the percussion sound in emphysema. There is not much likelihood of confusing emphysema and pleurisy with effusion, for the reason that the former is more or less two-sided. It occurs at times on one side only. It may be confusing from chronic pleurisy or empyema. You are to make the diagnosis a good deal by the history. Chronic pleurisy will, at times, give you the same signs as are present in this case, but, as a rule, you have fever and sweats, and much exhaustion, although it may be so confusing that the diagnosis is only to be made by withdrawing some of the fluid. Again, you cannot always tell with absolute certainty that the fluid in the chest is serous or (more or less) purulent. The differentiation from pneumothorax is to be made by the rapid dyspnœa which occurs. There is perforation of the pleural tissue, the result of destruction of lung tissue in tuberculosis; there is a sudden rupture into the pleural space, causing intense dyspnœa, coming on rapidly, and being persistent. This may also occur from gangrene, pneumonia, or, as in a case reported, by the bursting of a distended air-vesicle or dilated bronchial tube. Of course, after this has occurred, the physical signs will differ; you get dulness in the lower part of the chest cavity, where there is fluid, and tympanitic resonance above the fluid; you get the cavernous breathing of a metallic character at the point where the opening in the pleural membrane has taken place. If the opening is closed you may not get respiration of a metallic or cavernous character. You may get the sound or metallic tinkling, both of which are characteristic.

One peculiar feature about this case is the degree of displacement of the heart and the comparatively little dis-

tention of the intercostal spaces of the left side. The intercostal spaces, as you see, are not at all bulging. Bulging is laid down in the text-books as one of the prominent symptoms when there is a quantity of fluid present. You must take into consideration the size of the chest wall, its thickness, the resistance of the hard and soft parts, the character of the organs contained within the chest, the degree of development they have attained, and the likelihood of adhesions of various kinds which may limit their displacement. When a young boy has an even chest cavity, is perfectly healthy, there are likely to be no adhesions of the pericardium or pleural membrane to prevent displacement. When there are no tumors present in the chest, when the chest wall is elastic, you can readily see that the pressure may be felt more by the organs in the chest cavity than by the chest wall; therefore there is considerable displacement of the heart without very much distention of the intercostal spaces. We find the heart over on the right side of the sternum, and the lung is markedly compressed against the opposite side, sufficiently so to cause distinct bronchial breathing through considerable fluid.

It has been pointed out as important in distinguishing the character of the fluid contained in the chest, that in fluids containing pus you get little or no transmission of voice-sounds, although the fluid may be thin, but that in the case of serous fluids you are apt to get the transmission of sounds as you do in this case. That, of course, you would expect from the nature of the fluid —a heavier fluid moves with greater difficulty, and therefore the sounds are not so easily transmitted. It is sometimes difficult to determine whether these collections of fluid are unilocular or multilocular. You may have divisions of the pleural cavity into two or more compartments, and for that reason you may have localized collections of fluid. It has been pointed out that the zone extending around the side of the chest, about the level of the sixth intercostal space from the mammary region to near the spine, in which you obtain more marked vocal sounds than you do in any other portion of the chest, indicates that there are pleuritic bands which convey sounds to the chest wall. This can hardly be depended upon as a diagnostic sign, but it might be of use.

Now, as regards the treatment of this class of cases. It depends upon the stage in which you see the patient. It is good practice to occupy two or three weeks in trying to remove the effusions before you resort to surgical interference, provided the effusion is not great enough to compromise the patient's lungs by pressure in that short space of time. Such treatment will consist mostly in the use of diuretics, acetate and citrate of potash, and the administration of iodide of potash, citrate of caffein, digitalis, Fowler's solution of arsenic, if there is anæmia, and iron. In these cases you get little or no kidney action until you improve the general nutrition by the administration of iron. After some little time with the use of this treatment, if the fluid does not disappear it is proper to resort to surgical interference. In those cases in which, as in this one, there is marked compression of the lung, it is well to remove a certain amount of fluid in order to make room for expansion of the lung, and room for absorption by the pleural vessels. Take a chest cavity distended like this; the pleural vessels have all sustained a good deal of lateral pressure, and after removing a small quantity of fluid from one of these cavities the rest of the fluid will disappear rapidly, because it removes the pressure on the vessels and permits of their taking up the fluid, thus allowing expansion of the lung.

In cases in which the diagnosis is not so clear as in a typical case, there can be no harm by the introduction of a hypodermatic needle in order to determine the presence of fluid. The danger of the introduction from an aseptic hypodermic needle is practically nothing. I have for a long time practised the introduction of the needle in order to determine principally the character of the fluid. Even in a case like this, in which we are not in doubt as to the diagnosis, it is well to introduce it in order to determine if the fluid is flaky, and if it will run through a small needle. I have never seen any bad results from the introduction of the needle or from aspiration when the instruments were clean. I once had an inexperienced assistant reverse the action of the pump, and pump quite a quantity of air into the chest of a man seventy years of age, without any bad result. (Professor Patton then introduced the needle of an aspirator and withdrew about three quarts of serum.)

Here is the Le Noel pump, a very complete instrument, the needle of which, you see, has a blunt sliding point, arranged so as to cover the sharp end of the needle after it has entered the pleural cavity, and thus prevent injury to the lung. In this instance there is no danger of injury if the needle is properly handled and we will use the ordinary aspirator.

SIMPLE ENLARGEMENT OF THE THYROID GLAND.

The young lady I now present to you has been under treatment at the clinic here for some time. The case is one of those you frequently see, the diagnosis of which may be troublesome. She has an enlargement of the thyroid gland, a bilateral enlargement involving the isthmus, with a good deal of protrusion of the neck, which annoys her considerably, and she is unable to cover it. The gland is soft, does not exhibit any murmur, and is uniform in its enlargement. Now, the interesting point in this case is whether the diagnosis should be simple enlargement, cystic enlargement, hypertrophy of the gland, or whether it is exophthalmic goitre, which, of course, makes a great deal of difference in regard to both the treatment and prognosis. The differential diagnosis between simple hypertrophy of the thyroid gland and exophthalmic goitre is not the easiest thing in the world. Enlargement of the gland is one of the three classical symptoms of Graves' disease, and it is, as a rule, preceded by cardiac symptoms. The term cardio-vasomotor disease, which was applied by Simpson to exophthalmic goitre, is a much better term, because it expresses not only the pathological relations so far as we know them, but it expresses the clinical elements which present themselves. As a rule, the cardiac symptoms are the first to appear. There is palpitation of the heart, either constant or spasmodic, with a good deal of pulsation in the arteries, followed by some cerebral symptoms which accompany the change in the vascular tension—that is, giddiness, dizziness, and at times a tendency to syncope. As a rule, I say, these symptoms present themselves before the enlargement of

the gland. The enlargement of the gland may appear simultaneously with ocular protrusion, or may precede it, or may follow it; but in some cases the enlargement of the gland comes first, and it is difficult to tell whether you have a case of exophthalmic goitre or one of simple enlargement of the thyroid gland. You must remember that in young girls it is a very common thing to have simple enlargement of the thyroid gland with rapid action of the heart—that is, there is a tendency of the heart to run up to 120 or more, because the vascular tension is low, and there is a lack of innervation of the vascular system. Such patients are anæmic; their appetite is not good; the mucous membrane presents the appearance of chlorosis, only it is not so well marked. It is a frequent thing for girls in this condition to have enlargement of the thyroid gland, which, preceded by cardiac manifestations, may very readily be mistaken for exophthalmic goitre; but you will hear no murmur in the gland, and it will not be followed by ocular symptoms. In the case of this young girl the diagnosis of simple enlargement of the thyroid gland was made, and she was put on tonic and alterative treatment, and the result so far has been satisfactory. From quite a marked enlargement, the gland has become smaller and smaller. She has been under treatment some five or six months, until now there is simply a little broadening of the throat; and I think the cardiac symptoms have mostly disappeared. If you listen over the aortic area, there is little intensification of the second sound of the heart; it is a little more marked than it should be, showing that the heart and vessels have not quite regained their proper condition.

The treatment she has been under has been iron, iodide of potassium, and biniodide of mercury. The form of iron given in this case was the same as you give in chlorosis—Blaud's pills. In those cases which present vascular symptoms—and this is virtually a vascular disease—we give nux vomica to increase the innervation of the vasomotor system. The iodide of potassium she has been taking in ten- or twelve-grain doses, three times a day, with the biniodide of mercury externally. In using this ointment there is no advantage in employing a strength so great as to cause irritation of the skin. It should be used strong enough to be absorbed without blistering the skin. It will, perhaps, cause a little irritation, redness, or soreness, but it should not blister. The strength to be used would be about half and half, the biniodide ointment of the strength of the Pharmacopœia, with any of the excipients, such as vaseline, cosmoline, lanolin, or any of the bland ointments. She has been using half vaseline and half of the biniodide, which produces just enough redness of the skin so as not to be sore, and yet have plenty of it absorbed. She is doing nicely.

Some time ago I saw a young lady, about twenty years of age, who was troubled with thyroid enlargement accompanied by cardiac palpitation. Owing to the fact that another member of the family had died of exophthalmic goitre, her physician had made up his mind that her case was also one of the same kind. After careful examination of the gland, the circulatory organs, etc., I came to the conclusion that it was a simple enlargement of the gland from loss of innervation of the vessels, loss of tone, and anæmia, and under the same treatment that this patient has been under she recovered completely. There is now no enlargement of the gland, no palpitation of the heart, and she is in good health. These cases are interesting to me on account of the frequency with which we see them, the difficulty sometimes in making a diagnosis, and the necessity of making a diagnosis in order that you may promise relief by your treatment. Intra-parenchymatous injections of iodine, carbolic acid, etc., will sometimes be of benefit in thyroid enlargement, though some cases of hypertrophy of the gland do not seem to do well under such treatment. Electricity is also very valuable in some rapid enlargements of the gland, but the results are not always permanent. Finally, there are some cases of long-standing enlargement of the gland which can only be remedied by surgical procedures.

MEDICAL PROGRESS.

Excision of an Aneurism.—Kimura (*Sei I. Kwai. j.* December 27, 1890) reports a case of popliteal aneurism in which excision was successfully performed. After the preliminary incisions the popliteal nerve was held aside and ligatures applied to the popliteal artery above the aneurismal sac, and to the anterior and posterior tibial arteries, below, and the sac dissected out. The operation occupied an hour. The cure was complete.—*Revue Internationale*, April 25, 1891.

A New Method of Treating Ununited Fractures of the Patella.—Wolff (*Deutsche medicin. Wochenschr.*, May 14, 1891) approximated the fragments of a fractured patella, which had failed to unite, by means of four double-pointed nails bent in the shape of horseshoes, in the broad portion of each of which were two holes. Four openings were bored into each fragment of bone and into them the nails were introduced and made fast. Approximation was accomplished by means of silver sutures passed through the holes in the nails. Slight loosening of the nails necessitated a secondary operation, five weeks after which the nails were permanently removed. Though the union of the fragments was not osseous, the result was eminently satisfactory, there being no separation of the fragments and function being admirably restored.

Antiseptic Dentifrice.—Dujardin-Beaumetz:

℞.—Acidi carbolici	. . . .	gr. ss.
Acidi borici	. . . .	gr. x.
Thymol	. . . .	gr. ½.
Spts. menthæ piper.	. . .	♏j.
Tinct. anisi	. . . .	♏v.
Aquæ	. . . . .	fl℥ij.

Sig.—Rinse the mouth and brush the teeth after each meal.—*L'Union Méd.*, May 9, 1891.

For Pulmonary Tuberculosis.—Potain:

℞.—Sodii chloridi	. . . .	gr. xlviij.
Sodii bromidi	. . . .	gr. xxiv.
Potassii iodidi	. . . .	gr. v.
Aquæ destillatæ	. . . .	fl℥j.

Sig.—A teaspoonful every morning in a glass of milk.—*L'Union Méd.*, May 7, 1891.

Treatment of Chronic Articular Rheumatism.—During subacute exacerbations antipyrin or sodium salicylate should be administered in small doses, long continued. In the intervals, arsenic in doses of from one-twenty-fourth grain to one-eighteenth of a grain, and from five to ten grains of iodide of sodium, at meal time, or from ten to fifteen drops of tincture of iodine daily, may be given. POTAIN recommends warm baths, preferring pool-baths to tub-baths, of one or two hours' duration. With this should be combined tepid douches of sulphurous water to the diseased articulation. Galvanization with the continuous current is preferable to faradization. The latter acts rather upon the muscles, the former upon the nutrition. The action of the iodide is favored by administration in an alkaline mineral water. If tincture of iodine is used it should be largely diluted. The degree of tolerance can be increased by the conjoint administration of a preparation of opium, such as paregoric.—*Revue Gén. de Clin. et de Thérap.*, April 29, 1891.

Intra-laryngeal Thyroid Glandular Tumor.—PALTAUF (*Wiener med. Presse*, May 10, 1891) reported to the Society of Physicians of Vienna the case of a girl, twenty-one years old, admitted to Albert's clinic with extreme dyspnœa. After tracheotomy had been performed, a tumor was discovered below the right vocal band. Suppuration subsequently set in in the left lobe of the thyroid gland, followed by septicæmia and death. At the autopsy, among other things, below the right vocal band was found a tumor as large as a bean, acinous in appearance, seated upon a ring of cartilage and constituted of the normal tissue of the thyroid gland. On the hyoid bone was a supra-hyoid gland, a portion of which was contained within the bone. The growths were not considered to be accessory thyroid glands but normal thyroid tissues which had gained entrance by proliferation into the larynx through the intervening structures.

The Diagnosis of Pulmonary Cavities.—SCHULTZE (*Centralbl. für klin. Medicin*, May 9, 1891) quotes Weil: "The certain recognition of pulmonary cavities is one of the most difficult problems in physical diagnosis." There are few symptoms indicative of the existence of large cavities. Such a condition is to be suspected when "changes of position give rise to alternating dulness and tympany on percussion." That this symptom may prove deceptive and may result from the existence of a system of small cavities is illustrated by the case reported. A shoemaker, forty-eight years old, suffered from progressively increasing cough, expectoration, shortness of breath and loss of flesh. There was evening fever and the ends of the fingers were clubbed. The lungs were emphysematous, the sputum abundant and fœtid, containing elastic fibres. Râles were heard at all parts of the chest and loud, bronchial breathing at the lower part of the left lung. In the sixth intercostal space on the left, there was dulness on percussion, when the patient sat upright, which disappeared when the recumbent posture was resumed. A diagnosis of pulmonary gangrene, with a large cavity, was made. Operative interference was contemplated, but Trendelenburg suggested the existence of a number of small cavities. The patient rapidly failed and died. The administration of myrtol failed to overcome the offensive odor of the sputum. The autopsy disclosed the existence of extensive bronchiectasis in both lower lobes, with loss of pulmonary structure in places.

The Fermentations of Milk and their Prevention.—PROFESSOR H. W. CONN, in a lecture before the Connecticut State Board of Agriculture, thus summarizes his conclusions as regards this subject:

1. The fermentations of milk are varied, although only a few are commonly recognized, because the souring of milk usually obscures all other fermentations.

2. All of the fermentations, except that of rennet, are caused by microörganisms getting into the milk after milking and growing there.

3. The microörganisms are so abundant around the barn and dairy that they cannot be kept out of the milk by any degree of care.

4. The bacteria which produce the abnormal or unusual fermentations, like slimy milk, bitter milk, etc., are, however, not so common but that they may be prevented from entering the milk in sufficient quantities to produce serious trouble.

5. Filth is ordinarily their source, and cleanliness the means of avoiding them.

6. The souring of milk cannot be prevented even by the greatest cleanliness.

7. Salicylic acid in proportions of 1 : 1000 may be of some little value in delaying the souring, but its use is not to be recommended except in special cases.

8. Milk can be entirely deprived of bacteria by the exposure to a temperature of from fifteen to twenty degrees above that of boiling water, or by a long-continued boiling, or by a series of short boilings on successive days.

9. Such milk has the taste of boiled milk. This taste appears at about the temperature of 160° F. Hence has arisen the method of Pasteurization of milk. By this method it is heated to a temperature of 155° F. for a short time, and then cooled. This greatly delays the fermentations, and also kills the pathogenic germs that may be present.

10. In our large cities the popularity of sterilized milk is rapidly increasing, especially given to patients troubled with diseases of the digestive organs.

11. The cooling of milk immediately after it is drawn from the cow is of the greatest assistance in delaying the fermentation, and in the present state of our knowledge is probably the most practical method which can be recommended.—*Science*, May 15, 1891.

For Gonorrhœa —

℞.—Creasoti . . . . 10 drops.
Extract hamamelis fl. } of each 15 "
Extract hydrastis fl. }
Aquæ rosæ . . . . 2 fl. ounces.
Aquæ . . . . . 6 " " —M.

Sig.—Use as an injection.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 6, 1891.

AN INTRODUCTORY WORD.

THE incoming editor considers the duty of his journal to be that which, in large, is the duty of medicine itself—the furtherance of practical therapeutics. But a significant qualification at once arises—practical therapeutics must, at this time, be scientific therapeutics.

The worker in any abstract science does not think of practical ends, but pursues truth alone. And this is a noble ideal. But the family physician must often, and indeed generally, fix his attention almost solely upon the very practical details of the cure of concrete disease—an equally high and worthy aim. In the differentiation of function brought about by modern social conditions and progress, these two classes of workers are very prone to become too sharply contrasted, each pursuing its single way, forgetful of the other. Medical journals are bountifully present, the aims of which seem to be to furnish prescriptions for memorizing or copying, to satisfy childish or prurient curiosities, or to supply medical rules of thumb that should have been taught by common sense or learned during the first year of college study. This field having been so excellently occupied, we shall not attempt competition.

On the other hand, laboratories and periodicals devoted to pure scientific research, physiological, bacteriological, or pathological, have been everywhere multiplied, extended, and delimited until the humble practitioner of medicine almost despairs of keeping in touch with such amazing specialization and development.

It is the glory of medical science that in aim and strain it is at once genuinely scientific and intensely practical; and it is believed that the great majority of physicians in their work earnestly desire this union of science and utility.

Now it is precisely to this majority and with this purpose that THE MEDICAL NEWS would minister. It would keep in view this duty of becoming yet more adequately the medium for the dissemination of a scientific but at the same time a thoroughly practical prophylaxis and cure of disease. It is incontrovertible that true medicine is conditioned upon an accurate knowledge of pathogeny and pathology, but it is also beyond contradiction that the final end of all medical work is either to prevent or heal disease. The abstractly true or scientific must and will somehow become practical or useful, and the concrete or practical must always be the object of scientific study.

Our aim will, therefore, be to serve as the intermediary for bringing to the busy practical worker the useful results of original medical research, and the concrete lessons of many single rich experiences. In this work we confidently look for the sympathy and help of contributors and subscribers.

A brilliant and striking illustration and realization of such an ideal as we have described very appositely occurs in the present issue of THE NEWS: When, from the examination of a drop of blood taken from a patient's finger, hitherto unsuspected disease may be diagnosticated, and either a heroic treatment that saves life instituted, or a speedily realized fatal prognosis announced—our faith in our science at once rises, and our power over disease is vastly increased.

OBSTETRICAL AND EDITORIAL HOMOLOGIES.

IN his lecture before the American Academy of Medicine, PROFESSOR PARVIN most deftly hit off certain aspects of the work of the editor of a medical periodical. It is rare that great learning and experience, both scientific and literary, are so happily joined with a touch so light and accurate; one almost fails to see the seriousness behind the banter and the smile. *Inter alia* he said:

"No man should attempt the duties of a medical

editor unless he is a good obstetrician, especially as it relates to the diagnosis of pregnancy and the care of premature and feeble infants. Let me remind you that Socrates, in Plato's Theætetus, states that he is the son of Phanærete, a brave and burly midwife; that he practised midwifery; that he attended men and not women; that he practised on their souls when they were in labor; and, lastly, that his art had its triumph in thoroughly examining if the thought which the mind brought forth was a false idol or a true birth.

"Let me press the analogy a little further: The medical editor ought not only to differentiate between true and false pregnancy, but he should also be able to tell whether gestation has reached the normal term. Unfortunately, errors in diagnosis are very frequent. Pseudocyesis is not uncommon; tympanitic distention may be mistaken for pregnancy, and when the delivery takes place it is simply expulsion and explosion of gas. True brain-babies may be born, but they are too feeble to live unless carefully cared for in an incubator by the editor; an article, prematurely reporting a case alleged to be cured by an operation, may be kept by the editor until the cure is established; it may be written in execrable English, but the wise editor will put good clothes on the child before permitting it to appear in public. I am sure that we all meet every few weeks with papers appearing in reputable though probably not the best medical journals, to which the criticism just made can be justly applied.

"I am sorry to say that medical editors are sometimes ignorant of the characteristics of a child born at term; they fail to recognize the average weight such a child should have, the degree of development and activity it should manifest, and consequently present their readers with imperfect specimens of medical reproduction.

"It occasionally happens that a doctor without any reproductive power, or endeavoring to produce offspring every few weeks, when his pregnancy ought to last several months, is compelled to evolve from his inner consciousness, without any conception having occurred, that which passes for a baby with some, but is purely artificial. Laying aside metaphor, cases which never occurred are sometimes reported in medical journals; some keen and experienced eye will discover the sham, while many suspect that the story is pure fiction. May the day come when all medical editors will be wise enough and brave enough to exclude from their literary museums all artificial curiosities.

"The medical editor may be engaged in procuring abortion. Thus, there is a case of true pregnancy, but gestation has by no means reached its term; the editor with few contributors, and printers clamorous for copy, extorts from this pregnant doctor the promise of an article long before he can properly prepare it; it may be a fee, or friendship, or promise of influence, or something of like sort which is the abortifacient, but it does the work."

DA COSTA — BARTHOLOW.

IN unanimously electing DR. J. M. DA COSTA Emeritus Professor of Clinical Medicine and DR. ROBERTS BARTHOLOW Emeritus Professor of Materia Medica and Therapeutics, the Trustees of the Jefferson Medical College have paid a graceful tribute to the greatness of two distinguished teachers. Thousands will unite with us in hoping that, though withdrawn from their more active professorial duties, both may long continue to carry on their labors, each in the respective department of which he is a recognized representative, and to increase the number of their unexcelled contributions to medical literature and progress. Professor Da Costa will continue as heretofore to deliver his clinical lectures at the Jefferson College Hospital.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Forty-first Annual Session, held at Reading, June 2, 3 4, and 5, 1891.

TUESDAY, JUNE 2D.—FIRST DAY.

THE Forty-first Annual Session of the Medical Society of the State of Pennsylvania, and the first session of the Association as an incorporated body, convened in the Academy of Music, Reading, on the morning of June 2d. It had been almost forty years since the organization last met in this city, and the delegates from the various County Medical Associations of the State received a cordial welcome from their fellow-physicians of the County of Berks.

The President of the Society, Dr. Alexander Craig, of Lancaster County, called the meeting to order at 10 o'clock. After addresses of welcome by the Mayor of the city, the Hon. T. P. Merritt, and the Chairman of the Committee of Arrangements, Dr. S. L. Kurtz, the remainder of the morning was devoted exclusively to the hearing of reports and the transaction of new and unfinished business.

On motion of the permanent secretary, Dr. William B.

Atkinson, of Philadelphia, Dr. Hiram Corson, of Montgomery County, who was president of the Association forty years ago, and Dr. S. P. Ziegler, of Cumberland County, a president of more recent date, were invited to the platform.

Dr. Charles W. Dulles, Chairman of the Committee on Incorporation, announced that a charter had been granted to the Association through a decree of the Court of Common Pleas, No. 4, County of Philadelphia, and that the first meeting of the Incorporators of the Society had been held in Philadelphia on March 25, 1891, Drs. John Curwen, W. T. Bishop, A. M. Miller, John B. Roberts and Charles W. Dulles being present. At this meeting trustees had been elected, and the officers selected at the last annual meeting of the Association had been indorsed. Dr. Dulles offered a resolution that the officers of the Medical Association of 1890–91 be requested to hand over to the Incorporators at the present meeting all papers and other articles connected with their various offices. Carried.

Dr. George B. Dunmire, of Philadelphia County, submitted the Treasurer's Report. The total receipts for the year had been $2907.52, and the expenditures $2097.64, leaving a cash balance in the treasury of $809.88.

Dr. W. Murray Weidman, of Berks County, moved that a committee of one from each County Medical Association be appointed by the President of the Society to take measures toward the adoption of some method of raising funds for the erection of the Rush Memorial Monument, as proposed by the American Medical Association. Dr. Atkinson moved that each county be requested to suggest to the President the most available man for this purpose. Dr. Craig appointed Dr. Weidman chairman of this committee, after which the motion was carried as amended.

At the afternoon session the Address in Medicine was delivered by Dr. J. CHRIS. LANGE, of Allegheny, his subject being "Some Considerations Regarding New Remedies and their Use by the Profession." He founded his remarks upon the aphorism that disease is to be treated by the destruction of its cause—that is, it is to be antidoted, just as poisoning by arsenic must be antidoted by the hydrated oxide of iron. He included under the caption "New Remedies" all preparations and products not officinal in the United States or other Pharmacopœias, and dwelt largely upon the question of proprietary medicines in their relation to medical ethics. He claimed that such drugs should only be used upon a clear indication founded upon experimental study, and he proceeded to show that in the vast majority of instances the drugs which have been foisted upon the profession and public at large as specifics in certain diseases, or to antagonize certain symptoms, have, after careful investigation, been proved to be lacking in the virtues which have been ascribed to them. In support of this statement he cited the failure of Chian turpentine to produce a cure in carcinoma, although at one time highly lauded. He deplored the employment of such new and popular remedies, when other and thoroughly tested drugs are ignored or used only as a last resort. He argued that if the profession employ legitimate medicines in cases of extremity, why should they not all the more be employed in conditions of lesser gravity. While admitting that elegant pharmacy has been an acceptable outgrowth of the efforts of manufacturing pharmaceutists, and that the elixir and the coated pill are great improvements over the tincture and the old-fashioned pill, he feels that the physician deserts scientific medicine when he permits the druggist to delude him into believing that his combinations, in association with some pleasing vehicle, are more valuable than the physician's prescriptions.

DR. A. B. BRUMBAUGH, of Huntingdon, followed with an "Address in Hygiene." He spoke of sanitary science as having found its way into the highest esteem of the profession. In reviewing the older theories and beliefs upon the various departments of hygiene, he said that the time was when clear water was regarded as pure and suitable for drinking purposes, simply because of its transparency, although it emitted an offensive odor; and formerly a single dip in the neighboring brook, once in a summer, was deemed all that was necessary to insure proper cleanliness of the skin with attendant good health. He urged that to insure a better professional understanding of hygienic subjects, the course of medical instruction should be lengthened, and a knowledge of the microscope more generally diffused. He deplored the fact that in this country the physician's preliminary course of education was too elementary. Prevention, he continued, is better than cure, and he who finds a way of preventing consumption will be greater than he who finds a cure for that disease. As regards the disposal of the dead, he emphasized the truth that cremation is the one practical solution to this question. The proper disposal of the excreta of the living is an equally vital subject, and thousands are dying from criminal neglect in regard to this. As cremation is the only proper method of disposing of the dead, so fire is the only thing which will remove this other great evil. He believes that the day may come when preventable sickness will be regarded as a crime.

The subject of "Tapeworm" was considered by DR. JOHN M. BATTEN, of Pittsburg. After reporting some cases he dwelt upon the question of treatment. Dr. Shaw, of Pittsburg, recommended a mixture of kamala, ʒj, and ethereal extract of male fern, ʒij, in one ounce of the syrup of acacia, the whole to be given in two doses, half an hour apart. Barclay, of the same city, has had success with chloroform where other remedies have failed. Allison recommended the cocoanut, while Camp preferred doses of castor oil, followed by ten or twelve-grain doses of thymol at intervals of fifteen minutes, the whole followed by a dose of castor oil. At the time of the expulsion, the patient should sit over a pail of warm water to facilitate the discharge. He believes that in cases difficult of expulsion the head of the worm is attached low down in the intestinal canal. Squibbs recommends the following mode of treatment: After fasting, the administration of a saline aperient (two Seidlitz powders) to produce a copious effusion of serous liquid, which will wash away the mucus from around the head of the worm. In the morning a second dose of the aperient should be given, and after the bowels are open, one-third of an emulsion—made by beating four ounces of pumpkin seed, including the shell, in water enough to make a pint—should be given, and at two hour intervals the remaining two-thirds, the whole fol-

lowed by a dose of oil. Should this fail, the oleoresin of male fern, in ten-grain capsules, may be used, two every three-quarters of an hour until eight or twelve have been taken. It was formerly supposed that the tænia solium was the most common variety of tapeworm in man, but it is now known that tænia saginata is most frequently found.

DR. TYSON, of Philadelphia, called attention to the exceeding rarity of the parasite. In his large practice, including a large dispensary practice, he met with about one worm a year. The tænia saginata is the most common form in this country, Dr. Leidy recently asserting that during the last fifteen years no other variety had been sent to him for classification. Dr. Tyson also spoke of the better success of quacks in the treatment of worms. He believed the reason to be that they treat enormous numbers of cases and give larger doses than the regular practitioner. With regard to the remedies employed, all are useful, provided there is proper preliminary treatment. It is most important that the previous purgation be decided. Kooso flowers have been very efficacious in his hands, given in one-ounce doses in water. Strüppel recommends pomegranate root mixed with ethereal extract of male fern as very valuable. Dr. Tyson has noticed that if two remedies are united they are more valuable.

DR. COOPER has had four cases of tapeworm in thirty-five years. He believes that the head of the worm is often imbedded in some pouch of the intestinal wall where the remedy cannot reach it, and hence the lack of success in treatment.

DR. EARLY has succeeded in dislodging worms by the employment of turpentine.

Adjourned.

WEDNESDAY, JUNE 3D.—SECOND DAY.

The meeting having been called to order at 9 A.M., the address on Mental Disorders was delivered by DR. SAMUEL AYRES, of Pittsburg, his subject being the "Gastro-intestinal Disorders, especially Catarrh and Hepatic Diseases, in their Relation to Insanity." He particularly enlarged upon some of the obscure causes of insanity, including the relationship existing between dyspepsia and melancholia. An unpleasant feeling in the body induces a corresponding feeling in the mind, and mental disorders are thus produced reflexly from physical indispositions. The alterations in the liver in these cases are chiefly those of chronic congestion. Catarrh is probably the chief cause of these changes, while in many cases there is a feature of heredity. As a result of this catarrh, noxious gases, especially sulphuretted hydrogen, distend the viscera, while ptomaines and microörganisms are generated. All of these, together with the leucomaines which are not properly eliminated, are absorbed. Toxæmia follows and is manifested by headache, vertigo, morbid thinking—the effects of the poisonous action upon the nervous system. Cathartics or diuretics generally avail to remove this condition, but let the toxæmia as well as the chronic congestion of the hepatic system continue, and failure of the emunctories to act, and nervous and mental disorders follow, often resulting in insanity and suicide. Acute mania and delirium may readily be explained on the hypothesis of infection from microbic action secondary to gastro-intestinal disorders. Prophylaxis is the leading indication in the treatment of this condition. The question of heredity must be considered, while special treatment of the catarrhal trouble should be instituted, especially associated with diaphoretic elimination of the putrefactive matter in the system.

DR. ISRAEL CLEAVER, of Reading, read an interesting paper on the "History of the Medical Profession in Berks County." He showed that Reading was the first place to welcome the present Association under the name of the Medical Society of Pennsylvania. Berks was the second organized county medical society in the State, Philadelphia alone antedating it. It has furnished two presidents to the State Medical Association, Dr. Easter, in 1836, and Dr. Wallace, in 1862. Thirty of its members served as surgeons in the Union army. It was organized with 22 members, and at present has 55 members. The profession is represented in the county by 289 regular, 42 sectarian, and 60 nondescript members. The record of disease shows some interesting facts. Malarial fever, formerly very prevalent in the county, gave place in the decade from 1850 to typhoid fever, which in turn disappeared during the last decade to make room for malaria again. The records of the County Society show reports of some extremely interesting cases, including a unique treatment of epistaxis by insufflations of charcoal from burnt cork.

"The Treatment of Subacute Pleuritis," was considered by Dr. J. M. ANDERS, of Philadelphia. He said that the therapeutics of the first stage of the disease embraced measures to limit the extent and diminish the intensity of the inflammation, and to remove the acuteness of the pain. If the temperature is high, and not associated with cachexia, veratrum viride and quinine are indicated. The effusion is the result of inflammatory action and not a mere transudation. So long as there is inflammation, as shown by the rise of temperature, there will be exudation, and the absorption of the latter begins with the defervescence of the temperature. To minimize the inflammation, an ointment of iodine ʒss, iodide of potassium gr. 15, and lanolin ʒj, should be rubbed into the side twice daily. Blisters and poultices should be eschewed. Owing to their depressing influence, antipyretics are injurious. Quinine, ten grains every two hours, should be administered. The removal of the effusion constitutes the other leading feature of the treatment, and this should be done only by the use of diuretics, such as the iodides of iron and potassium in combination, associated with a moderately dry diet. Diaphoretics are depressing, and purgatives are apt to be followed by alarming symptoms of collapse. Thoracentesis is indicated should the effusion persist a week after the defervescence of temperature. The amount withdrawn should not exceed one-half pint, but the tapping should be repeated every second day. During convalescence the strength of the patient should be stimulated by proper measures, the muscles toned up by the use of strychnine and electricity, with the sytematic use of the wall machine and parallel bars.

DR. TYSON prefers the employment of stronger counter-irritation in the form of blisters. In regard to paracentesis, the longer the lung is compressed the more difficult will it be for it to return to its normal condition, hence he favors early action, especially if pus be present. He

emphasized the value of lung gymnastics during convalescence.

DR. ROBERTS said that the danger in delay is mechanical. Early evacuation hastens the absorption of the fluid, and he operates irrespective of the temperature chart. He objects to the preliminary use of the hypodermatic needle, and to repeated tappings.

A paper on "Typhoid Fever" was read by DR. WILLIAM F. WAUGH, of Philadelphia, in which he laid stress upon the bacterial origin of the disease. As to therapeusis, he objected to all empirical management of the cases, and to the use of antipyretics in particular. Intestinal antisepsis is the only proper method of removing the cause of the disease. The good effect of the oil of turpentine is due largely to its antiseptic properties. The sulpho-carbolates, especially of zinc, are the most efficient of these intestinal antiseptics. He administers it in doses of two and a half grains every two hours until the stools are deodorized. The use of this drug is followed by an amelioration of all the symptoms, and the disease may even be aborted. In case of any complication it must be supported by the employment of other remedies.

CORRESPONDENCE.

ARTIFICIAL FEEDING.

To the Editor of THE MEDICAL NEWS,

SIR: The communication which I send herewith struck me as very interesting. I submit it to you for publication with the writer's permission. Very respectfully, BARTON COOKE HIRST.

DR. B. C. HIRST,

DEAR DOCTOR: Your article in THE MEDICAL NEWS of January 31st attracted my attention by its title. . . . This is a subject I have thought of and worked on for ten years, and as yet have not been able to arrive at any satisfactory solution to the problem. I wish, however, to give you the advantage of a little experience I gained in Japan, as, though in itself it may be of little value, still if added to some experience of another observer, it might come into use. I went to Japan in 1884 as medical officer to the American Episcopal Mission. One of the first things I noticed was the immense amount of condensed milk imported there, and what astonished me was that it was mostly of American manufacture—"Gail Borden's Eagle Brand." I next noticed only one other brand in the market—"The Anglo-Swiss Milk." On making inquiries I found out that most of the children of foreigners—*i. e.*, Europeans and Americans residing there—were fed almost entirely on condensed milk. You will wonder at this, but it is owing to the following facts: The monthly nurses are Chinese women, who, realizing the fact that children come oftener when the women can be persuaded to have their breasts dried up, of course endeavor to do this and thus make business for themselves; they usually succeed in persuading the mother to abandon her babe to artificial feeding.

The next fact is that, as there are few unmarried ladies there, the dictates of fashion require married women to do all the entertaining, and to fill the place of the unmarried woman in society. Of course, it will not do for a society mama to have a turgid breast that must be relieved, to say nothing of a hungry, crying babe at home that needs feeding every three hours. Pursuing my inquiries further I found that over ninety per cent. of the children of foreigners born in Japan were brought up on the bottle. Being a new-comer, I took it for granted that in a hot climate, artificial feeding must produce a great deal of intestinal trouble, and expected to see much of it, but this was not the fact. On making inquiries of the leading physicians of Yokohama, Tokyo, Nagasaki, and Kobe, I found that such a thing as a death from summer complaint, or from other intestinal trouble brought on by improper feeding, was utterly unknown. The reason for this could not be explained. True, many of the children had slight, and some even very severe troubles of digestion, yet there were no deaths. The usual mode of administering the milk was by the bottle or cup, extreme cleanliness being observed. The rule of washing the bottle in strong bicarbonate of sodium solution was invariably observed, many people using a simple feeding-cup with a nipple on the spout, as it was easier to clean and required the child to be held each time it was fed, and of course was not so hard to draw from as the usual nursing bottle, because of its being open. Lime-water is usually used with the condensed milk. "The Eagle Brand" was noticed to be more constipating than the "Anglo-Swiss," but was less apt to be rejected by a delicate stomach. Ordinary cow's milk was used when a child was constipated, and after using the condensed milks it, in fact, acted as a laxative. Nestlé's food was used to a certain extent with older children, but the condensed milks were generally used for the first six months. The physicians disregarded the directions on the cans entirely, as the proportions given were much too strong. The children there are exceptionally strong and robust-looking. Such rosy cheeks and bright eyes were good to see. Of course, there is one factor to be considered; these children had parents who were picked for their strength. All of the mercantile and missionary corporations *require* a man to stand a good physical examination before he is allowed to go to Japan. The missionary societies require a certificate of robust health from the wives of their agents. Again, these people are all well-to-do. There is no foreign laboring class in Japan. The foreigners there are all either professional men or merchants and their clerks.

I remained in Japan six years, and was during that time in general and hospital practice, and in my own experience knew of no deaths from intestinal troubles among infants, though there were three epidemics of Asiatic cholera during that time. Dr. Duane B. Simonds, who had been a practitioner in Japan for twenty-six years, told me that he had never known of a death from artificial feeding. While children are exceptionally healthy there, adults are the reverse. Nervous troubles are particularly frequent. Wet-nursing was not much practised on account of the fear of syphilis, leprosy, tuberculosis and skin diseases. Parasitic diseases of all kinds are frequent among the lower classes of the natives. Filaria—distoma hepat. and pulmonal.—and guinea-worm are met with in Japan, and on account of the extensive use of human fæces as manure,

the round-worm is a usual habitant of the average intestinal tract. Yours very truly,

FRANK W. HARRELL, M.D.

SEATTLE, WASH., March 18, 1891.

CONCERNING A TWO-YEAR MEDICAL COURSE OF STUDY.

To the Editor of THE MEDICAL NEWS,

SIR: The last issue of your journal contains a remarkable plea for two years of undergraduate medical study as being more just and fair, and more effective in their results, than a three-years course. Dr. Young J. Bond, of St. Louis, in a truly disinterested manner, champions the cause of the brilliant but impecunious young man, and dwells upon the hardships three years compulsory attendance would inflict upon such a student. In conclusion, the writer favors the appointment of a State Board of Examiners.

As has been stated in a recent issue of your journal by Dr. C. A. Todd, of St. Louis, the physicians all over the State favored the passage of the bill on medical education before the last Legislature. The principal object of this bill was the raising of the standard of medical education, and the three-course requirement was one of the features of this bill. It was urged that inasmuch as similar laws had been passed in surrounding States, the enactment of this law would become necessary in order to protect our State from the influx of incompetent physicians from those surrounding States. The bill passed the House, by a large majority, but the persuasive powers of the tongue (or the pocket-book?) of these disinterested champions of the brilliant but impecunious young man were responsible for its defeat in the Senate.

The fact that the brilliant young man is eminently well qualified to take care of himself seems to have been entirely lost sight of; as also the circumstance that the public in general is much more in need of protection against incompetent and ignorant physicians than the brilliant young man is in need of protection against the possibility of learning too much. It is reasonable to suppose that any young man can learn more in three years than he possibly could in two years, and no one can deny that even more than a three-years' careful study is needed for the acquirement of a thorough education in the different branches of medicine and surgery. I am persuaded that even the brilliant young man, with profit and benefit to himself and his future patients, can utilize three years in the study of the medical sciences. The physicians of this State are almost unanimously in favor of any measure that will insure every student a thorough qualification for his important life-work. If a State Board of Examiners will accomplish this end, we will certainly favor and urge the appointment of such a board. But it would seem that inasmuch as the members of such a board are appointed by the Governor, political influence might at times insure bad appointments, and in this manner even a State Board of Examiners might not prove an unmixed good.

The bill referred to was a step in the right direction, a step toward the securing of a State Board of Examiners, or any other measure having for its ultimate result the elevation of the standard of medical education, and those opposing it may proudly claim the questionable honor of having secured the defeat of the bill. H. H. V.

ST. CHARLES, MO., May 25, 1891.

FEL BOVIS.

To the Editor of THE MEDICAL NEWS,

SIR: In answer to the many inquiries which I have received as to the time of administering, and the preparation of "fel bovis" used, will you kindly grant me space in your columns to say: As a rule, the "fel bovis inspissatum" yields the best results in digestive disorders when given before each meal. As an antipyretic it should be administered every two or three hours. As to the preparation, great care should be taken to secure a fresh sample from any of the well-known manufacturers. The old and often decomposed "fel bovis" of the shops will prove a total failure, as has often happened to my patients. But when a fresh and undecomposed article was used, it has never failed to produce the desired result. "Fel bovis inspissatum," when in good condition, has a semi-solid consistency, and will rub up with glycerin into a smooth paste without frothing, but when altered by age, or impure in quality, this result cannot be obtained. WILLIAM HENRY PORTER, M.D.

OBITUARY.

DEATH OF FORDYCE BARKER.

ON last Saturday afternoon, May 30th, DR. FORDYCE BARKER died at his home in New York City, after a brief illness, his age being seventy-three years.

The death of this eminent member of the American profession calls for more than a brief notice. A native of Maine, and a graduate in Arts of Bowdoin College, his medical studies were pursued in Boston, Edinburgh and Paris; he received his degree in the city last named. He was made Professor of Midwifery in Bowdoin eight years after receiving his literary degree, holding this position until his removal to New York many years ago. For more than thirty years he was a medical teacher in the city of his adoption, occupying the chair of Clinical Midwifery and Diseases of Women in Bellevue Hospital College. He was an active participant in the meetings of various medical societies, and a diligent contributor to medical literature. The work upon which his fame chiefly rests, and which made him most widely known, both at home and abroad, is his volume upon *Puerperal Diseases*, published in 1874. It was his intention to collect some of his many fugitive contributions to medical literature, carefully revise them, and then have them issued in a single volume—indeed, a good deal of work had been done in the preparation of this proposed volume, which was to have been published by a well-known Philadelphia house, and the writer of this sketch had promised the distinguished author to exercise some supervision in its publication. It is cause of great regret that Dr. Barker died with this purpose unaccomplished.

As a practitioner in obstetrics, as a teacher of his favorite department of medicine, and as a writer, he had no superior upon the continent—hardly an equal in any,

certainly not in all of these functions. His authority in obstetrics scarcely anyone would be bold enough to challenge, and, in the main, his teaching was true and wise; in a very few things he was slow to fully accept recent views, clinging with great tenacity to some old theory or hypothesis, as, for example, that puerperal fever was in some cases an essential disease.

Dr. Barker's kindness to the younger members of the profession, generously giving a helping hand to the worthy who were struggling up the slippery steps to firm position, must be reckoned as one of his marked characteristics. His earnest and zealous efforts for professional advancement were well known and usually successful. His social and professional relations with many of the wealthiest citizens of New York enabled him to awaken warm interest in, and secure generous contributions for, different objects of professional concern and for important charities. His loyalty to his friends was generally known. His generous hospitality was proverbial; he was a perfect host, seeing that no guest was unnoticed or uncared for. His conversation was not only instructive, but delightful. No one could listen to his words upon professional subjects, whether uttered at his home or in societies, without becoming wiser for his wisdom, and deriving practical lessons for his daily work. Probably Dr. Barker's most valuable contributions to professional knowledge, independently of his medical teaching, were made in the New York Academy of Medicine and in the American Gynecological Society, of which he was one of the founders and the first president. For many years he suffered from a laryngeal disorder, certainly for thirty years, over which the writer's acquaintance with him extended, and utterance was difficult and only understood when most carefully listened to; but wherever he spoke, whether in societies, at home or abroad, every hearer gave strict and constant attention, and felt abundantly rewarded. His abilities and his work brought him great recompense, not merely in a most lucrative practice, but more and higher, in fame and honors. Among the latter must be mentioned his having the degree of LL.D. twice conferred upon him by British universities, the last time by that of Glasgow.

We may murmuringly ask why a man, so great and good, capable of doing such great and good things for his profession, might not, with eye undimmed, natural strength unabated, and in the vigor of his intellectual powers, have been spared a little longer to continue his noble work. Nay, rather let us rejoice that such a man has lived and labored, bringing honor to medicine and glory to the American profession. But he did not belong exclusively to this country, for no American physician had greater European fame. How often one of the first questions asked of a doctor from the United States, when he was in Great Britain or on the Continent upon his summer vacation, was, "Is Barker coming over?" Loved by friends who knew him best, admired and honored by all, at home and abroad, he rests from his labors, but his memory and fame live, and will live, probably longer than those of any other American obstetrician of this or of any other century.

The funeral services, on Tuesday afternoon, June 2d, in the Episcopal church of St. Thomas, of which the deceased had for many years been a member, were conducted by Bishop Potter and Rev. Dr. Morgan Dix, and were impressive. The auditorium was filled with representatives of the medical, legal, and clerical professions, as well as of the social, the commercial, and the industrial life of the city of New York; physicians of Philadelphia, Boston, and New Jersey were also present. The remains were taken to Norwich, Conn., for burial in the cemetery in which Dr. Barker's father and his daughter, who died in childhood, were interred. Dr. Barker's wife and son, Fordyce Barker, are the only members of the family living.

DEATH OF DR. JAMES W. WHITE.

ON Wednesday, May 27th, DR. JAMES W. WHITE, long known to Philadelphians as a philanthropist and successful business man, died suddenly of cardiac disease. During the war Dr. White was an active member of the Sanitary Commission, and since then has been constantly engaged in charitable and beneficent pursuits. His connection with the Maternity Hospital in this city consisted in more than the mere perfunctory position of manager, and his office of President of the Board of Charities gave him still further opportunities for the exercise of many kindly traits.

Firm in his opinions as to right and wrong, fearless in the discharge of every duty, kind to the young man and gracious to his colleagues, Dr. White leaves a blank in the city life which many must regret.

NEWS ITEMS.

Dr. Wyman—the Surgeon-General of the Marine-Hospital Service.—Dr. John B. Hamilton has resigned the position of Surgeon-General in the Marine-Hospital Service to accept the chair of Surgery in the Rush Medical College of Chicago. Dr. Walter Wyman, who had for a long time been the assistant to Dr. Hamilton, was, upon the recommendation of the latter, appointed by the President to fill the vacancy. Dr. Wyman is forty-two years old, a native of St. Louis, and a son of the late Edward Wyman, widely known as an instructor.

He graduated from Amherst College in 1870, and from the St. Louis Medical College in 1873. After serving for more than two years in the city hospitals of St. Louis and engaging in private practice, he was, in 1876, appointed Assistant Surgeon in the Marine-Hospital Service and placed in charge of the Marine Hospital at St. Louis.

In 1879 he was transferred to Cincinnati, and for three years remained in charge of the service there, temporarily acting as Surgeon of the U. S. revenue cutter "Chase" (cadet ship) on her annual cruise to Spain and the Azores in 1881.

In March, 1882, he was placed in charge of the Marine-Hospital Service at Baltimore, and in November he was detailed as Medical Inspector of the crews of the Life-saving Stations on the New Jersey coast.

Between December, 1884, and June, 1885, he visited the principal hospitals and laboratories of Europe and pursued studies in Vienna. On his return he was assigned to the command of the service at New York, remainining three and a half years, when he was ordered to Washington as Medical Purveyor and Chief of the quarantine division.

During the absence of the Surgeon-General in Europe last summer and fall, Dr Wyman was in temporary charge of the bureau. On the return of the Surgeon-General, an additional officer having been detailed at headquarters, Dr. Wyman was relieved of the purveying division, and assumed charge under the Surgeon-General of the National Quarantine Service and the publication of the *Weekly Abstract of Sanitary Reports.*

In the fall and winter of 1890, Dr. Wyman made an inspection of the quarantine stations of the Atlantic and Gulf coasts from the Delaware Breakwater to New Orleans, and visited Havana to familiarize himself with the local conditions of this perennial menace to the health of the United States.

Dr. Wyman is an active member of the American Public Health and American Medical Associations and was secretary of the Section of Public and International Hygiene in the International Medical Congress in Washington in 1887.

He is the author of a number of published papers on matters relating to public health, the most recent being an exhaustive article on "Quarantine" in *Rohe's Textbook of Hygiene.* Other articles are: "Hospital Records, with description of a New System;" "Hospital Management;" "River Exposure and its Effect upon the Lungs;" "Hygiene of Steamboats on Western Rivers;" "Hardships of the Chesapeake Bay Oystermen;" "System of Sewerage Disposal in Berlin;" "Treatment of Cholera by Paris Physicians in 1884;" "Government Aids to Public Health."

University of Pennsylvania.—The Trustees of the University of Pennsylvania have elected—Dr. George A. Peirsol, Professor of Anatomy; Dr. Harrison Allen, Professor of Comparative Anatomy; Dr. John B. Deaver, Assistant Professor of Applied Anatomy; and Dr. Edward Martin, Clinical Professor of Genito-urinary Surgery.

New York Post-Graduate Medical School and Hospital.—At a recent meeting of the Directors of the New York Post-Graduate Medical School and Hospital, H. J. Boldt, M.D., was made Professor of Diseases of Women; William James Morton, M.D., Professor of Electrotherapeutics, and Aug. Caillé, M.D., Professor of Diseases of Children.

Resolution on the Death of Dr. Fordyce Barker.—The Medical Board of the New York Maternity Hospital adopted the following resolution:

"*Resolved*, That by the death of Dr. Fordyce Barker, consulting surgeon to the hospital, we have met with the loss of a warm personal friend, as well as of a valued counsellor. Although unable, by reason of increasing infirmities, to take an active part in the work of the hospital, his interest in its welfare and in the branch of medicine in which he was so eminent never abated.

"In common with the whole profession we cherish his memory as that of a wise physician and a good man, who died full of years and honors."

The Medical Examiner.—This new journal was launched at New York City, April 1, 1891, as a proposed organ for medical men who are engaged in life insurance, accident assurance, prudential relief, pension matters, railway surgery, the army, the navy, and as police surgeons. It will appear monthly. Dr. George W. Wells will be its editor.

Long Island College Hospital.—The Long Island College Hospital has made the following interesting changes in the course of its instruction and in its faculty:

1. The regular course of lectures will hereafter be six months in duration.

2. Three courses of lectures will hereafter be required for graduation.

3. Joshua M. Van Cott., Jr., M.D., has been appointed Professor of Histology and Pathological Anatomy, *vice* Frank Ferguson, M.D., who has resigned.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 26 TO JUNE 1, 1891.

CARTER, EDWARD C., *Captain and Assistant Surgeon.*—Will proceed, without delay, to Fort Canby, Washington, and report to the commanding officer for temporary duty, relieving John D. Hall, Major and Surgeon, who will proceed to Fort Sherman, for duty as Post Surgeon.—Par. 1, *S. O. 74, Department of the Columbia*, May 22, 1891.

By direction of the Secretary of War, JEFFERSON R. KEAN, *Captain and Assistant Surgeon*, is assigned to temporary duty at Fort Myer, Va., until the return of Robert H. White, Major and Surgeon, to duty at that post.—Par. 8, *S. O. 122, A. G. O.*, May 28, 1891.

WATERS, WILLIAM E., *Major and Surgeon.*—Is granted leave of absence for twenty days.—Par. 6, *S. O. 122, A. G. O.*, May 28, 1891.

By direction of the Secretary of War, leave of absence for three months, on surgeon's certificate of disability, is granted MARLBOROUGH C. WYETH, *Captain and Assistant Surgeon.*—Par. 6, *S. O. 119, A. G. O., Washington*, May 25. 1891.

BROWN, PAUL R., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, with permission to apply for an extension of one month.—Par 4, *S O. 59, Department of the Missouri, St. Louis*, May 26, 1891.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MAY 23, 1891.

VANSANT, JOHN, *Surgeon.*—Granted leave of absence for seven days, May 22, 1891.

IRWIN, FAIRFAX, *Surgeon.*—Granted leave of absence for twenty-one days, May 11, 1891.

GUITERAS, G. M., *Assistant Surgeon.*—Relieved from special duty at New York, N. Y.; ordered to San Francisco, Cal., May 11, 1891.

GROENEVELT, J. F., *Assistant Surgeon.*—Relieved from duty at New York Marine Hospital; ordered to Gulf Quarantine, May 22, 1891.

YOUNG, G. B., *Assistant Surgeon.*—Granted leave of absence for thirty days, May 11, 1891.

PROMOTIONS.

PERRY, T. B., *Passed Assistant Surgeon.*—Commissioned as such by the President, May 23, 1891.

WOODWARD, R. M., *Passed Assistant Surgeon.*—Commissioned as such by the President, May 23, 1891.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment, provided that the request for reprints be noted by the author at the top of the manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

ORIGINAL ARTICLES.

LINEAR CRANIOTOMY FOR MICROCEPHALUS.

BY JOSEPH RANSOHOFF, M.D., F.R.C.S.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY, MEDICAL COLLEGE OF OHIO.

LESS than a year ago Lannelongue reported two cases in which, by the removal of a long strip from the cranium, he hoped to provide room for the cerebral development of microcephalic children. Whether the defective brain-growth is the result of early synostosis of the cranial sutures or the reverse obtains, the data for consideration are a small brain and a firmly closed capsule resisting what little impetus toward development the former might possess. To reduce this resistance by surgical procedure seems rational enough. The ingenious operation of Lannelongue aims to restore the firmly closed microcephalic head to the infantile conditions existing before closure of the fontanelles and obliteration of the sutures occurred. From a recent article by Dr. Keen (*American Journal of the Medical Sciences*, June, 1891) it would appear that six cases have been operated on. At the recent meeting of the French Surgical Congress M. Lannelongue reports upon twenty-five cases. Altogether, therefore, the cases are as yet sufficiently few in number to justify my recording the following one, which presents some points of unusual interest:

Emma S., aged three years and seven months; referred to me by Dr. Jenkins, of Newport, Ky. The parents were living and healthy, having six children, one of them an imbecile, aged sixteen years. The mother states that the little child's head "closed" soon after birth. To this fact she ascribed its backwardness in mental development. At the present time the child is well formed, healthy, of normal bodily development, and ruddy complexion. A glance reveals the relatively small size of the head and the almost incessant twitching of the ocular muscles. The patient is unable to walk or sit up, even if supported. When raised on a pillow the body rolls over to one or the other side. The child gives no evidence of knowing her mother and seems absolutely unconscious of persons or things about her. The brightest objects placed before her eyes do not attract her attention. The only sound of which she is cognizant is the click of the spoon against the porridge-bowl when food is brought to her bed. When she hears this she protrudes the tongue in efforts at suction. Swallowing is accomplished with some difficulty, some food being regurgitated. In the incoherent movements which from time to time the child makes it is evident that the left arm is very rarely used, and that in such movements as scratching or picking at the bedclothes the range of motion is greatly limited as compared with that of the right arm. Every hour or two during the twenty-four the ward in which the child is placed resounds with a short, sharp cry of the patient not unlike the *crie encéphalique* preceding an epileptic seizure.

The head is small and sugar-loafed—typically oxycephalic. The sagittal suture presents itself as a distinct solid ridge, with a well-defined groove on the right side. During the process of ossification the left had doubtless overlapped the right parietal bone. The measurements as taken by calipers are as follows: Bi-frontal diameter, 3 inches; bi-parietal, $4\frac{6}{8}$ inches; occipito-frontal, 6 inches; circumferential measurement between ears, $9\frac{1}{4}$ inches; between occipital protuberance and supra-orbital ridge, 10 inches.

The operation was performed on February 9th, the anæsthetic being chloroform. Aseptic preparations of the head were observed. Application of the flat Esmarch strap was made around the head to control hæmorrhage from the scalp. The incision was parallel with and one-half inch to the right of the sagittal suture, from the lambdoidal suture to within an inch of the orbital margin. The posterior and anterior extremities were curved outward. There was no hæmorrhage from the scalp. The flap, including the periosteum, having been removed sufficiently from the bone, a half-inch trephine was applied at the posterior end of the exposed cranium and a button removed. With rongeur forceps a strip three-eighths of an inch wide and five and one-half inches long was then cut from the skull. The alleged greater adherence of the dura in the undeveloped skull presented no obstacles, except where the frontal crossed the line of incision. It was only by the greatest care that the wounding of the dura at this point was obviated. The cleft in the bone was extended subcutaneously to within one-half inch of the orbit. Although there was considerable oozing, the hæmorrhage yielded readily to compression. A strip of the periosteum corresponding to the groove was next removed. Catgut drainage was next provided for, and the wound closed with the continuous catgut suture. The operation from the beginning of the anæsthesia to the end lasted forty minutes. A very considerable shock from loss of blood followed it. Within twenty-four hours there was recovery from this. The operation was not followed by an absolutely "normal" course of repair. There was some suppuration from the posterior end of the wound, probably from an imperfectly steril-

ized catgut strand. The temperature on the third and fourth days ran to 103° in the evening. Yet, with the exception of the posterior end of the wound, where a fistula continued for some months, the wound, long as it was, healed by primary union.

And now as to the result three and one-half months after the operation, before the patient's discharge from the hospital: The antero-posterior measurements show no change from those taken prior to the operation; the transverse measurements (calipers) are increased, the bi-parietal ¼ of an inch, and the bi-frontal nearly ⅜ of an inch; the binauricular measurement is 9¾ inches.

In mentality the child presents the intelligence of a child of six months. With its eyes it follows persons and objects moved before it. It reaches for a watch with either hand, the left having a power of coördination equal to that of the right. When a watch is placed beyond the visual field, as, *e. g.*, on the side of the pillow, either or both hands are used in searching for it. The patient amuses herself with a picture-book, and when tired of one picture she with some difficulty turns the page to look at the next. She recognizes her nurse and occasionally attracts her attention by tugging at her apron when her back is turned. Evidently reason is present, though in a very primitive state. The difficulty in deglutition has entirely disappeared. The *quasi* epileptic cry has ceased to annoy the other inmates of the ward. When the patient is supported on a pillow she will sit up for an hour at a time looking about, seemingly interested in her surroundings. The voluntary efforts which she makes to raise herself to the sitting posture are not as yet successful, although a little help is all she requires.

REMARKS.—The improvement already obtained in this case justifies the operation. If in six months there should appear an arrest in the development of mentality, a similar operation on the left side will be performed. The right side was first operated on because of the apparently limited usefulness of the left arm. If any part of the result thus far achieved may be designated as brilliant, it is in the freedom with which this member is now used by the patient.

The conditions of the microcephalous are so deplorable that any interference promising a shadow of success seems to me justifiable. That the danger to life is very great, I cannot believe. Of twenty-five cases operated on by Lannelongue, only one died of sepsis directly due to the operation, and two from croup, one or two months after operation. It is possible, though not probable, that the laryngeal spasms were of meningeal origin. Even if included with the fatal cases the death-rate would be only 12 per cent. In the article referred to, Keen reports six American operations, excluding two which were not really craniotomies. Of this number two were fatal—one from heart-failure and one from acute anæmia. I believe that the use of the Esmarch strap will largely tend to limit the fatality from either of these sources, since most of the hæmorrhage comes from the divided vessels of the scalp. The suggestions made by Wyeth to operate on both sides of the skull at one time, and also to forcibly separate the cranial vault from the underlying dura, do not commend themselves. The added shock and hæmorrhage would doubtless increase the immediate danger, and the intra-cranial pocketing of blood would add to the risk of sepsis.

THE PATHOLOGY AND TREATMENT OF CHRONIC OVARITIS.

BY ALEX. J. C. SKENE, M.D.,
OF NEW YORK.

THE study of the pathology of ovaritis derives a special interest from the fact that the ovary differs from all other organs of the body in that its function is performed at the expense of a portion of its structure which is never restored to its original condition. The rupture of each Graafian vesicle in ovulation causes the destruction of the vesicle. Rudimentary vesicles mature and repeat the function of their predecessors and are in turn destroyed. Finally the supply ceases, and the ovary, worn out in structure, becomes functionally incompetent long before the general organization has reached the end of its life and activity. In all other organs of the body, function is effected through cellular disintegration and restoration. This peculiarity in the natural history of the ovary makes it difficult for the superficial observer to distinguish between physiological degeneration and the structural changes which result from chronic ovaritis. Experts also find it no easy matter to distinguish, by gross appearances, the atrophy of old age from the cirrhosis of inflammation.

In discussing the pathology of ovaritis I shall briefly point out some of the established facts which are of most interest in relation to the diagnosis and treatment of this affection, and omit everything which is ill-defined, uncertain and of little interest to surgeons. The pathology of ovaritis is characterized by changes of structure brought about chiefly by areolar hyperplasia first, then by atrophy of the normal tissues, and finally by a condition of cirrhosis. In this respect the morbid process and its products resemble degeneration rather than inflammation such as is observed in other organs. In the natural history of its pathology it is more like certain forms of chronic nephritis. Owing to these peculiar and distinguishing features, the affection has little in common with acute puerperal or non-puerperal ovaritis, or with secondary acute ovaritis due to peritonitis, and all such conditions will, therefore, be carefully excluded from the discussion of the subject in hand.

The first variation from the normal toward the

pathological is deranged innervation—the ovary, owing to its important office and intimate relations to the other organs, being peculiarly prone to reflex disturbances. These, though as a rule temporary, when oft-repeated and prolonged in duration induce changes in the circulation that impair nutrition and finally produce changes of structure. This ovarian hyperæmia, the first step in the process, may subside and complete recovery follow. Reliable evidence of this has been obtained: first by clinical observation of cases which gave all the signs and symptoms of ovarian congestion, and which, under careful management, completely recovered; secondly, by inspection after laparotomy. I have not infrequently found a prolapsed, tender and painful ovary which, upon inspection, after opening the abdomen, was markedly hyperæmic, but presented no apparent change of structure except œdema. After fixing it in place by stitching the utero-ovarian ligament to the upper border of the broad ligament, the signs and symptoms have all subsided. The continuation of the hyperæmia slowly produces those structural changes which are invariably effected by prolonged malnutrition. The first noticeable changes take place in the blood-vessels themselves. These become dilated and a peculiar degeneration of their walls occurs. These changes have been elaborately studied by Dr. E. Noeggerath, who advanced the idea that they were closely related to the genesis of ovarian cystomata. This may be true in certain cases, but the changes more frequently end in hyperplasia of the stroma, which gradually goes on and in time crowds out all the normal structural elements of the ovary. Finally, a true cirrhosis is produced. With these changes in the bloodvessels the circulation is interrupted to a degree that causes œdema, which increases the size of the ovary and renders it softer. Apoplexies sometimes occur, and occasionally one or more of the blood-clots may be seen near the surface. These conditions can be distinguished from a diseased vesicle by the staining of the tissues around the clot. This last-mentioned lesion occurs in the early stage of ovaritis, and becomes less common as the process of hyperplasia proceeds to complete cirrhosis. These changes explain some of the important facts in the clinical history. The ovary which is found enlarged, softened, and tender to the touch will months afterward appear subnormal in size. Likewise the same lesions may be recognized upon inspection after laparotomy, if by previous study one has become familiar with them. While hyperplasia of the stroma is going on, the follicular elements undergo certain changes. The contents of the follicles become cloudy from degeneration of the epithelial elements. The gross appearance of the ovary at this time would lead one to suppose that there were a number of vesicles approaching maturity, but the uncommon number of these distended vesicles is evidence that they are abnormal.

The full value of a knowledge of the gross pathology of ovaritis can be fully estimated by those who have mistaken the physiological for a pathological degeneration of the ovaries, and have removed them, to learn subsequently, through the microscopist, that they were not diseased. I well remember hearing an interesting discussion regarding cases in which one ovary has to be removed for advanced disease. The question was: Should the other ovary be left, or removed, if there is no positive evidence of its being diseased? Much was said pro and con, but not a word was uttered about how to detect pathological changes which should decide the matter. The morbid appearances which aid the surgeon in deciding when to remove an ovary and when not to remove it are as follows: Follicles which, from their size, number and dark color are evidently diseased should be removed. Enlargement, congestion, and softening from œdema, and patches of induration with irregular distention of the vessels and the evidence of small blood-clots, as described above, are conditions indicating removal. Cirrhosis, indicated by subnormal size, induration and rough surface, when found in a young subject, can be easily passed upon; but in a subject near or after menopause this appearance of the ovary does not decide with certainty whether there is cirrhosis or simply senile atrophic degeneration. I have thus briefly described this part of the subject, introducing only such facts as I have obtained from observation, and which have appeared to be of possible use in guiding the surgeon. This brevity arises in part from my limited knowledge, but mostly from the hope of raising a discussion which will doubtless bring out much that we need to know.

Much might be said about the influence of chronic ovaritis upon the functions of the sexual organs and the nutritive and nervous systems, but time will only permit me to say that menstruation is often deranged and in various ways. Dysmenorrhœa is often present; in some the menses are retarded and scanty; in others too frequent and profuse. When the latter condition exists, the ovaritis is more easily controlled than in patients having a scanty flow. The effect upon the nervous system is peculiar and marked, depression and irritability being usually pronounced. The hystero-epilepsy which has attracted much attention from the neurologists is really an epileptiform affection, due, in all cases that I have seen in my own practice, to ovarian disease. Ovaritis also ranks first among all diseases of the sexual organs in the causation of mental disorders.

The causation of chronic ovaritis demands a brief

notice, owing to its intimate relation to the question of treatment. According to my observations, the cause which most frequently obtains is imperfect menstruation. When the uterus is undersized or flexed forward or backward, and the menstrual flow scanty and attended with pain, the ovaries are liable to take on chronic inflammation. This is far more liable to occur if in this class of subjects the sexual function is perverted. Specific causes, such as those producing the eruptive fevers, are said to affect the ovaries, and I believe that acute ovaritis is more liable to occur under these circumstances. It is probably true, also, that gonorrhœa causes acute rather than chronic ovaritis. The strumous diathesis (which I understand to be that condition of organization which invites tuberculosis) predisposes to chronic ovaritis, and inherited or acquired syphilis does likewise. Much has been written about endometritis as a cause of ovaritis upon the ground that the structures of the endometrium and ovaries have a common embryonic genesis, and the fact that the two diseases are often found together, but this is still an open question.

In regard to the diagnosis of chronic ovaritis I refer all interested to the able paper on the subject by my esteemed friend, Dr. Howard A. Kelly, in the *American Journal of Obstetrics* for February, 1891.

TREATMENT.—The advancement of abdominal and pelvic surgery in recent times has led to the removal of the ovaries as the most prompt and effectual treatment of chronic ovaritis. There are reasons for this upon theoretical grounds: the ovary is causing much suffering; there is a likelihood that it will be a long and tedious trouble, and this is especially true if general treatment has failed; the ovaries are not necessary to existence and can be removed with safety; it is according to the rules of surgery to remove any organ, or other portion of the body, that one can live without, in case a disease of the part tends to take life or cause unlimited suffering and invalidism; hence, from this way of looking at the matter, the ovaries should be removed. It is true (and the facts have been proved almost sufficiently) that chronic ovaritis does not end fatally, and is self-limited, though often of long duration. The removal of the ovaries is not free from all danger, though all cases properly operated upon have recovered, and the operation may not in all cases give complete relief. In fact, many of the cases are not much, if at all, improved; even those who are nearing the menopause and who bear the loss of the ovaries better than younger subjects, occasionally suffer much from those nervous disturbances which follow an abrupt menopause, and have to endure pelvic pain in the region of the stumps. The clinical history of cases in which the ovaries have been removed does not, in all cases, show great advantage over those in which the ovaries are left to complete the natural history of the disease. Younger subjects do not bear the loss of their ovaries agreeably. Some become fat, indolent, inefficient and subject to headaches. Others are irritable, dyspeptic and despondent, while but few enjoy general good health and mental vigor. This statement is contrary to much of the published literature, but is closer to the actual facts. The cases cured are those operated on when near the menopause; those improved are generally such as have suffered from complicating affections—for example, dysmenorrhœa; while the unimproved are the younger subjects in whom the disease was uncomplicated. The objections to surgical treatment apply to the removal of both ovaries. In cases in which one ovary alone is affected, and especially when there is prolapsus of the affected ovary and retro-displacement of the uterus, ovariotomy is perfectly satisfactory. The removal of the diseased ovary gives relief and the retro-displaced uterus can be restored, while the remaining ovary performs its functions, and the general health of the patient is preserved. I desire to be understood as advocating the removal of the ovary only when there are structural changes from inflammation and prolapsus at the same time. Prolapsus can be relieved by fixing the ovary to the upper border of the broad ligament, and the welfare of the patient can thus be better conserved. From advocating conservative measures in regard to abdominal and pelvic surgery it may be inferred that I am behind the age in experience, but I have had a large field for operative surgery and have acted to the fullest extent that I considered justifiable and according to my judgment. In fact I have in the past violated the rules I now advocate, but I have not been satisfied to have my patients simply survive the operations. I require that they be cured, and failures in this regard have, I trust, led to a rational conservatism. I have no word of condemnation for those who have removed and are still removing ovaries for the relief of chronic ovaritis. Their work, while not always beneficial, has been of vast interest to science. Their doings help to perfect surgery. The rough, unsightly scaffoldings employed by builders are temporary necessities which are all cleared away when the structure is perfected and completed. In like manner the heroic, daring experiments of the surgeon are valuable stepping-stones which lead to mature science and art.

The indications for general treatment are to lessen the blood-supply and relieve pain by correcting the deranged innervation. This, in the early stages, demands rest in the recumbent position. At the same time general exercise should be advised either by massage or by gymnastics in the re-

clining position. I specially desire to commend systematic calisthenics in the recumbent position as a most valuable aid in improving or maintaining the general health in many diseases of the pelvic organs which require rest as an important part of the treatment. The condition of the digestive organs should be carefully watched. The poor appetite, coated tongue and constipation, or the capricious appetite, flatulence, and occasional diarrhœa can be relieved by a number of small doses of mercury and a laxative. The saline laxatives are the best when they act without causing flatulence. The use of Saratoga waters often gives good results by improving digestion and keeping the portal circulation active. In keeping up a free elimination by the bowels and kidneys much benefit is obtained. This applies to cases that are apparently debilitated. Many times I have taken cases away from tonics, stimulants and forced feeding, and given saline laxatives, with the effect of increasing the patient's strength. To relieve the pain and lessen the hyperæmia, the bromide of sodium and fluid extract of hydrastis canadensis are by far the most potential agents that I have found; they are given in combination and in doses sufficient to produce the desired effect—twenty to thirty grains of the bromide and ten to twenty minims of the hydrastis, three times a day, until the physiological effects of the bromide are noticed in a mild degree. If the hydrastis in such doses is given alone it sometimes causes pelvic pain of a dull character, but when combined with the bromide it has no such effect. These agents are most efficacious in the beginning of the attack, and hence they should be discontinued as soon as the pain is, in a marked degree, relieved. Should the pain and tenderness return at the succeeding menstrual periods, the bromide and hydrastis should be resumed. In some cases much larger doses of bromide are required, and in others it fails altogether to relieve pain. Then it is necessary to employ other agents, especially during menstruation. Ten grains of salicylate of sodium and five of antipyrine, given between meals and in the night when the stomach is empty, answer for some; others, more especially those markedly debilitated, do better on full doses of aromatic spirits of ammonia, camphor, and chloric ether, with small doses of cannabis indica. This combination is best suited to those who get relief from gin or whiskey, but it is to be preferred, because alcoholic stimulants, though they may give temporary relief, ultimately do harm. Direct or local treatment should be adapted to the social state of the patient, and the presence or absence of complications, such as endometritis. In the unmarried, local treatment is often injurious. In fact, in such cases it is better to avoid any examination of the pelvic organs if the history is sufficiently clear to enable one to make a diagnosis with reasonable certainty. Hot sitz-baths, counter-irritation and hot vaginal douches, the latter to be given by a competent nurse, comprise about all that I employ in the way of direct treatment. The vaginal douche should not be continued unless it is decidedly sedative in its effects.

In married women (and in those who are married in all but the name) local treatment is more valuable. The treatment of any disease or displacement of the uterus that coexists should be managed in the usual way, and such local applications should be used as may aid in relieving the tender and hyperæmic ovaries. I employ a small tampon or pledget of cotton or wool saturated with equal parts of tincture of belladonna and glycerin, applied behind the cervix uteri, and permitted to remain forty-eight hours, and after its removal a hot douche. These are continued during the first days of treatment. The effect is to support or steady the ovaries while the sedative effect of the belladonna and the depleting effect of the glycerin are obtained. This I have followed with applications of tincture of iodine after the manner of Dr. Emmet. Recently I have with good effect used the sulph-ichthyolate of ammonium, five parts in ninety-five of glycerin, applied in the same way as the belladonna and glycerin.

The general and local treatment thus briefly outlined gives relief to the more pronounced symptoms. The pain becomes less, and also the tenderness. The general health improves and the pelvic congestion subsides. This is apparent in the color of the mucous membrane, the improved menstrual functions and diminished leucorrhœa. The local treatment may then be employed at longer intervals or suspended altogether. The constitutional treatment should now be modified. Tonics and laxatives may still be required, but alteratives are also indicated. Iodine and mercury are the chief agents. They act upon the ovaries as they do upon all glandular organs, and modify or arrest the morbid histological changes which take place slowly. Small doses of bichloride of mercury, with chloride of iron, when iron is indicated, followed by syrup of the iodide of iron, in doses as large as can be borne, may be administered. These can only be used when the bromides are given up. When giving these alteratives the patient often misses the bromides used to give sleep. Sulphonal, at such times, is of great value. In fact it is the most potent sedative, that is at the same time free from unfavorable ultimate or after-effects, that we have in gynecological practice. When a sedative is required while iodide of mercury is being used, I find that ten grains of salicylate of sodium and five grains of antipyrine, given three times a day, an hour before meals, give much relief,

especially in those who suffer from nervous dyspepsia and flatulence.

One important element in the treatment is that of patience and careful watching. Improvement comes, and the patient or the physician gives up treatment and there is danger of relapse. The poor in hospitals often suffer for want of time for prolonged treatment, and this often tempts the surgeon to seek more prompt relief by removal of the ovaries. This does not apply with the same force to those who have time and means to secure the needed care.

THE TECHNIQUE OF PELVIC SURGERY.[1]

BY WILLIAM E. ASHTON, M.D.,
GYNECOLOGIST TO THE PHILADELPHIA HOSPITAL.

THE advancement made in the science and art of surgery during the past few years by the great principles of asepsis and antisepsis, has brought about a revolution in our ideas and methods, positive in its results. The "exploratory incision"—the natural outgrowth of these principles—has placed in the hands of the surgeon the means of making a diagnosis in a large number of cases that were previously improperly diagnosticated and treated. This method has rendered possible and suggested operations hitherto never thought of, and, being absolutely safe in the hands of the careful surgeon, it has placed the surgery of to-day in a position of comparative certainty, and raised its principles almost to the level of an exact science. The genius of Lawson Tait marked an era in the history of our art when it gave to the profession those principles which have placed the surgery of the female pelvis upon its present sound basis. His mind and masterhand are clearly seen in the results, whereby countless women have been and will be restored to health and usefulness.

It is my purpose in this paper to consider the technique of pelvic surgery, limiting myself, however, to the practical side of the subject. I shall rely entirely upon my own experience for the selection of such points in the detail of pelvic work upon which I believe success depends.

First, then, let us consider the necessary preparation of a patient about to undergo an abdominal section. If possible, we should have at least twenty-four hours in which to regulate the excretions and secretions, and to properly cleanse the skin. Furthermore, the patient should remain in bed for a day prior to the operation, as, under these circumstances, she will be less restless and nervous subsequently. The hair should be shaved from the pubes, and a general bath of hot water with soap given; care being taken to see that the abdomen, external organs of generation, and the vagina are thoroughly cleansed. A flesh-brush should be used in washing the abdomen, to get rid of all exfoliated epithelium and sebaceous matter. The umbilicus is to be most carefully cleansed, as septic matter is likely to remain between the folds of skin. After the bath, the external organs of generation and the abdomen are made antiseptic with a 1 to 1000 bichloride solution. A thick layer of bichloride gauze is then placed over the site of operation and surrounding parts, and held in position with a bandage until it is removed at the time of operation. It is my custom to thoroughly "salt" my patients. I order a tablespoonful of a saturated solution of the sulphate of magnesia to be given every hour, until six free movements from the bowels are produced; if the stomach be irritable, I reduce this dose to a teaspoonful every half-hour. About six hours before the time fixed for operating, I order an enema to be given, composed of a tablespoonful of the sulphate of magnesia in a pint of warm water. Too much stress cannot be placed upon the necessity of thus caring for the condition of the bowels, if the surgeon hopes to obtain good results. By thoroughly cleaning out the alimentary tract there is less tendency to subsequent tympany or to paralysis of the intestines, and should sepsis develop, the chances of recovery are greatly increased. The diet should be nutritious, easily digestible, and give rise to the smallest quantity of waste material. The importance of having a properly prepared room in which to perform abdominal sections is, I believe, exaggerated. I do not mean to undervalue the advantages of properly conducted and arranged hospital wards and rooms, but when we take into consideration the brilliant results of "alley work," where the environments are all of the most septic character, and the fact that a great number of operations are now done in amphitheatres, before large classes of students, many of whom are just from the dissecting-room, we are forced to place less importance upon our surroundings.

After the patient is placed upon the operating table, the lower extremities are wrapped in a woollen blanket, which should reach to the level of the great trochanters upon the sides and to the lower margin of the mons veneris in front. The upper extremities are kept out of the way by flexing the forearm upon the arm and securing the wristband of the nightgown to the shoulder of the garment by means of safety-pins. A blanket is then placed over the chest to protect that portion of the body from exposure during the operation. The parts surrounding the field of operation are covered with dry bichloride towels. The instruments, sponges and ligatures must be thoroughly aseptic. Every surgeon has his

[1] Read before the Northern Medical Association of Philadelphia, April 10, 1891.

own method of accomplishing this, and the special means employed are of no importance so long as the result is obtained. In making the hands and forearms aseptic the operator and assistant must use the greatest care. The finger-nails should always be kept short and well cleaned. I first wash my arms and forearms for five minutes in hot water and soap, using at the same time a stiff nail-brush. They are then soaked in a 1 to 1000 solution of bichloride for one minute, after which I immerse them in pure alcohol. The operator should see that his assistant and the nurse, who looks after the sponges, etc., have their hands and forearms thoroughly aseptic. A surgeon cannot be too careful in all matters that pertain to clean work. Every point of detail must be conscientiously looked after, and he must be fully imbued with the spirit of the principles of asepsis if good results are to be obtained. No pelvic case can die of sepsis, except when pus or fæcal extravasations have entered the abdominal cavity through some neglect of the operator. The surgeon should not delude himself, as many do, with the idea that all precautions were taken, if his patient, under these circumstances, dies of blood-poisoning. The fault is his; he is responsible for the death, and the burden of responsibility must rest heavily upon his conscience, unless he learns from his failures and endeavors by all possible precautions to guard against a subsequent like result. I speak feelingly upon this subject because I have seen so many lives sacrificed that could have been saved if it were not for dirt. Some power should stay the hand of the surgeon who does not grasp with all the powers of his mind the principles of asepsis.

It is now generally held by surgeons that the incision through the abdominal wall should be as small as is consistent with the necessary manipulations. Certainly, the dangers of a subsequent ventral hernia are lessened when we make use of a small opening. An incision of two inches is sufficient in most cases in which the abdomen is opened for pelvic disease. Those who make long incisions disregard the fact that touch, not sight, is employed in pelvic work; the surgeon must, therefore, train his finger—not his eye. Again, a long incision is a great disadvantage, because it allows the intestines and omentum to escape, thus interfering with the rapidity of work, and possibly the success of the operation. The ligation of the pedicle in the removal of diseased appendages is of the utmost importance. The appendages should be ligated and cut off close to the uterine cornua. A failure to do this often necessitates a secondary operation for the removal of the stump. Given a case of pyosalpinx, of what earthly good will an operation be if the entire diseased mass is not removed? And yet I have repeatedly seen surgeons contented in simply delivering such a mass and throwing a ligature around it without the slightest reference to the amount of diseased tissue included. There can only be one result of such careless and ignorant surgery, namely, failure. There will be no improvement after the operation, and the diseased stump must subsequently be removed by a more experienced surgeon. Always do clean work in the pelvis, should be the key-note to all successful surgery in that region of the body. In tying the pedicle I use No. 5 Chinese silk. It is sufficiently strong and at the same time not too heavy. A very thick ligature is liable to cause irritation, and in some cases to produce sinuses. The ends of the ligature should be cut off close to the knot, otherwise they will interfere with the process of repair at the site of the stump. The figure-of-8 knot is safe and secure; therefore I always use it in preference to others. The Staffordshire knot I mention only to condemn; it is unsafe and should not be employed, as secondary hæmorrhage is liable to follow its use. I use irrigation in those cases in which there are adhesions, or when pus or fæcal extravasations have been poured into the abdominal cavity. Irrigation must always be thorough and complete. My apparatus, which holds nearly a gallon, has attached to it a tube with a diameter of half an inch. This gives me a strong and full stream of water, which thoroughly floods and washes out the abdominal cavity. It is utterly impossible to irrigate properly with an ordinary fountain-syringe; and yet I have seen surgeons use such a contrivance, fully believing their technique to be above criticism. Washingout the abdominal cavity after a section is one of the most important of details, and success depends, in a large measure, upon its thorough employment.

The question of drainage has in the past, as well as at the present time, engaged the attention of surgeons; there being many different views upon the value of its frequent or its infrequent use. For my part I am draining less and less. Cases that one year ago I would not have dreamed of closing without drainage I now close without hesitation, and they make prompt and good recoveries. In pus cases I always employ drainage if the abscess contents have escaped into the abdominal cavity. There are some forms of pus which seem to have no injurious effect upon the peritoneum, and yet, again, there are other forms most virulent in their action. As it is impossible to say in a given case what the character of the pus may be, I keep on the safe side and drain. One word in reference to closing the abdominal wound: To guard against ventral hernia I use four sutures to every inch, taking the precaution to include in the stitches the sheath of the rectus muscle. In some of my late cases I have adopted the plan of stitching the aponeurosis separately before tying the deep sutures, which in-

clude all the tissues. I shall use this method in the future, believing that I may thus very greatly reduce the dangers of hernia. The integrity of the abdominal wall depends upon the aponeurosis, and unless it be properly united a hernia is almost certain to result. As to the after-treatment in cases in which drainage has been employed, the greatest care should be used to guard against septic infection through the tube. The syringe is to be kept in a solution of soda when not in use, and, just before using, boiling water is employed to render it aseptic. In passing the nozzle of the syringe down to the bottom of the tube, the first must not come in contact with the opening or side of the tube, since, unless this precaution be taken, there is always danger of infection.

The question of diet and drink following section is of very great importance. I never allow anything to be taken by the mouth as long as there is any irritability of the stomach remaining from the anæsthetic. Should the patient complain of thirst, from four to six ounces of warm water are given per rectum and repeated as often as it is necessary. I begin to allow fluids by the mouth generally in from twelve to twenty-four hours after the operation. I most earnestly condemn the use of anything given by the mouth to arrest the irritability of the stomach following abdominal section. What nature needs is rest, and the irrational plan of flooding the organ with all sorts of remedies only serves to make worse the condition already existing. No food is given for twenty-four hours following the operation, at which time, if the stomach be quiet, I allow the patient to have liquid diet. I am very partial to koumyss, as it is liked and agrees with most cases; any light broth may, however, be given. Milk should not be taken unless peptonized, as it is very apt to give rise to the formation of gas in the intestines. As a drink, a siphon of soda-water is very agreeable to patients, and I always order it for that purpose. I allow no solid food to be given until the bowels are moved; after which, I allow my patients anything they may desire, provided it is not in itself liable to disorder digestion.

My experience has led me to believe in the advantages of early emptying the alimentary canal. To accomplish this I begin the use of salts twenty-four hours after section, if the stomach be quiet. In cases in which the stomach is unable to bear the salts I employ calomel in quarter-grain doses every half-hour. The importance of emptying the bowels as soon as possible after section is often overlooked. In cases in which we have pus or fæcal extravasations, early evacuation of the bowels, as a prophylactic measure against sepsis, is of the greatest value. In ordinary cases, also, adhesions between loops of intestines or between the gut and the pedicle stump are much less likely to occur if the bowels are kept in an active state; and finally, my experience has taught me that all patients make a more rapid and satisfactory recovery if the bowels be emptied early.

I use silkworm gut for suturing the abdomen. It is readily made aseptic, is easier to tie, and is less irritating than any other material I have employed. One of the objections which have been urged against this suture is that it is stiff and hard to tie. This is true unless the gut is properly softened before being used. It should be put in boiling water before the operation, and when used it will be found soft and pliable. It is, however, liable to become rotten if placed in boiling water several times. I therefore prepare only what I require for an operation, and if any is left over I throw it away. It is my practice to remove the stitches in the abdominal wall at the end of the first week. By that time they are no longer of use, and furthermore, I find that unless they are removed at that time, the patients complain of a stinging sensation in the wound, which is at once relieved upon their removal. After the removal of the abdominal sutures I support the incision with a single strip of adhesive plaster, placing directly over the wound a piece of lint to keep it from being irritated.

While the patient is in bed, and especially after she is up and about, she should wear a properly fitting bandage. This should be made of Canton flannel, and cut so that it will fit closely to the figure, being held securely by straps. I always instruct my patients to wear this supporter for one year. A bandage cannot ordinarily maintain in apposition the lips of the incision or prevent the formation of a ventral hernia, but I believe it is of service for that purpose when any great strain is put upon the abdominal walls. Patients should not be allowed to get out of bed too soon. Three weeks is sufficiently early, and I earnestly condemn the practice of sending patients home in two weeks after section. Our object in doing abdominal sections is to cure our patients and not simply to make additions to our statistics. It is a mistake to keep a patient lying too long upon her back. My rule is, in cases not requiring drainage or the extra-peritoneal treatment of a stump, to change the position from the back to the side after the first twenty-four hours. I do not mean by this that the patient is allowed to roll from side to side at will, but to have the nurse place her hands under the shoulder and hip and slip a soft pillow beneath the patient, so that the body rests upon the opposite side. After some little time, the pillow can be removed and placed under the opposite side of the body; thus the patient can be kept very comfortable. In one week after section, I allow my patients to assume a half-sitting position in bed. I feel certain that by following this plan my cases make quicker

recoveries, and as there is no reason for doing otherwise, except, perhaps, that of custom, it seems to me more sensible to take advantage of the golden rule of surgery, which teaches us to look after the comfort of our cases.

As regards the use of opium in the after-treatment of abdominal and pelvic cases, I firmly believe the drug has no place even for consideration under these circumstances. It has alone done more harm in the surgery of the abdomen than even unskilful operators or faulty technique; but those who still cling to this relic of the Dark Ages cry out, "What are we to do with those cases which suffer with severe pain following section?" My answer to them is, "Let them suffer, if opium alone can relieve." Our duty is to save life, not to allow a sentiment of sympathy to control our judgment and thereby cause death. A surgeon whose judgment is controlled by his sympathies should never use a knife, for he is more dangerous under these circumstances to his patient than a poisoned arrow. Those who confide themselves to our care ask for life, not for tears. When we look about us and see the daily and weekly sacrifice of life to the use of opium, we may well feel sorry for ourselves and envious of the next generation, when the entire profession will appreciate the pathology and treatment of such conditions as peritonitis, appendicitis, and like affections.

SOME EARLY PSYCHICAL SYMPTOMS OF TRAUMATIC BRAIN INJURIES.[1]

BY T. D. CROTHERS, M.D.,
OF HARTFORD, CONN.

THE department of neurology in the practice of medicine has attained such proportions that it would be almost impossible in the limits of a single paper to give any complete history of the advances of even one year. In this country there are six large journals devoted exclusively to this branch—five quarterlies and one monthly, viz.: *The Journal of Insanity*, *The Alienist and Neurologist*, *The Journal of Psychology*, *The Journal of Mental and Nervous Diseases*, *The Journal of Inebriety* and *The Review of Insanity and Nervous Diseases*. Abroad, the periodical literature is more voluminous, and books and pamphlets follow each other rapidly. A neurological library of to-day, to be complete, would include thousands of volumes and pamphlets. This would be exclusive of the literature which appears in the general journals, comprising records of cases, theories and discussions of diseases of the brain and nervous system.

The different fields of neurology have been studied until the specialists find it almost impossible to master more than a single phase of the subject. The lunacy specialists, the specialists of nervous diseases, the specialists of alcohol and drug-diseases, the specialists of idiocy and congenital diseases, the experimenter and teacher of psychology, and the electrician are all examples. The unknown regions of the physiology and pathology of the brain and nervous system are attracting an increasing number of most ardent students, and already the discoveries are very numerous and startling, and the process of learning and unlearning is more and more difficult.

In the department of medical jurisprudence progress and change are less rapid. Seven medico-legal societies and one large quarterly present the many practical topics which are constantly arising. The confusion of theory and practice in both law and medicine, relating to questions of crime and responsibility, has given rise to many strange conceptions of the teachings of science. Thus, from the text-books and legal rulings of judges, the lines of sanity and insanity are laid down as absolute facts. Free will and accountability, judgment, punishment, equity, brain control and capacity, are theoretically regarded as settled facts. All these questions constitute a realm of the densest superstition and error that will continue until this subject is studied scientifically. To-day, the student of medical jurisprudence must pursue his studies above all present theories, text-books and rulings of law. The questions of motive and human conduct must be decided from a knowledge of natural laws of physiological and psychological growth. Science calls for a great revolution and evolution in the medico-legal solution of many of the disputed questions of to-day. The insane, the inebriate, the defectives of all grades and conditions; and the tramp and criminal, can never be restrained or prevented from being sources of peril to all law and order, by theory, or metaphysical abstractions of mind, or legal rulings. Medical jurisprudence of the future must depend on the progress of scientific medicine.

Both neurology and medical jurisprudence are largely influenced by the neurotic element of American civilization. This is a tremendous factor in degeneration and disease, and enters into all degrees of life and living. The family physician and general practitioner are most favorably situated to become the earliest and most accurate students of most of these confusing problems in neurology and jurisprudence. Every year it becomes more and more apparent that the failure to recognize the early symptoms of brain-degeneration and disease constantly increases the army of incurables. The crowded insane asylums, almshouses, jails and hospitals all refer back to early neglect and failure to

[1] Read before the Section of Neurology, American Medical Association, May, 1891.

recognize and apply the means of prevention and cure. A clearer knowledge of neurology. would point to conditions and methods of treatment that could be successfully applied at that time only. An outline of some of these early stages is the central topic of this paper.

There is probably no one disease more often mistaken in its early stages than general paralysis. Even after the symptoms have become apparent, there are confusing halts and a delusive masking of symptoms that often puzzle even experts. A long formative stage precedes the well-defined symptoms, beginning in slight changes of conduct and character, elation of spirits, increased activity of the intellect; the disposition, the manner, the temper, the habits and general character all become altered. Then come acts and words that are unusual; the friends and associates are conscious of some change which they seek to remedy by moral advice. Finally, when some reckless conduct or strange disposition is manifest, the physician is called and the disease is clearly made out. To the patient, this has no foundation in fact, and sometimes the physician joins in this belief, and explains these changes of mind and conduct from some moral basis. Symptoms of alcoholic and sexual excesses are explained in the same way. After a period, in many cases extending over months and years, the nature of the disease is above all question, and beyond all medical skill. This formative stage has been attended by distress, loss, sorrow and most serious blunders. In some cases, criminal acts and sad domestic and pecuniary afflictions have marked this period. If the family physician had made an early diagnosis, and the treatment been based on this, a different history and result would have followed.

Some of the ataxies have a similar obscure, early stage, marked by psychical disturbances which are regarded as moral lapses. Nearly all forms of insanity begin with this obscure failure of the higher brain centres. Early changes of temper, conduct and character, defects of emotional control, defects of reason, slight and obscure at first, are clearly the oncoming shadows of disease that should be anticipated and pointed out. These changes and early symptoms are not new to science, but in most cases they are overlooked and seldom receive the attention they deserve.

There is a class of symptoms that is already becoming the centre of serious controversy. Such symptoms are not only not recognized in the early stages, but are sharply disputed by both laymen and physicians. I refer to the alcoholic, opium and other drug-symptoms, which are affirmed to be purely vicious acts and the voluntary giving way to the lower animal impulses. Public opinion has sought to control them by fine and imprisonment. The medical profession accepts this view, only asserting that after a time the use of these drugs brings on diseased states. The impulsive desire for alcohol and other narcotic drugs is always a symptom of some form of brain-palsy. There are two classes of cases in which this fact seems very clear. The first class includes cases with a history of a distinct traumatism—noticeably, sunstroke, blows on the head, profound wasting illness and severe injury of any kind. Recovery follows, but with it appear changes of temper, character and emotions, and then comes the drink-impulse or the use of some form of opium. These drugs cover up other changes and are interpreted as the cause of all subsequent degeneration and disease. Many of these cases die of pneumonia or some other acute disease, others go on to insanity and become inmates of asylums, while the majority remain as common drunkards or inebriates, slowly growing worse year after year. They are treated as low, voluntary inebriates, despised, persecuted and punished, and die the types of wretchedness and misery, frequently leaving defective families that are always burdens to the world.

Cases belonging to the second class of inebriates or drug-takers have a distinct history of psychical traumatism. A man, previously temperate and well, will have a history of profound mental shock, such as sudden, overwhelming grief at the loss of wife, or children, or property, or of failure to realize some absorbing ambition, or of some calamity causing great distress. His entire character and disposition will change, and the drink-impulse will, without any cause, appear suddenly and continue persistently. Several instances have been noted in which the effect of a railroad accident, as a result of which no external injury was produced, was the beginning of the drink-impulse. The sense of sudden fear seemed to so paralyze the brain as to demand alcohol or opium ever after. In these cases, alcohol may be taken at first as a medicine and in moderation, but the degeneration which calls for it is apparent when efforts are made to discontinue its use. Another class of cases shows these symptoms equally marked; thus, persons who fill positions of great care, of business or professional responsibility, and also persons who are most active in business in the prime of life, previously temperate —will suddenly begin to take spirits and rapidly become excessive drinkers, and defenders of its value as a medicine. Such cases are soon incapacitated and die. The drink-symptom is always treated as a moral condition in these cases.

In the first class of physical traumatism, some form of brain-degeneration is apparent in this morbid desire for alcohol and opium. The beginning

and progress of the case confirm this. In the second class of psychical traumatism, a brain-palsy and sudden perversion of brain function and activity take place, and the demand for alcohol and opium is the expression of this state. In the third class, the use of spirits is a symptom of exhaustion and general brain-failure. All these forms of palsy and degeneration are rapidly intensified by the chemical action of the spirit or drug used.

The pathological condition which calls for relief by these drugs has a uniform order of events: beginning at a certain point and passing down, marked by a regular succession of symptoms, reaching a certain termination that rarely varies. The drink-craze is a symptom which should never be misinterpreted or overlooked. Anyone who persists in using alcohol or opium to excess is suffering from brain-degeneration and disease, which requires medical study and care. The use of alcohol or other drugs is, in a certain number of cases, a marked symptom of insanity. This fact has been noted for many years; the abuse generally occurs in neurotics who, after some great strain or mental perturbation, become excessive users of spirits, and continuously or at intervals stupefy themselves with such drugs. When arrested and deprived of spirits in jails, acute mania or melancholy follows; then it appears that the spirit- and drug-craze were only symptoms of insanity concealed and masked by the spirits. The facts in this direction are numerous and startling, and unknown except to the few students who are at work in this field. Scientific study has established this fact, viz.: that the "drink-craze" (meaning the impulsive, unreasoning desire for spirits or narcotics) is a symptom of disease. Whether this is so in all cases at the beginning is not yet established; yet nothing can be more certain than this, that the use of spirits will cause disease and disease conditions in all cases. Another fact is becoming more prominent, that the number of inebriates of all forms is increasing; and with it the army of neurotics and defectives is likewise rapidly growing larger. The problems of causation, prevention and cure are still involved in the realms of obscurity and quackery. Great parties and numerous societies are attempting its solution from the moral side alone.

As a scientific problem it is practically unknown, and yet no question of modern times is so eminently one of causes and conditions that are tangible and within the range of science to understand. The neurologist must point out the road and stimulate the family physician to study these early psychical symptoms, which, like signal-flags of distress, are becoming more apparent. Scientifically, the abnormality of an increasing army of neurotics and suicidal drug-takers, who receive no care or medical attention until their condition becomes chronic, is a reflection on modern medicine. Over five millions of laymen in this country are agitating the question of means and remedies to check this disease. Of the sixty thousand physicians, less than a hundred have given any special attention to the cure and prevention of this wide-reaching malady. The specialists can study these cases in asylums, but the family physician must be the scientific student to point out the early causes and remedies. The drink-problem can never be solved except by physiological and psychological study. This must begin with heredity, growth, nutrition, culture, surroundings and all the phenomena of life. The early psychical symptoms must also be studied, the traumatisms, the beginnings of pathological changes that manifest themselves in the drink-impulse.

This is the path along which science must seek the solution of this problem. The temperance agitator and reformer must give way to the physician. The roar and conflict of parties and societies will die away, and only the voice of science will be heard. Then the armies of inebriates, criminals and insane will be halted, disbanded and forced back to health and rational living. The inebriates will be protected and housed. The saloon will disappear, and alcohol will be unknown. This will be a reality when medical men take up this study from a purely scientific point of view.

A CASE OF TABES DORSALIS WITH UNUSUAL SYMPTOMS.

BY HOWELL T. PERSHING, M.Sc., M.D.,
PROFESSOR OF NERVOUS DISEASES IN THE GROSS MEDICAL COLLEGE, DENVER, COL.; PHYSICIAN TO THE ARAPAHOE COUNTY HOSPITAL; NEUROLOGIST TO THE COLORADO STATE WOMAN'S HOSPITAL.

ALTHOUGH so much has been written on tabes dorsalis that its cardinal symptoms are familiar to every educated physician, the disease not rarely passes unrecognized years after its onset. As a rule, the patient has no suspicion of the sinister meaning of the earlier symptoms, and when he consults a physician some one of the very numerous special features of the disease may be so pronounced that its true nature is entirely overlooked. Although the classical type of the disease is well known, reports of individual cases are not withoutvalue.

Mrs. L. F., aged forty-seven, a housekeeper, had had two miscarriages; finally bearing one living child that died at eight months. The family history is negative, and there is no venereal history.

About three weeks before I saw her, she had consulted Dr. L. C. Brasher for an attack of colic, setting in suddenly and attended with severe pain referred to the umbilical region. There was vomiting, but no diarrhœa. The attack lasted two days and was accompanied by elevation of temperature.

There appeared to be no sufficient cause for the attack. Subsequently the patient stated that she was subject to rheumatic pains in the legs, sudden and sharp in character. According to her statement, the attacks of pain were usually preceded by chills, accompanied by fever and followed by sweating. She had recently been alarmed by a sudden, involuntary drawing-up of the knees, attended with stabbing pain "like string-halt in a horse." On account of these nervous symptoms, Dr. Brasher kindly brought her to me.

Inquiry disclosed that in about four years she had fallen in weight from 137 to 96 pounds, and that her "rheumatism" had troubled her for about the same time. Her appearance was suggestive of phthisis, but the heart and lungs were normal. The knee-jerks were absolutely gone. Standing with the feet together and the eyes closed, great unsteadiness was at once apparent, the patient falling unless supported. The pupils did not react to light, but reacted well with accommodative effort. There was decided awkwardnesss, but no true ataxia, of the arms. The movements of the legs were uncertain and lacking in precision, unless guided by the eyes. The gait was ataxic. Irregular movements of the toes and of the tendons on the dorsal surface of the foot indicated great uncertainty as to the relation of the foot to the floor. The inside of the foot and the great toe especially were not properly applied to the floor. There was no distinct paralysis. The plantar reflex and the superficial reflexes generally were active. In the lower limbs the touch-sense and pain-sense were not impaired, but localization, as tested by the calipers, was imperfect. On the outer side of the big and little toes the application of cold gave rise to a sensation of heat. The sense of posture was good.

The acuity of central vision was almost normal— $\frac{5}{VI}$ in each eye. The ophthalmoscope revealed no change in the fundus of either eye. The visual fields for white were slightly but distinctly contracted, and the right field for green was irregular. Central color-vision, as tested by Snellen's equally illuminated colored letters on a neutral background, was normal. There was no ptosis or other insufficiency of the ocular muscles.

Hearing: right, $\frac{3^{0}}{LX}$, bone conduction impaired; left, watch heard only when pressed against the auricle, but bone conduction only moderately impaired, the defect being principally due to injury of the drum. The sense of smell is absent, though stated as formerly good.

Occasionally there is some difficulty in passing urine, the flow being sluggish, so that a long time is required to empty the bladder. The urine is normal. The skin is harsh and dry.

Nitrate of silver was prescribed; in a few weeks the patient returned, reporting an entire absence of the "string-halt" symptom and comparative freedom from the stabbing pains; but a new and curious symptom had appeared. In standing or walking, both knees suddenly give way, and the patient makes an involuntary and rather comical bow, immediately recovering her position. She is at times seized with general tremor, attended with this painless doubling-up of the knees. On the whole, the nitrate of silver seemed to have done good.

In this case there can be no doubt as to the diagnosis. The lancinating pains, the loss of knee-jerk, the Argyll-Robertson pupil, the swaying with closed eyes, and the ataxic gait, form a clinical picture that is complete and unmistakable. It is not necessary to speak of the points of differential diagnosis. The disease is often overlooked, not from a want of knowledge of the points of differential diagnosis, but because its first clinical appearance is obscure and ill-defined. Thus, the abdominal cramps and vomiting, for which the patient sought medical advice, were indistinguishable from gastric or intestinal crises, except by the rise in temperature, which does not occur in the crises of tabes; yet such attacks hardly suggest tabes in one case out of a hundred. When the pains become severe enough to attract attention, they are commonly supposed to be rheumatic or neuralgic. The chill, fever and sweating, said to have been associated with the pains, would in many localities be regarded as malarial; inquiry developed the fact that the chill was merely a sense of chilliness, and that the sweating was at least partly due to hot bottles used to relieve the pain. There was no opportunity to measure the fever with a thermometer.

When failing vision is the first symptom, it is easy to ascribe it to presbyopia and to disregard it until the atrophy of the optic nerve is far advanced. Fortunately the ophthalmologist is alive to the diagnostic importance of atrophy of the optic nerve in relation to degenerative processes in the central nervous system. The ear is more or less diseased in a majority of tabetics, while laryngeal palsies[1] or crises are not rare; so that the patient may first consult an aurist or laryngologist. More rarely a perforating ulcer or trophic joint-disease, or an eruption of herpes or pemphigus,[2] may give the case a surgical or dermatological aspect.

With all of these avenues of error we must constantly be on our guard. The only way to avoid mistake is to examine all cases thoroughly. The habitual testing of the knee-jerk and allied phenomena would not only prevent tabes passing unrecognized, but would often lead to the early detection of other nervous diseases. It is especially necessary in cases supposed to have chronic rheumatism.

In cases of failing vision, not explicable by errors of refraction, ophthalmoscopic examination should never be omitted. Gray degeneration of the nerve

[1] Marina: Zur Symptomatologie d. Tabes Dorsalis, Arch. f. Psychiatrie, xx. 1.

[2] Buzzard: Diseases of the Nervous System, chap. viii.

is alone sufficient to render tabes probable. Mapping the visual fields is of diagnostic value in many forms of nervous disease, and should not be omitted in tabes, even when vision seems to be unaffected. Changes in the field for white and for colors will reveal incipient atrophy before there is loss of central vision or confusion of colors, and even before an expert with the ophthalmoscope can be sure of any change in the appearance of the nerve.

The sudden involuntary movement and sudden weakness of the legs in the case here reported are worthy of attention. Gowers[1] says: "A sudden, sharp pain may be accompanied by a sudden reflex, spasmodic movement of the legs or by inhibitory weakness. In one case sudden pain would often make the patient fall on his knees." This spasmodic movement is doubtless dependent upon the same cause as the exaggeration of the superficial reflexes, namely, irritation of sensory fibres. The sudden giving way of the legs was first described, I believe, by Buzzard. In his admirable lecture on "Little-Recognized Phases of Tabes Dorsalis"[2] he cites four cases of his own in which it occurred, and in one of them it was the only symptom for which the patient sought relief. It can hardly be, however, as he states, "of very common occurrence." Marina[3] found it in but one of forty carefully observed cases. Gowers speaks of it as an inhibitory effect of pain, but in three of Buzzard's cases it appears that it was not associated with pain, and in my case it was not. Possibly, as has been suggested, there are other afferent fibres than those conducting strictly sensory impulses, irritation of which may inhibit muscular action.

The fact that both sudden spasmodic action and sudden paralysis occurred in this patient makes it probable that both depend upon the same condition.

ORIGINAL LECTURES.

SKIN-GRAFTING.

A Lecture delivered at the Philadelphia Hospital.

BY ERNEST LAPLACE, M.D.,
PROFESSOR OF PATHOLOGY AND CLINICAL SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE, AND SURGEON TO THE PHILADELPHIA HOSPITAL.

LECTURE I.

GENTLEMEN: Before you is a patient who had an indolent and ugly ulcer of the leg, one of that class of patients that haunt the hospitals, and make the surgeon despair, because all that could be done for them had been done. These cases, which resist the best efforts, are just those which should be taken up and if possible cured, for they are surgical cases, and there is no problem which should be given up as impossible of solution. I have told you what these ulcers are and what must of necessity be done in order to heal them. You know they are generally due to varicose veins, that have so distended the tissues and altered their nutrition as to cause the surface of the skin to slough; the skin having fallen off, there is a solution of continuity, which readily becomes infected. Granulation-cells develop on the surface and Nature tries to heal the parts, but being ill supplied with blood, they are destroyed by micro-organisms, and a foul appearance of the surface is the result. After giving the required tonic, the foul cells should be removed by scraping the parts, thus leaving a healthy bleeding surface that should be protected from the atmosphere, and hæmostasis or stoppage of the blood permitted, thus preventing germs from gaining access. Then you will have a surface covered with healthy granulations. That being the case, all that is required for permanent cure is to clothe the surface with epithelium. You know that a little epithelium placed on an ulcer, if the parts are prepared, will grow and form a small island, which will spread in all directions, forming new sources of epithelium, which would have to start from the edges of the ulcer had nothing been done. Success having followed the surgeon's efforts, it was evident that if a small piece would spread, a large piece, the conditions being equal, would do likewise. Now, instead of taking a small bit of epithelium, we take as large a piece as we choose, and cover the whole ulceration with this, the parts first having been prepared, and hope that it will adhere to the subjacent structure.

You saw how I covered nearly the whole surface of the ulcer with epithelium. The epithelium was taken from the outside of the thigh. The place has healed beautifully; the epithelium has been restored; it has spread from the side and covered the whole surface that was made bare; but this is more intensely red than the rest, and shows a trace of having been tampered with. That is so, but there is a reason for it: the bloodvessels are nearer the surface here than in the surrounding skin. There is less of an epithelial covering here than there, but sufficient to cover the surface—about the same amount that would exist about the mouth, where, as you know, the mucous membrane resembles the skin, minus the horny layer; but the patient will not be deprived of this horny layer, as there will be a continued irritation of these spots, and in the course of a year, instead of remaining red, they will become thicker from the continual irritation. Not only that, but, very curious to say, the condition of these epithelial cells will be slightly altered, as a result of which pigment will be deposited, and, instead of being rosy, the surface will have a brownish appearance. Therefore do not hesitate to remove epithelium, but remove as large a piece as you wish; it will always grow again if you use aseptic measures and prevent the entrance of microörganisms.

Now for the ulcer itself. The dressing was left during two weeks, until a few days ago, and on being removed we found pretty nearly the same condition as you will see here now. All of you who have seen this ulcer will remember that it presented an ugly appearance; now it is still uncovered by epithelium in some places, but more than four-fifths of its surface

[1] Diseases of the Nervous System, Am. ed., p. 292.
[2] Op. cit., Lecture XV.
[3] Op. cit.

have practically healed. It has not the two layers of epithelium found in mucous membranes, still less the three layers of the skin, but only the beginning, the lowermost layer of epithelium. This layer is transparent, and you can almost see the granulations beneath, but still it is here. There are some islands that are perfectly clear, and here the epithelium is as clear as on the surface of the gum. None of you will tell me that the gum is ulcerated, and this ulcer has as much epithelium as is on the surface of the gum.

The point to which I wish to call your attention is this: Here is a perfectly sterile wound; there is no suppuration; all granulations are doing their duty, that is, building fibrous tissue; a delicate layer of epithelium covers the surface of the ulcer; practically, it is healed, and there is nothing more to do with it. All the epithelium has engrafted itself upon the underlying granulations, and the whole surface is protected from the atmosphere by this very delicate layer of epithelium. What should be done at present, in order to give this patient the fullest chance of a perfect result? Nothing but keep him in bed and keep this covered with a sterilized dressing, because, delicate as this covering is at present, it would be possible that a little excoriation would open many mouths to receive germs from the atmosphere and cause infection of the part. Therefore, the precaution to take is to place a sterilized dressing on the part and leave the patient alone for a week or two, and by that time the skin will have thickened, and there will be the same appearance as we saw upon the thigh.

Now that you have looked at this, I wish to call your attention to another point. Remember, when you graft, that all you can hope to have grow must have life. As we know, the surface layer of epithelium is not alive; it is dead, horny epithelium; it receives no nutrition from the vessels below; it falls off as dandruff; we cannot expect this to grow. Hence, do not be surprised, when you remove the dressing, to be faced with the fact that the procedure seems to be a failure. It looks as if the whole graft is coming off as a pellicle. No! the lowermost layer does plant itself on the underlying structures, and it is only the horny layer that comes off. When I take a graft I leave the fibrous layer below, and I know I have cut to the papillary layer because I have hæmorrhage. I know I have gone deeply enough to cut the top ends of the capillaries, therefore I transplant all above the fibrous layer. When implanted, the deeper layer proliferates and gradually pushes off the superficial layer, and this falls off; the cells are too far away from the bloodvessels to receive nutrition. Remember, therefore: you must expect this horny layer to fall off, because it is dead. What grow are the epithelial cells in the papillary layer and the mucous layer of Malpighius.

This patient was brought before you two weeks ago, suffering with a keloid. He is an epileptic, and in one of his attacks grasped a steam-pipe and burned the palmar surface of the hand and thumb. You know the great tendency of a burned surface to develop a keloid, which is simply a scar that does not stop growing. Here you have injured yourself and the wound heals, because a scar forms on the surface and it stops there; but it does not always end so; sometimes a hard tumor grows where there ought to have been a soft scar. That was this man's condition; he had a keloid on this surface. It did what cicatricial tissue does everywhere else, and the tendency was for the man's thumb to be drawn into the hand and to be bound down. The keloid was also growing on the palmar aspect of the fingers. Looking at it from that standpoint, and knowing that the man would simply be losing the use of the thumb, the indication was to remove the growth and treat the wound as if it were a simple ulcer.

I removed the growth thoroughly and the skin for half an inch about it, laying bare the adductor pollicis and flexor brevis pollicis. Here was muscular tissue laid bare, and we could not expect epithelium to grow on muscular tissue. What was to be done? Simply leave the patient alone until the surface should develop granulations, and then graft. A week after having removed this keloid, we proceeded to graft the surface as in the case of the ulcer which you have just seen. Here the tissues being plentifully supplied with blood, and being perfectly healthy—not diseased as the leg was—there was less trouble in getting perfect union, every graft "taking," and covering the surface perfectly with epithelium.

You notice a certain darkened appearance of this surface, which you must not mistake, as it is merely a scab. The parts were healthy, and there was a little oozing of serum, which is nothing but liquor sanguinis and fibrin. The water of the serum evaporating, left the scab which you see. Therefore do not be puzzled as to what a scab is: it is simply serum from which the water has been evaporated, leaving the albumin and fibrin and some epithelial cells in the meshes of the fibrin. Here the whole epithelial surface has been restored. Secondly, I wish to draw your attention to these two fingers. You know the tendency of a wound resulting from a burn to contract. These fingers were already turned in, and the tendency was that they would be more and more turned in. Knowing that the tendon was surrounded by fibrous tissue, we stretched the fingers and cut directly down upon the tendon, not separating it entirely, but cutting about three-fourths of it away, leaving the remaining fibres to be kept in apposition by means of suture. Remember, when you wish to perform tenotomy and do not require much stretching, that it is well to leave a few of the fibres which will act as a suture. A splint was put upon the fingers, and the space between the ends of the tendon was filled up with granulations. Here we will have the tendon restored, but much longer than it was before.

UTERINE MYOMATA.

BY E. E. MONTGOMERY, M.D.,
VISITING PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

GENTLEMEN: The first patient I bring before you is a colored woman, who entered the hospital two days ago. I have not, as yet, had an opportunity to examine her. She presents the following history: She says she is sixty years old, and has had twelve children, all dead. Her health has been fairly good, until three years ago, when she noticed an enlargement of the abdomen, which has steadily increased. This enlargement is at times greater than at others; she suffers much pain and distress in the abdomen and particularly in the pelvis.

As the abdomen is exposed, you see that its walls are thin, and through them two irregular projections are visible. The larger projection is on the left side, while the smaller and more distinctly outlined projection is on the right. As we look at the abdominal surface, we see that the skin is striated, showing cicatrices resulting from previous distention; also that the abdominal walls move freely over the subjacent structures. In the examination of a patient presenting such a condition we at once ask ourselves what structures may be involved, and what growths are most likely to occur at the time of life of the patient.

From a study of the case we at once arrive at the conclusion that it is not one of pregnancy, on account of the age of the patient and the peculiar appearance of the tumor, although upon inquiry she informs us that she has not ceased to menstruate, and that she suffers from an irregular bloody discharge. Pregnancy is an exceedingly rare occurrence after fifty years of age, although there are cases on record in which women have become pregnant and given birth to children at as late a period as sixty.

Without further examination we will proceed to discuss the possibilities in the case before us. Besides pregnancy the abdomen might be distended by fibroid tumors; by tumors of the kidneys, ovaries, omentum or alimentary canal. Fibroid tumors are uncommon after the climacteric period, unless they have existed previously. Fibroid tumors are likely to become quiescent or even reduced in size with the occurrence of the menopause. After the cessation of menstruation, ovarian growths are more common than growths of the uterus. Disease of the ovaries and tubes often makes its appearance after menstruation has ceased, but in the majority of such cases the disease is of a malignant character. Tumors of the omentum or of the intestinal tract are also likely to be malignant. That the tumor in the case before us is not one of the kidney is probable from its situation in the lower part of the abdomen, and because the entire mass is somewhat symmetrical, while a renal tumor would be situated to one or the other side of the median line.

What has been said of the character of this abdominal growth does not necessarily preclude the possibility of its belonging to any of the conditions named, excepting that of renal tumor. The enlargement is irregular and somewhat nodular. The larger mass, situated upon the left of the median line, extends above the umbilicus, presenting a convex surface laterally and a sharp margin medianly, and is without question a solid tumor. It is freely movable in all directions, and evidently has a small pedicle of considerable length. The tumor on the right side is less movable; it presents a conical projection, recognizable on inspection, and evidently extends downward into the pelvis. Both masses are dense and resistant to such a degree as to scarcely permit us to believe that they are cystic in character. The tumor upon the left, with its sharply defined edge, is certainly not cystic, as a cystic tumor would be likely to be spherical in shape.

We are accustomed to divide the abdomen into different regions by means of arbitrary lines; remembering the viscera that are contained in each region, we can specify the organ from which a peculiar growth originates. The situation of these growths in the lower part of the abdomen indicates that they have originated from the uterus, the ovaries or the omentum. We would infer that the omentum is not involved, because the tumor is freely movable. Omental growths are generally malignant and do not attain great size without forming firm adhesions to adjacent viscera or surfaces.

Is the growth ovarian in origin? Ovarian growths are usually cystic, although they may be solid, such as fibroma, sarcoma; the contents of colloid or dermoid cysts are thick and viscid, and fluctuation would be indistinct or not discernible. Fibromas of the ovary are usually small in size. Sarcomas do not attain to large size without giving rise to greater or less effusion. Colloid cysts usually form extensive adhesions. For these reasons we are obliged to eliminate the possibility of the growths being ovarian.

By a process of exclusion we are driven to the uterus as the only source of development of the tumors. The finger, introduced into the vagina at a point one inch from the vulva, comes in contact with a hard, dense mass, which fills up the pelvis; the finger can be passed around the mass in every direction; but passes with difficulty between this mass and the symphysis; above the symphysis is felt a small teat-like projection, which we recognize as the remains of the cervix; movement of the tumor on the right side is transmitted to the finger kept in contact with this pelvic mass, demonstrating that both parts belong to the same tumor. Notwithstanding the inference from the age of the patient, we are forced to the diagnosis of uterine fibroid or myoma. Rectal examination enables us to pass a finger over the posterior surface of the tumor, which has made pressure upon the rectum, interfering with the evacuation of the bowels, in this way giving rise to the occasional increase in the size of the abdomen, of which the patient has complained. From the size of the tumor, and from the persistence of the menstrual flow, it is probable that the tumor has existed for a number of years, and had attained considerable growth before it was recognized by the patient or her attendant.

Uterine tumors or fibroids are divided into three classes, according to their situation or relation to the uterus. Thus, we have submucous tumors, which have originated from the inner portion of the uterine walls, and, attaining such size as to be no longer accommodated in their original situations, are pushed into the cavity of the uterus. Attached to the uterine wall by a stalk or pedicle such a tumor is known as a polypus. Situated in one or the other wall, with a broad base, it is called a sessile fibroid. If the tumor has developed from and occupies the greater part of the muscular layer of the uterus, it is known as an interstitial fibroid. Such a tumor may attain considerable size and involve the greater portion of the structure of the uterus. It is quite possible that the tumor upon the right side belongs to this class. Tumors of the third class are known as subperitoneal myomata; they develop in the external muscular layer of the uterus, and in their growth are pushed beneath the peritoneum, and may be attached to the uterus by a pedicle of varying length and thickness. The tumor upon the left side probably belongs to this class. Adhesions sometimes form between such tumors and the abdominal viscera. The peristaltic action of the intestines may cause lengthening or even

separation of the pedicle, so that a mass may be found in the abdomen at some distance from the uterus.

Now, if the tumor is pushed into the cavity of the uterus, suspended by a pedicle, it can readily be removed by grasping it with a pair of volsella forceps and twisting its pedicle until separation takes place; or the pedicle may be severed with a knife, with the galvanic cautery, or with a wire *écraseur*. If an interstitial tumor is present and the cervix can be dilated so that the tumor can be readily reached through it, the wall of the uterus may be incised and the tumor enucleated, partly with the finger and partly by means of Thomas's serrated spoon curette, and then removed. If a tumor is too large to be delivered *en masse*, it may be cut away in parts with the scissors until entirely removed. Such operations, however, are attended with much danger. In the case before you, however, the removal of the mass through the vagina is not feasible, as the tumor is entirely too large. Even were it possible, the removal of a mass constituting a portion of the fundus of the uterus would be attended with too much hæmorrhage to be justifiable.

In such a case is an operation for the removal of the tumor feasible or justifiable? From the level at which the cervix is felt it is evident that it could be drawn out through an abdominal incision and used as a pedicle. Before proceeding, however, to such an operation it is important that the condition of the viscera and secretory organs be carefully examined, as not infrequently, when tumors fill the pelvis, pressure is made upon the ureters, leading to their distention and hydro-nephrosis; indeed, in some cases, the kidneys become sacculated, their pelves dilated and their parenchyma attenuated. Under such conditions operative interference would be attended with serious complications and the probable death of the patient.

Careful examination will be made, and if an operation seems feasible, and the patient is willing to submit to it, an effort will be made to relieve her of this growth and its consequent distressing symptoms.

MEMORANDUM.

METHODS OF STAINING BACILLI.

BY C. F. GARDINER, M.D.,
OF COLORADO SPRINGS, COL.

THE method of staining bacilli in early cases of lung trouble, when the physical examination shows little or nothing, has now become such a matter of routine with most physicians that it holds a place as an aid to diagnosis as important as that of examining the urine for albumin and casts in diseases of the kidneys; and a rapid and reliable method of staining the sputa, one requiring but a limited number of solutions and simple technique, is valuable not only to the busy practitioner, but especially to the medical examiner for life insurance, who, more than the average physician, has to condense his scientific researches.

Articles have appeared in the journals from time to time upon rapid and easy methods of staining, but so far as I have been able to observe, they all have the objection, either that heat is applied to solutions, or much time and manipulation is required. The following method, shown me by Dr. T. Mitchell Prudden, College of Physicians and Surgeons, New York City (it first appearing, I believe, in a Swiss medical journal), I have now used here for three years, often several times daily. In my hands it has been most convenient, rapid, and successful, enabling me at times to report upon several cases in a very short time.

Two solutions are made, the first being practically a carbol-fuchsin:

SOLUTION NO. 1.

℞.—Fuchsin	15 grains.
Alcohol	2½ drachms.
Carbolic acid (sat. sol.)	½ drachm or 30 minims.
Water	2 ounces.

Dissolve the fuchsin in the alcohol by shaking, and to this add the carbolic acid and water.

SOLUTION NO. 2.

℞.—Methyl-blue	2 ounces.
Sulphuric acid, C. P.	½ ounce.
Water	1½ ounces.

Dissolve the acid in the water, and when cool add to the methyl-blue. The cover-glass, being prepared as usual, but with rather a thin film of sputa and lightly flamed, is placed for three minutes in solution No. 1, taken out and washed well in water to remove excess of red, then put in solution No. 2 for two minutes, then washed in water and examined. If reddish masses appear after solution No. 2 is used, the specimen can be inserted again in No. 2 for another minute or so. These solutions can be kept in properly labelled bottles ready for use, and will keep unchanged for some months.

Solution No. 1 is apt to have a coating form on the surface if exposed to the air too long.

There is one point to be observed, which is a vital one: only reliable dyes should be used, such, *e.g.*, as Professor Grübler's aniline dyes. In trying other and inferior dyes I have had decided difficulty in making these solutions stain satisfactorily. It may be well to mention that to clearly see tubercle bacilli, a microscope having at least a good one-sixth objective, that, with an Abbe condenser, will magnify from five to six hundred diameters, is a necessity.

[The foregoing is practically what is known as Gabbett's method. The search for bacilli may be further facilitated by adding dilute caustic soda to the sputum and gently heating. In the course of from twenty-four to forty-eight hours the bacilli will have fallen to the bottom. The supernatant fluid is decanted and cover-glass preparations made from the sediment. In this way bacilli may be detected when present in small numbers, and when they might elude detection by another method.—*Editor of* THE MEDICAL NEWS.]

MEDICAL PROGRESS.

American Inventions and Discoveries in Medicine, Surgery, etc.—At the recent celebration of the beginning of the second century of the American patent system, DR. JOHN S. BILLINGS, U. S. A., delivered an address upon American inventions and discoveries in medicine, surgery and practical sanitation. He could learn of but one system of medicine to which a patent had been

granted—Thomsonianism. "The right to practise this system, with a book describing the methods, was sold by the patentee for twenty dollars." Patent medicines, the recipes of which must be furnished, are much less numerous than proprietary medicines, which can be protected by trade-marks and copyright. Between the years 1880 and 1890, 540 patents were granted for medicines.

According to the census of 1880 there were in the United States 592 establishments devoted to the manufacture of drugs and chemicals, the capital invested being $28,598,458, and the annual value of the product $38,173,658, while there were 563 establishments devoted to the manufacture of patent medicines and compounds, the capital invested being $10,620,880, and the annual value of the product $14,682,494.

"We are a bitters- and pill-taking people. From the commercial and industrial point of view the great importance of patent and proprietary medicines is connected with advertising. The problem is to induce people to pay twenty-five cents for the liver-encouraging, silent-perambulating family pills which cost three cents."

Dr. Billings said further:

"The most important improvements in practical medicine made in the United States have been chiefly in surgery in its various branches. We have led the way in the ligation of some of the larger arteries, in the removal of abdominal tumors, in the treatment of diseases and injuries peculiar to women, in the treatment of spinal affections and of deformities of various kinds. Above all, we were the first to show the uses of anæsthetics—the most important advance in medicine made during the century. In our late war we taught Europe how to build, organize and manage military hospitals; and we formed the best museum in existence illustrating modern military medicine and surgery. Our contributions to medical literature have been many and valuable; and our Government possesses the largest and best working medical library in the world. We have more doctors and more medical schools, in proportion to the population, than any other country, and while this is not good evidence of progress, I am glad to be able to say that the standard of acquirements in medical education has been and is now rising, and our leading medical schools are now being equipped with buildings, with apparatus, with laboratories, and most important of all, with brains, which enable them to give means of practical instruction equal to any to be found elsewhere."—*Boston Med. and Surg. Journ.*, April 9, 1891.

A Case of Pseudo-Syringo-myelia.—At a clinical lecture CHARCOT (*La Semaine Médicale*, May 13, 1891) presented a baker of twenty-three, who was injured by a bullet which entered the body to the right of the seventh cervical vertebra, following which right hemiplegia developed. The bullet was not found. The wound healed kindly, the hemiplegia disappeared, and in two weeks the patient returned to work. Three years subsequently, in lifting a heavy weight, he felt an intense pain in the back, followed by paresis of the right lower extremity. Other symptoms of spasmodic hemi-paraplegia developed. The right upper extremity in turn became involved. The thenar and hypothenar eminences became wasted, the flexors and interossei enfeebled. On the inner aspect of the forearm the tactile sense was unimpaired, while the perception of heat, cold, and pain were lost. The atrophied muscles presented reactions of degeneration, but no fibrillary twitching. Slight scoliosis existed in the dorsal region. There was no nystagmus or diminution of the visual field. The right pupil was small, but responded to light. The eyeball was retracted. On the left side, below the level of the axilla, was a zone of dysæsthesia. A touch, a puncture, heat and cold were all perceived as painful sensations.

The explanation of the symptoms depends upon the lodgment of the bullet, in the primary accident, in the body of the first or second dorsal vertebra, which, undergoing softening, gave way when the heavy weight was lifted, with consequent compression of the right half of the cord and first pair of dorsal nerves.

Thymolo-acetate of Mercury in the Treatment of Pulmonary Tuberculosis.—TRANJEN, a military surgeon of Bulgaria, makes (*Berliner klin. Wochenschr.*, April 20, 1891) a preliminary report upon the treatment of pulmonary tuberculosis by means of intra-muscular injections of thymolo-acetate of mercury. Three parts of the latter were carefully mixed with forty of liquid paraffin; every seven or ten days fifteen minims of the mixture were injected deeply into the gluteal region. After the second or third injection, unless fever existed, six grains of iodide of potassium were administered thrice daily. One hundred and eleven injections were made in fifty-two cases, mostly out-patients. In two cases stomatitis developed; in others there was considerable pain at the site of injection; otherwise there were no complications. Tranjen thus formulates the conclusions arrived at from his observations: Decided improvement took place in cases of incipient phthisis; in cases not too far advanced, more or less considerable improvement, subjective and objective, resulted; no injurious effects were observed in grave cases. Ewald, at whose clinic most of the observations were made, in a supplementary note admits that the results of the injections in suitable cases were as favorable as from any other method, but admonishes against extravagant expectations from the treatment.

Glycerin-alcohol.—To assure accurate dosage and rapid absorption, PETIT (*Journ. de Méd. de Paris*, March 15, 1891) proposes the following menstruum for the administration of alkaloids, glucosides, and other active medicinal agents:

℞.—Glycerini (sp. gr. 1.250 at 66°)	.	333 parts.
Aquæ destil.	.	147 "
Alcoholis (95 per cent., q. s. ut fiat at 66°)	.	1000 "

This mixture may be preserved indefinitely; it does not suffer by evaporation; it is a solvent of most medicaments.

Sterilization of Catgut.—CURTILLET (*Prov. Med.*, No. 20, 1890) states that catgut can be sterilized by heating for a half-hour in a partially closed glass vessel at a temperature of 284°, gradually increased to 302°, and then placing in absolute alcohol. Catgut thus treated will remain for an indefinite time sterile, strong and pliant.—*Centralblatt für Gynäkol.*, May 9, 1891.

Resopyrin.—By combining resorcin and antipyrin ROUX has obtained a mixture to which he gives the name of resopyrin. It is an odorless body of feebly pungent taste, which crystallizes in colorless, oblique, rhomboidal prisms; it is soluble in 100 parts of alcohol, in ether, and in chloroform, but is scarcely soluble in water.—*Journ. de Méd., de Chir. et de Pharmacol.*, April 20, 1891.

Pharyngitis Due to Pneumonia-cocci.—RENDU (*La Semaine Médicale*, May 13, 1891) has reported the case of a woman, twenty-four years old, who developed an intense pharyngitis after having slept in the same dormitory as three others with pneumonia. A mouse inoculated with some of the saliva died in eighteen hours; its blood and viscera contained large numbers of pneumonia-cocci, which also developed in agar cultures made with blood from the mouse. Several days subsequently, a second case of pharyngitis developed in the same ward; inoculation and cultivation were omitted. Pneumonia-cocci may be found in the saliva in health, but then are not virulent.

Paroxysmal Salivation in General Paralysis.—FÉRÉ (*La Semaine Médicale*, May 13, 1891) reported to the Société de Biologie the case of a man of thirty-nine, with symptoms of general paralysis—bilateral ptosis, inequality of the pupils, right hemiparesis, intellectual enfeeblement, etc.—in the course of which numerous epileptiform attacks, involving the right side of the face and right arm, occurred. Each paroxysm was preceded by profuse salivation, which never took place independently. The salivation was attributed to an irritation similar in character and situation to those upon which the epileptiform seizure depended.

Œdema of the Glottis Following Influenza.—Before the Imperial Society of Medicine of Constantinople, BAVACHI (*Gazette Méd. d'Orient*, April 15, 1891) reported three cases of influenza in which œdema of the glottis developed. One was in a man of fifty, the second in a man of thirty, and the third in a girl of three. The first died, the general condition not being favorable for tracheotomy; the other two recovered without operative interference.

Cholagogue Tablets.—HUCHARD:

℞.—Sodii benzoatis, Sodii salicylatis, Rhei pulv. } of each . 1 drachm.
Ext. nucis vomicæ . . . 5 grains.
Ft. tabellæ no. xx.
Sig.—One at each meal.
—*La Méd. Mod.*, May 7, 1891.

Fumigant for Asthma.—PLANT:

℞.—Stramonium leaves, Green tea } of each 1 ounce.
Lobelia inflata . . . 3 drachms.

Add a saturated solution of potassium nitrate, dry, and preserve in a well-stoppered bottle. A teaspoonful suffices for a fumigation.—*La Sem. Méd.*, April 29, 1891.

Boro-glyceride Cream.—Dissolve one part of boric acid in twenty-four parts of glycerin, and add to the mixture five parts of lanolin and seventy parts of vaseline; cool and perfume according to taste.

Methods of Making Corrosion Preparations.—In an address before the American Academy of Arts and Sciences, PROFESSOR DWIGHT describes the methods of making corrosion preparations in use in the Harvard Medical School. The object of the method thus named is to preserve the shape of cavities—ducts, vessels, or spaces—by injecting them with a hardening fluid and then destroying the organ with corroding or digesting substances, leaving the cast intact. Three methods are described:

1. The injecting mass is a mixture of resin and white wax colored with paint dissolved in balsam of copaiba. The organ is destroyed by hydrochloric acid and water, and the cast given a gloss and greater strength by pouring over it a solution of gelatin in acetic acid. Different vessels or parts of an organ may by this method be injected in different colors. The objections to it are that it is difficult to carry out, and the preparation is brittle.

2. The use of Woods' fusible metal. This consists of bismuth seven parts, lead four parts, tin two parts, and cadmium one part. It melts at a low temperature, and can usually be injected merely by its weight. The tissues are destroyed by caustic potash. By this method different vessels cannot be made of different colors, and, owing to their weight, the casts in time tend to become distorted.

3. By celloidin, injected cold and slowly, by repeated forcings through a syringe, of which the piston is driven by a screw. This method allows fine and variously colored casts to be made. The soft parts are destroyed by an acid or digesting substance.—*Boston Medical and Surgical Journal*, May 14.

The Operative Treatment of Goitre.—In an inaugural dissertation BALLY reports the results of operation in 77 cases of goitre, treated at the clinic of Socin at Basle, in the period between January, 1887, and September, 1889. Of these 24 were cystic, 24 colloid, 19 mixed, 7 parenchymatous, 1 fibrous, 1 a cystic adenoma, and 1 a fœtal adenoma. In one case two operations were performed. Five were treated by puncture and injection, 1 by total extirpation of the thyroid, 14 by partial removal of the gland, and 58 by intra-glandular enucleation. The conclusions arrived at, as a result of a study of these cases and of those reported by others, are as follows: Intra-glandular enucleation of one or several goitrous nodules is usually practicable, excepting in the case of malignant strumæ, diffuse parenchymatous or colloid hypertrophies of the thyroid, exophthalmic goitre and goitres with numerous disseminated nodules; the layer of tissue separating the capsule of the gland from the goitre is readily detectable; hæmorrhage is usually not alarming. In the rare cases in which it becomes alarming, the thyroid vessels may be ligated and partial extirpation performed. Injury of nerve-fibres, and the resulting palsy of the vocal bands, is avoidable. The probability of recurrence is not greater than in the case of partial extirpation. Unfavorable results, as tetany or symptoms of cachexia, were observed in no case, and in none of the cases in which partial extirpation was performed did the tissue left behind disappear.—*Correspondenzblatt für Schweizer Aerzte*, May 1, 1891.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 13, 1891.

THE TREATMENT OF EXTRA-UTERINE PREGNANCY BY EXTIRPATION PER VAGINAM.

As the literature of this subject increases it may be observed that, although in the early stages of extra-uterine pregnancy the difficulty of diagnosis does not lessen, the indications for treatment become more clearly defined. As is true of many surgical procedures, the surgeon has learned when and how to operate by imitating Nature's treatment.

From one aspect cases of extra-uterine pregnancy may be divided into acute and chronic; in the former the indication for operation is the immediate saving of life; in the second, the destruction and removal of the foreign body that imperils the patient's existence; both are accomplished by the processes of Nature in a manner which may to advantage be supplemented by the obstetrician.

There can be no question of the duty of operating upon a patient seized with symptoms of rupture of the sac of an extra-uterine fœtus; and when these symptoms persist and threaten life, the method of operating by abdominal section admits at present of no criticism.

In cases, however, in which the fœtus has grown and developed, the surgeon will do well to adopt an equally radical but more protracted treatment. Nature waits until the death of the fœtus has taken place before attempting to remove the product of conception; when the period of viability has not been attained, and the fœtus is so situated that it cannot, without menace to the mother, grow until term, the surgeon may with advantage wait until Nature has ended fœtal life.

The removal of the fœtus is naturally effected by a process of necrosis in the wall of the fœtal sac. This process may even invade the abdominal wall, as illustrated by a remarkable case described by SHEILD at a recent meeting of the Obstetrical Society of London, in which, in a primipara, sloughing of the abdominal wall near the umbilicus occurred, with the protrusion of a fœtus nearly at term; other cases, in which the fœtus has been discharged piecemeal through tissues near the uterus, have been not infrequently reported. In cases coming under the notice of the obstetrician when fœtal death has occurred and the fœtus is so situated that its removal by abdominal incision is difficult, it is occasionally justifiable to open the fœtal sac, remove its contents, and treat the condition as one would an abscess cavity, by approaching it *per vaginam*. An interesting operation of this sort has recently been reported by FENGER.

The patient was a primipara, and the head of an extra-uterine fœtus could be felt through the vagina. After making a median incision through the perineum, to give room, the fœtal sac was opened by the cautery, craniotomy was performed upon the head which presented at the opening, and the skull was extracted piecemeal; the body easily followed; the sac was irrigated with boric acid solution and thoroughly drained; the vagina was tamponed with antiseptic gauze, and an antiseptic dressing was kept over the vulva. The placenta, which was attached in the left iliac fossa, came away on the seventeenth day. With continued drainage and antisepsis the patient recovered.

The vaginal operation for these conditions is to be reserved, FENGER remarks, for cases in which the tumor is low in the pelvis, the placental circulation has ceased, and suppuration has begun; it may also be chosen in cases of prolonged extra-uterine pregnancy, when the fœtus disintegrates and an attempt is made to discharge it piecemeal. FENGER could distinguish the placental souffle in his case when first examined, but he waited for a week after it had ceased before operating, thus avoiding very

largely the danger of hæmorrhage from the placenta. Cultures were made from the fœtus as soon as it was removed to ascertain the presence or absence of bacteria in the fœtal sac: it was found sterile and in a thoroughly aseptic condition.

As our knowledge of the subject increases, indications for operation will become more clear and fatal results less in number. The choice of a method of operation based upon the pathology of each individual case will always be of paramount interest and importance to the obstetrician.

PROFESSOR DA COSTA'S VALEDICTORY.

THE graduating class of 1891 of the Jefferson Medical College enjoyed a unique privilege; they received in an especial and personal sense the deeply significant valedictory of the teacher who for nineteen years had faithfully and brilliantly taught his pupils and the world the mysteries and cure of disease. The address breathes throughout a spirit of almost pathetic tenderness and solicitude for the individual student and worker in medicine, but below all other notes there is the clear, strong, dominant tone of love for medicine in the abstract, for the healing of the world's diseases, and the forefending of the world's ill. In these days, when the old-time courtesies are so apt to be neglected in the furious battle for worldly success; when scientific aims are pursued in disregard of a desirable respect for one's self and one's fellows; when manner and method are forgotten in pursuit of objects and things; when professional success is often prized more than professional ethics, how grateful seem the following words from one who has reached the highest and most honorable success, both worldly and professional:

"As men, I know you wish what all men wish—for friends, for esteem, for worldly success. Yet, if even all these were granted to you, you would not be satisfied, unless with them you had the approval of your conscience in your work. There will be dark days to you, as there will be joyous days; and in those dark days the feeling that you have done right, that you have striven manfully to the best of your ability, that no one has suffered whom you could have relieved, that no life has been lost which greater care could have saved, will be a joy. And the faithfulness and the care are not only of use to those in whose behalf they are exerted, but they also become a help to others, stimulating them to the same. Thus the humblest, the least gifted, may strengthen the resolves of the most self-reliant, the most gifted. One life reacts on another—its good increases the good in others. . . .

"Only let the fire of science burn within you as a vestal fire. If you do, it will not only benefit others, but will benefit you. When discouraged by drudgery and by long waiting for opportunity; when chilled and choked by battling with pretentious commonplace; when awe-stricken with the power of dense, invincible dulness, it will glow, if you fan it, and warm and cheer you. It has been kindled by a divine spark, and cannot go out while you are true and honorable and keep it alive for pure purposes."

To himself, the teacher *par excellence*, his own words have especial application, and in him striking exemplification:

"If you lead a teacher's life you must accept with it a teacher's duty. One of his duties is to hand down the best traditions of medical life, and to try to do that which in time will add to them. He will, then, not simply instruct; he will do more, he will educate. He must also foster investigation, and be himself an investigator. His love for learning must never weaken: when he ceases to be more than an elder student, he ceases to be fit to be a teacher. A teacher's work does not die with him. It lives long after, and may give great results. . . .

"Through his pupils a teacher lives; the man passes away, the teacher remains in his pupils and becomes part of them. What a thought that they, the lenient judges of his endeavor, the pledges of his aspirations fulfilled, the subsisting signs of his responsibility, transmit his life! What a thought that through them he may influence action for more than one generation; that from his impulse may spring what is far above himself! . . .

"What a stimulus, then, all this is to him who has the aspiration to instruct! And when the hour comes that I shall lay down this robe of teaching, when the time arrives that I address you no more, there will always remain the thought—I say it in all humility—that I shall live in you. I shall be with you in your struggles, shall share with you your successes. At every bedside of distress, at every bedside of hope, we meet again. The teacher is inseparably joined to you, to all his pupils. Awful, ever-present responsibility—constant excitant to truthful arduous effort; and happy he who has been so guided that he has never forgotten his responsibility nor relaxed his exertion; that he has used God's gift of teaching for God's purposes."

WORSE THAN VIVISECTION.

THERE are few things occurring in our modern life more fitted to give one severe moral nausea

than the outrageous facts, none too plainly exposed by a writer in the April number of *The Nineteenth Century*, in a description of the hideous agonies suffered by cattle during their transfer from their prairie homes to the English abattoirs. It is plain that, far from exaggeration, the worst part of the matter is touched as lightly and with as little insistance as possible. It would seem impossible that men and women with the faintest remnants of humanity and kindness yet remaining in their hearts, would, for the saving of a paltry penny or two per pound in their purchase of meat, command such things to be done. But apart from these aspects of the question, one cannot forbear asking what may be the physiological effect of such meat upon the human organism. If the milk of an angry human mother or a sexually excited cow will, in a child, produce very serious illness, what may not be the effect of the eaten flesh of these animals, beaten as they have been, bruised, starved, trodden to death, stifled, the whole organism every moment for weeks a quivering mass of fever, pain and passion? The writer of the article in question thus closes his story:

"It was found impracticable to fatten up range cattle on their arrival in England, and, after a few days' rest, to allow them to recover from their fevered condition: all these cattle were sold for immediate slaughter. They were fat when they left the range; at the end of their month's journey they were not only reduced to mere frames, gaunt and narrow beyond belief of people who have seen cattle only in the fields and farmyards of England, but with their sterns rubbed raw and swollen out of all natural shape, their legs also swollen, and in many cases raw around the fetlocks, and with their hides scored with horn-marks. When one considers the amount of bruising which these external marks represent and the way in which steers had been thrown about in the pens by the motion of the vessel, it is difficult to suppose that any of the little beef that is on them can be healthy human food. I can only suppose it is made into sausages."

It is greatly to the credit of our Government that the Secretary of Agriculture has issued the most stringent and detailed orders, which to some extent, will lessen the horrors of the ocean passage.

FOOD, MORTALITY, AND A PROTECTIVE TARIFF.

PROFESSOR ALBERTONI, of Bologna, demonstrates that there is an intimate and causal relation between the price of food and mortality. In Europe during the past fifty years vegetable foods have increased in price about 30 per cent., whilst meat has increased 140 per cent. The poor, eating less meat, have less resistance to disease than the better classes. A great number of boys in Turin were weighed, and the poor boy of fourteen weighed about the same as the well-to-do boy of eleven and one-half years. The greater mortality of the poorer classes is clearly traced to insufficient nourishment.

And now comes MR. MATLEKOVITS, who, in a statistical study on the subject, finds, as a result of the protective tariff rates of Austria and Germany, that in these countries the poor man's cereals, his flour and rye bread, have, since 1878, been advanced in price one-third or more. As a result, there is increased mortality and a great increase of crimes both against property and the person.

DOMESTIC SCIENCE AT WELLESLEY COLLEGE.

IT has always seemed that a work upon which so much human happiness and well-being depend, and, moreover, a work necessarily devolving upon women, should in female colleges be left to haphazard and whim, instead of being converted into a science and an art. Girls are taught everything but the one important and necessary thing they must do all their lives. Wellesley has at last seen the absurdity and met it by establishing a department of Domestic Science. Although it is only an optional year put at the end of the course, it is still a good beginning in a good work. The lectures cover such subjects as the sanitary conditions of a house, the chemistry of food, cooking, nutrition, proper clothing, the art of housekeeping, domestic economy, etc.

A FOUR-YEARS' COURSE AT THE HARVARD MEDICAL SCHOOL.

HARVARD College has decided to lengthen her course of medical study from three to four years, each of nine months' study. The change will go into effect September, 1892. It is thought that a similar change is under consideration in New York, and if decided upon, the simultaneous action in the three principal cities of the East will, it is hoped, annihilate the two-years' course throughout the country, and spur even the worst laggards to the adoption of a three-years' course, thus greatly advancing the interests of a sound education. American medical education will then cease to be the target of European ridicule.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Forty-first Annual Meeting, held at Reading, June 2, 3, 4, and 5, 1891.

[Continued from p. 649.]

WEDNESDAY, JUNE 3D.—SECOND DAY.

THE afternoon session was devoted to the subject of Phthisis. DR. T. J. MAYS, of Philadelphia, read a paper upon "The Treatment of Pulmonary Consumption." He opposed the view that houses in which consumptives have lived are centres of infection, and that the commingling of consumptives is detrimental. He does not believe that consumption is propagated by contagion. He advocated the non-specific or rest treatment, which, when thoroughly carried out, gives excellent results. No chronic disease responds more quickly and satisfactorily to proper treatment than does pulmonary consumption.

DR. HUGH HAMILTON, of Harrisburg, followed with a scientific paper on the "Physiological Behavior of Koch's Remedy," which was illustrated by numerous charts. DR. C. W. DULLES, of Philadelphia, cited instances demonstrating the curability of phthisis, and dwelt upon the importance of treating phthisical patients in suitable institutions. DR. L. F. FLICK, of Philadelphia, insisted upon the value of the specific treatment. He has been using inunctions of iodoform dissolved in olive oil, with most gratifying results.

A resolution, presented by W. B. Ulrich, of Delaware County, authorizing the appointment of a committee of seven to urge the passage by the Legislature of a bill for the appointment of a Board of Medical Examiners, and appropriating $200 for the expenses of the year, was adopted, and the following committee appointed: Dr. H. G. McCormick, Wyoming; Dr. J. B. Roberts, Philadelphia; Dr. W. S. Foster, Allegheny; Dr. W. M. Weidman, Berks; Dr. C. L. Stevens, Bradford; Dr. J. C. Gable, York; and Dr. J. W. Moore, Northampton.

The Committee on Nominations proposed the following officers for the ensuing year, all of whom were unanimously elected: President, Dr. Samuel L. Kurtz, of Reading; Vice-Presidents, Dr. John B. Roberts, of Philadelphia, Dr. H. G. McCormick, of Williamsport, Dr. H. H. Whitcomb, of Norristown, and Dr. J. C. Gable, of York; Secretary, Dr. W. B. Atkinson, of Philadelphia; Assistant Secretary, Dr. Charles W. Dulles, of Philadelphia; Treasurer, Dr. George B. Dunmire, of Philadelphia. Delegates to attend the meetings of the various medical associations were also elected. The next meeting will be held at Harrisburg, the third week of May, 1892.

THURSDAY, JUNE 4TH.—THIRD DAY.

At the morning session, after the election of a Board of Censors, DR. ALLIS read an address, rich in valuable suggestions, on "Problems in Surgery." He regarded the general practice of operating during shock following injury as wrong. The patient should be permitted to react before any additional risk be incurred by adding to the existing shock.

In injuries of the foot requiring amputation, he advocated removal of the limb just below the knee, in preference to operation upon the foot. He claimed that an artificial limb is of more service than a natural heel. In the treatment of fracture of the neck of the thigh-bone in old persons, the patient should be taken out of bed as soon as possible, and treated as if no fracture existed. In case of the division of a nerve or artery, he suggested the possibility of suture. In the treatment of hydrocephalus or abscess of the brain, he advocated the removal of a section of the skull, and after the evacuation of the fluid the application of a bandage to produce pressure. He would prefer to remove the fluid of hydrocephalus by means of diuretics rather than resort to tapping. This principle of compression in the treatment of abscess cavities would in cases of phthisis apply also to the lungs; he suggested the advisability of resecting the ribs of the affected side, with subsequent application of gentle pressure by means of straps.

DR. PACKARD thought it would be impossible to make it a fixed rule, in all cases of injury of the foot, to amputate below the knee; excellent results can be obtained by preserving the heel, and he would always make an effort to do so. In fracture of the neck of the femur, he has had excellent success from treatment by extension. He believes that aneurism would result from the suturing of divided vessels.

DR. M. PRICE did not believe in waiting until shock is recovered from before operating, save in extreme cases. In injuries of the foot he strongly advocated amputation below the knee. He believed the day is approaching when the skull will be opened to remove clots in apoplexy, as well as to evacuate the contents of abscesses.

DR. E. E. MONTGOMERY, of Philadelphia, read a paper on "Conditions Requiring Abdominal Section Following Parturition." Septicæmia after labor from the formation of pus has caused many deaths. In all such cases he urged early surgical interference, as the most gratifying results follow laparotomy and drainage. A small dermoid cyst of the ovary which has undergone bruising, or has been ruptured by the pressure of the head, is a frequent source of septicæmia. Another frequent cause is the incomplete removal of the membranes, placenta, and clots—which, if not remedied, will result in metritis and inflammation of the peri-uterine tissues, with formation of an abscess. In all septic cases he recommended careful examination of the condition of the uterus; dilatation and thorough curetting of the uterine cavity; when evidences of pus are present, opening the abdomen, cleansing the peritoneal cavity, and drainage. When no source of infection can be detected, an exploratory incision should be made, with puncture of the ovaries, if enlarged, to determine the presence or absence of pus. If the uterine wall is the seat of an abscess, the organ should be removed.

DR. EDWARD JACKSON, of Philadelphia, read a paper on "What to Do for Incipient Cataract." He dwelt upon the influences to which the eyes are exposed in various trades, such as blacksmithing, puddling, and glass-blowing, and recommended the use of dark glasses by those exposed to great heat and brilliant light.

DR. J. A. LIPPINCOTT, of Pittsburg, delivered the address in Ophthalmology, chosing as his theme the subject of "Trachoma," an affection largely prevalent in

orphan asylums, public institutions, and among emigrants.

At the afternoon session DR. J. M. DUFF, of Pittsburg, read the address in Obstetrics. He paid a glowing tribute to the value of asepsis in parturition. A putrefying funis may cause septicæmia in both mother and child, and is frequently the cause of trismus in the latter. Antiseptic treatment of the cord is therefore insisted upon. He objected to the eliminative treatment of septicæmia by means of subcutaneous injections of pilocarpine and large draughts of sterilized sodium chloride solution, as apt to give rise to cardiac collapse. When this method of treatment is adopted it should be supplemented by the use of strychnine. The wet pack is the rational treatment for this condition. The diagnosis of placenta prævia is to be made by external palpation. The Braxton-Hicks method is the best. Post-partum hæmorrhage is best treated by hydrastin, hypodermatic injections of caffeine, and packing the vagina with iodoform gauze. When transfusion is demanded, the injection between the scapulæ of a salt solution, one drachm to a pint, will answer perfectly. In rupture of the uterus, laparotomy is indicated. The curette should never be used after abortion. The placental forceps or the index finger are proper. He called attention to the fact that la grippe had caused a great increase in the number of abortions during this year.

DR. S. SOLIS-COHEN, of Philadelphia, read a paper on "Patent Medicines and Newspapers." He forcibly denounced the popular method of advertising proprietary medicines in daily and other journals, and called upon the editors of such papers to assist in eradicating this palpable evil. He claimed that many a patient has suffered not only an aggravation of his condition but has been hastened into the grave as a result of adopting some method of treatment recommended in the newspaper advertisements.

A paper by DR. C. R. EARLE on "Catarrh" was followed by a paper on "The Pharmacology and Therapeutics of Euphorbia Pilulifera," by DR. JOHN AULDE. Dr. Aulde dwelt largely on the benefit following the use of this drug in cases of asthma and other bronchial affections.

An amendment to the constitution to prevent the publication in the medical journals of abstracts of the addresses read before the annual meeting before the appearance of the *Transactions* of the Association, was defeated on the ground that the interest in the papers would be dead by the time the *Transactions* was published.

FRIDAY, JUNE 5TH.—FOURTH DAY.

The last session of the annual meeting was occupied in the discussion of business matters, no scientific paper being read. The retiring President, Dr. Craig, announced the following appointments:

Committee to visit the Governor and urge the appointment of a female member to the Board of Public Charities in case a vacancy should occur: Dr. W. B. Ulrich, Dr. E. Corson, Dr. S. C. Ayres, Dr. S. J. Raus, and Dr. J. L. Ziegler.

Committee on Pharmacy: Dr. H. A. Hare, Dr. C. W. Bachman, Dr. J. C. Lange, Dr. W. T. Bishop, and Dr. T. J. Mays.

To deliver addresses at the next meeting: On Medicine, Dr. J. H. Musser, Philadelphia; on Surgery, Dr. T. D. Davis, Allegheny; on Mental Diseases, Dr. J. W. Phillips, Delaware; on Obstetrics and Diseases of Children, Dr. H. G. McCormick, Lycoming; on Hygiene, Dr. A. A. Woods, Erie; on Otology, Dr. G. R. Rohrer, Lancaster.

Dr. Craig made a brief address on surrendering the chair to the incoming President, Dr. Samuel L. Kurtz, of Reading, who in a graceful manner expressed his thanks for the honor conferred, saying that he accepted the office as a compliment to the medical profession of Reading and of Berks County.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, April 7, 1891.

B. SACHS, M.D., IN THE CHAIR.

THE PATHOLOGY OF LANDRY'S PARALYSIS.

DR. HENRY HUN, of Albany, reported the case of an unmarried man, forty-five years old, free from syphilitic or rheumatic taint, who suddenly observed paresis of the legs, which, in the course of four days, progressed to complete paralysis. Following this, the muscles of the trunk, arms, and parts supplied by the bulbar nerves became paretic in the order named, the loss of power becoming more and more decided, until death occurred with the symptoms of bulbar paralysis. The paralysis was purely motor, the sensory nerves not being involved; neither were the sphincters, although paralysis of the abdominal muscles made expulsion of the contents of the viscera difficult or impossible. The only lesions found by careful microscopical examination were the evidences of cerebral and spinal meningitis of recent origin, and a degeneration of some of the fibres of the anterior roots of the cauda equina.

After a careful consideration of the diseases of the nervous system most nearly resembling Landry's paralysis, the conclusion was reached that no evidence had been brought forward which justified the abandonment of the term "acute ascending" or Landry's paralysis. It had not been shown that the cases of the disease, in which no lesion had been discovered, depended on faulty methods of examination, nor had any case clinically typical of Landry's paralysis been reported in which, after death, characteristic lesions were found, either in the central or peripheral nervous system. Acute ascending paralysis, excluding cases in which sensory symptoms were prominent, or in which well-marked bulbar symptoms were absent, must, therefore, be regarded as a clinical entity for which no characteristic lesion has as yet been discovered. That there was some change in the nervous system causing the severe symptoms could not be doubted, but this change was probably of a chemical rather than of an anatomical character. From the many points of resemblance between acute ascending paralysis, myelitis of the anterior horns and multiple neuritis, this chemical change must affect either the motor cells of the spinal cord and medulla or the fibres springing from them; and although this chemical change is so great as to cause an entire arrest of the functions of these cells or fibres, yet it leaves no trace in alteration of character of cell or fibre, no more than does morphia or

strychnia leave in the structure of the nervous system any trace of its fatal action. As to the nature of this supposed chemical poison nothing is known. The general tendency of the present day is to consider it a ptomaine, and indeed the acute course, the fact that it often follows an infectious disease, and that it is associated with enlargement of the spleen, makes it not improbable that Landry's paralysis is a germ disease. In further support of this view is the fact that Centanni and Eisenlohr have each found bacteria in the central nervous system. In neither case were the bacteria cultivated. The case of Centanni was so imperfectly observed during life that the diagnosis was doubtful. In a number of cases, bacteria have been looked for, but were not found, so that the hypothesis that Landry's paralysis is due to bacterial agencies is far from being proven, and the pathology of the disease still remains to be discovered.

DR. IRA VAN GIESON thought Landry's paralysis much more closely associated with cases of acute multiple neuritis and acute poliomyelitis than is generally supposed. Landry, in 1859, first accurately described several cases of ascending paralysis, although several observers had previously referred to the existence of such a disease. The speaker referred to several cases of acute multiple neuritis which have been reported, in which motor symptoms predominated, and in which the whole course of the disease had been in close accord with that of Landry's disease. He also reported several cases of acute poliomyelitis which very closely resembled the disease in question. The clinical resemblance of these diseases is striking. It is well known that multiple neuritis and poliomyelitis are usually caused by poisons of different kinds, such as the ptomaines resulting from the infectious diseases and from phthisis. Etiologically, Landry's disease seemed to come under the same category as these two diseases. Before a definite conclusion as to the true pathology of Landry's paralysis could be arrived at, a more thorough examination of all the nerve trunks, their branches and terminal filaments would have to be made. Hitherto, such observations had been unsatisfactory, because, for obvious reasons, all the nerves could not be examined. On this account, it should not be concluded that the peripheral nerves are not diseased in Landry's paralysis, as thorough examination may reveal the existence of such a condition. As to the hyaline thrombosis found in the central nervous organs, similar formations follow ptomaine-poisoning, but are not confined to cases of Landry's disease, as they may be present in any case of poisoning.

DR. LEONARD WEBER, some six years ago, reported a typical case of Landry's disease, in which the patient entirely recovered in the course of three months. The symptoms of the disease appeared after a shock sustained in stopping a runaway horse. Dr. Weber did not think that the trauma militated against the theory of intoxication. He was satisfied that if a more thorough examination of the nerves were made in these cases our ideas of the pathology would become more clear.

DR. M. A. STARR thought it a question whether or not the disease was of sufficient duration to be attended with neuritis and degeneration of the peripheral nerves. It is certain that a myelitic process might cause a suspension of function, without causing recognizable microscopical changes. He had never seen a typical case of Landry's paralysis, but had seen two cases which presented many symptoms of the disease. One was manifestly a case of diphtheritic paralysis, the other a case of beri-beri.

TENNESSEE STATE MEDICAL SOCIETY.

Fifty-eighth Annual Meeting, held in Nashville, April 14, 15 and 16, 1891.

DR. T. J. HAPPEL, of Trenton, said, concerning "Abscesses," that so far as the treatment of the last stages goes, the Latin expression *ubi pus, ibi incisio*, gives us the therapy of such cases in a few words. The prophylactic treatment is a different matter. Everything that can be done to prevent the formation of pus, and the development of an abscess, must be resorted to, but when pus is present the knife is the instrument of relief. An aspirator can remove the pus itself, but the cause of it, the pyogenetic something, is left behind. A free outlet must be given to the pus, the cavity carefully cleaned, perfect drainage secured, arrangements made for thoroughly flushing the diseased part with antiseptic fluids, the strength of the patient maintained by a generous diet, and Nature aided by an abundance of pure, fresh air to repair the broken-down constitution.

DR. HAPPEL reported a case of "Abscess of the Spleen." He said this was a rare disorder, many of our best authorities never having met with a case. He had in the course of seventeen years' practice found two cases; one due to pressure upon the organ, and the other to chronic malarial poisoning. He called attention to the peroxide of hydrogen as one of the best, if not the best, of all agents, to cleanse and restore to a normal state all pyogenic membranes, surfaces and cavities. As one writer expressed it: "It hunts out pus in all its ramifications as a ferret does a rat."

After giving a *résumé* of the literature on the subject of "Ovulation and Menstruation," DR. GEORGE R. WEST, of Chattanooga, drew the following conclusions:

1. That the increased familiarity with the pelvic organs, the result of modern surgery, has not materially added to our knowledge of their functions.

2. That though the ovular theory of menstruation has not been overthrown, yet the weight of accumulating evidence seems against it.

3. That the most recent observations point to a common nervous origin for both ovulation and menstruation, and yet an individual independence.

DR. THOMAS M. WOODSON, of Gallatin, contributed a paper entitled "Treatment of Pneumonia; the Past and Present Methods; has the Rate of Mortality been Changed?"

He briefly reviewed the literature on pneumonia to illustrate the opinions of medical teachers and writers. He was glad that Hare, of Philadelphia, in his work on *Practical Therapeutics*, revived the old lines of treatment. He extolled veratrum viride, and said that in the first stage of the disease it is very useful. Its two alkaloids exert different influences and between them they fulfil every object sought for. Jervine, a powerful vasomotor depressant, relaxes the walls of the blood-vessels everywhere; at the same time it quiets the action of the heart by an action upon its muscle or ganglia, reducing its force, thus preventing engorgement of the

lung; while veratroidine, by stimulating the inhibitory nerves of the heart, also slows its beat, fills the ventricles and allays excitement. The advantages of veratrum veride are its completeness and rapidity of action; the fact that it preserves in healthy bloodvessels the blood which may be needed in the crisis, if the disease is not aborted; and its safety is a point largely in its favor. In the second stage, to prevent heart failure by engorgement from over-distention, Dr. Hare, to stimulate the respiratory centres, gives digitalis with strychnine. He thinks alcohol in the second stage is inferior to digitalis, and that carbonate and muriate of ammonia are valuable adjuncts in the second and third stages. For troublesome cough in the later stages he uses opium sparingly, but not in the first stage.

In the first stage of croupous pneumonia the indications, said the speaker, are clear: 1. To control the circulation and diminish the determination of blood to the lungs. 2. To reduce the temperature, if high. 3. Allay pain by both physical and physiological rest. 4. Support the vital powers.

The first two indications are met by veratrum veride better and with more certainty than by any other drug. For the third, to allay pain, we have but one remedy—opium or its derivatives, which stand without rivals. Fourth, to support the patient with especial reference to failing heart and respiratory centres; digitalis, strychnine and alcohol for the later stages.

More than twenty years ago, the speaker expressed the opinion that in inflammatory affections veratrum viride was a sedative of the greatest value, controlling the action of the heart as effectually as blood-letting, without the exhaustion incident to the latter. Arterial excitement is reduced by it, while the vital forces are economized. It is especially adapted to pneumonia in the stage of engorgement in which it appears to bring about prompt resolution. It may with safety be used in the treatment of children. Its constitutional effects having been secured, there are reduced force and frequency of the circulation, reduction of temperature and respiration and an amelioration of all the symptoms of the disease. While extolling the virtue of veratrum viride, he would not rely on it alone in pneumonia, as opium was unquestionably entitled to a prominent place palliative and curative in its action, allaying pain, cough, and nervous irritation, and available in the latter as well as in the early stages.

DR. J. S. CAIN, of Nashville, said that "Chronic Endometritis" and the conditions necessarily allied therewith are the most common as well as the most important diseases with which the gynæcologist has to deal. This condition is often a sequel to the acute form of the disease, and grows out of repeated acute attacks. It matters not how or from what source the acute outbreaks originate, whether from catarrhal, specific, traumatic internal or constitutional causes, they are often, but not always, the starting-point from which not only the endometrium but the entire uterine and peri-uterine parenchymatous structures become involved. He would here venture the assertion, that while the changes in structure and function of the lining membrane of the uterus often seem to be the most prominent conditions, and those demanding first and most careful attention, this tissue is probably never chronically diseased without a corresponding involvement of all the uterine structures. As to treatment, while the curette, as has been said, is a blind instrument and capable of doing harm in careless and incompetent hands, yet for the removal of fungoid vegetations and adenoid degenerations from the endometrium, it affords the surest, speediest and safest means yet devised. Dr. Cain is accustomed to following the curetting by an application of Churchill's tincture of iodine or diluted carbolic acid, as is the usual practice, and always precedes the treatment by a careful washing out of the vagina and uterus with corrosive sublimate, 1 : 2000.

In cases in which this treatment is not admissible, or when it has failed to afford relief, his next reliance is on the method of Apostoli. This consists in the introduction into the uterine cavity of an electrode insulated to near the point, and connected with the negative pole of the battery, the other pole being connected with a large pad of moistened potter's clay, sponge, or prepared cotton, placed over the abdomen. The current should be employed for from ten to fifteen minutes, about twice a week. The strength of the current will much depend upon the acuteness of the particular case and the susceptibility of the patient to electrical treatment. The chronic cases always require stronger currents. The dosage may be fixed at from ten to three hundred milliampères; in his judgment the minimum is too small to accomplish any good results, and yet physicians with much large experience have had to employ it.

This line of treatment he considers free from many of the objections of others; it is cleanly, free from pain, and exempt from danger. Unlike cauteries and escharotics, it can be limited in its influence, and produces no deleterious effects upon the sound tissues, nor does it, like the curette, leave a raw and exposed surface, to absorb poisons and aseptic matters; while it removes the vegetations it imparts renewed tone and vitality to the diseased organ.

DR. A. J. SWANEY, of Gallatin, contributed a paper on "Retained Placenta in Miscarriage: How Shall We Treat Such Cases?"

He said the dangers fom retained placenta in miscarriage were hæmorrhage and septicæmia. When the delivery of the placenta is protracted, ought we still to abstain? Ought we to wait, or interfere actively in order to forestall these dangers which will almost certainly result? Those who favor active interference are Tyler, Smith, Murray, Simpson, Leishman, Mundé, Grandin and many others. The reasons given for active interference are the frequency of these dangers in protracted delivery of the placenta. If the cervix is dilated or patent, Simpson directs immediate interference; if it is not dilated, he dilates it at once. The woman is then anæsthetized, the uterus depressed as much as possible by one hand externally, and with the index finger of the other hand he removes the placenta and membranes. If he cannot sufficiently depress the uterus with the hand, he does not hesitate to forcibly drag it down with a double tenaculum fixed in the cervix. Mundé and Grandin go still further, and curette the cavity of the uterus with special instruments made for the loosening of adherent placenta and its removal from the uterus.

The authorities who before interfering counsel waiting for serious complications are just as numerous as

those who advise immediate interference. We mention Ramsbotham, Davis, Burns, Fleetwood, Churchill, Grailey Hewitt and many others. Active intervention does not mean unnecessary interference. Nature is always to be given a chance, but when her efforts are futile, it is but rational to assist her, and this should be done as directed by Mundé—by placing the woman in the left lateral position, and with a dull wire-curette through a Sims speculum removing the placenta or any part of the secundines that may remain. This is far better and easier than the method advised by Simpson of dragging or pressing down the uterus and introducing the finger. The uterine cavity should then be washed out with hot water, slightly carbolized, through a Jameson uterine douche, and this should be repeated every six or eight hours until all fœtor disappears from the lochial discharge.

Hæmorrhage after miscarriage, said the speaker, even when we believe the placenta and secundines have been removed, invariably means retention of a part of the placenta or secundines. Profuse hæmorrhage from this cause may occur for weeks; in such cases we should boldly explore the uterine cavity and remove any offending matter that may be present. In the first twelve weeks of pregnancy, the dangers from hæmorrhage and septicæmia are not so great and the expectant plan is more justifiable. After the third month, it is criminal negligence to wait and subject a woman to the dangers arising from retained placenta, when she can be relieved by an operation, which, if properly done, can do no harm and spares her the risk of hæmorrhage and septic poisoning. In short, the author believing the early removal of the secundines is easy and safe, forthwith guarantees the woman against the dangers of hæmorrhage and sepsis.

DR. J. L. JONES, of Bells, read a paper entitled "Indigo as an Emmenagogue."

His first case was a lady, twenty years of age, who had not menstruated in five months. He had been treating her for three months with the usual remedies, without any effect; he therefore made up his mind to give indigo a trial. He ordered two ounces of indigo and half an ounce of subnitrate of bismuth, well mixed. Of this the patient took one-half teaspoonful, in one-third of a glass of water, three times daily, for nearly four weeks. One day he was sent for in great haste. On his arrival, he found the patient in bed and comfortable. He was told by the mother that her daughter, while walking in the garden, without pain or warning of any kind, began to flow. The gush was followed by a gentle flow, which lasted for only a short time. In five days she was well, and has not suffered from amenorrhœa since. Dr. Jones has since used indigo in thirteen cases, with but one failure, and this proved to be a case of pregnancy.

During the administration of the drug the os uteri becomes soft and patulous, admitting the end of the index finger. There is often a serous discharge from the vagina. The urine becomes brownish-green in color, and its odor bad. The stools are watery and offensive.

Dr. Lasser.—The order of the French Legion of Honor has been conferred upon Dr. Lasser, the General Secretary of the Tenth International Medical Congress.

CORRESPONDENCE.

THE VOTE OF THE MISSOURI STATE MEDICAL ASSOCIATION ON THE THREE-YEARS' COURSE.

To the Editor of THE MEDICAL NEWS,

SIR: Believing that the readers of THE MEDICAL NEWS will be interested in following the struggle for reform in medical education that is going on in this State, I take the liberty of sending a statement of the attitude of the Missouri State Medical Association upon the question. It had been denied that the State supported the more progressive schools in their desire to make the term of study more thorough in accordance with the greater demand upon the practitioner of medicine. At its late session (May 20, 1891), the State Association indorsed the three-years' obligatory course by a practically unanimous vote. The only visible opposition came from a college recently organized in St. Louis, making the *eighth* in this city. When we consider the fierce competition for students sure to arise among such a throng of colleges in one city, the reason why the last comer desperately opposes increasing the length of the term of study becomes apparent. Hence, the denunciation of such conduct by Secretary Rauch, of the Illinois State Board of Health, as dishonorable, unprofessional, and mercenary. Much indignation was expressed over the failure of the Three-years' Bill in the Legislature. Its passage was unanimously recommended by the committees of both Senate and House. The House gave a large vote in favor of it, but the Senate, at the last moment, voted adversely. It was plainly a manipulated vote, and in the teeth of the will of the people.

The outcry of "oppression of the poor young man," as an argument against three years' study, was ridiculed as pure demagoguery—familiar enough in stump speeches, but disgraceful when used by "professors" to obstruct necessary reform in education. May we not ask since what exact date have the youths of America become paupers and demand charity at our hands, even at the expense of suffering humanity, whose anguish they volunteer to study to relieve? It is a slander upon our young men to accuse them of such cowardice and lack of self-respect. It is a crime in the light of our day to try to mislead them as to the true nature of the task they undertake when beginning a medical course. Every intelligent physician knows that medicine can only be learned in the laboratory and clinic—it is a question of time as well as of brains. Three years spent in practical work, under the direction of competent teachers, is little enough time even for the most diligent and gifted students. Were thoroughness of training more generally appreciated in America, we should not at this late day be arguing for a three-years' course in medicine. There is an alarming waste of talent in America from lack of early and sufficient training. As a cure for the evil of badly educated doctors the establishment of State Examining Boards is urged. We must note, first of all, that such a scheme, to be successful, must include restrictions upon the candidates for examination. The Boards cannot have their time wasted by examining all who apply, irrespective of proofs of fitness. In Germany the State Board requires of candi-

dates that they do practical work; that they dissect, demonstrate specimens, take charge of cases—medical, surgical, and obstetrical—writing out the records, etc. The candidate, also, must have already had years of elaborate training. This is the ideal state of things. No wonder Germany is looked upon as the centre of medical science. We cannot hope to attain such perfection in the present, but we can move in that direction, and a long step would be to require of all candidates that they show proof of having taken a graded course of study extending over a term of not less than three years, and in a reputable college; *i.e.*, one having sufficient laboratory and clinical facilities and a competent corps of teachers. Such proof will guarantee that the student has done so much practical work, and will exclude from the examination men who have specially crammed out of books, and who, in a merely verbal or written examination, might make a fair show without having any practical knowledge at all. Yet, as everyone knows, it is just this practical knowledge that makes the doctor.

New York has lately created a State Board of Examiners entirely removed from political influence, and its further efficiency is insured by requiring of applicants for examination that they shall have studied three years in some legally incorporated college. Eight other States make the same condition. In time we hope all the States will have efficient Boards, but there must first be a solid organization of the profession in all the States to insure satisfactory appointments on the Boards. Missouri does not yet possess such an organization throughout all its districts. The State Association is laboring to that end. Respectfully, C. A. TODD, M.D.

ST. LOUIS, MO.

ACONITE IN ACUTE NEPHRITIS.

To the Editor of THE MEDICAL NEWS,

SIR: On the 21st inst. I was called to see a young married woman, about three months *enciente*, who had been suffering severely for five days with lancinating pains in the region of the kidneys, more particularly of the left. She had passed almost no urine during all that time—what little she had passed looked more like gelatinous mucus tinged with blood than urine. It is strange that the thermometer went up only to 102°. She was quite thirsty, however, and very restless, crying out with agonizing pain all the time.

I gave her Flemming's tincture of aconite, six drops in a glassful of water every three hours, with directions that it be kept up until tingling numbness should be felt, unless relief were obtained short of that effect; but to be discontinued if that effect should be produced, until it had passed off, then to be resumed again if needed. I also had plain hot-water stupes applied over the kidneys, and gave a vegetable cholagogue cathartic. The stupes immediately proved soothing, and the remedies promptly began to relieve all the symptoms. In about twenty-four hours she was entirely relieved and passing plenty of healthy urine. D. W. FOSTER, M.D.

PLAISANCE, LA., May 28, 1891.

NEWS ITEMS.

Michigan State Board of Health.—The annual meeting of the Michigan State Board of Health was held at the Capitol, April 14, 1891. Prof. Fall, Drs. Avery, Hazlewood, Vaughan and Baker were present. Dr. Avery was reëlected president.

Dr. Vaughan reported that, at the State Laboratory of Hygiene, he had made analyses of all the different kinds of baking powder found in the market, also of 112 samples of water from different parts of the State, and that he was ready to report the results, with those of his researches on typhoid fever.

Dr. Baker reported that he had worked out the cause of influenza. He said its greatly increased prevalence during the last three months is alarming because so many other diseases follow that disease, and increase after it increases. Those which so increase are consumption, pneumonia, cerebro-spinal meningitis, rheumatism, osteo-myelitis, etc. Influenza seems to bring in its train all of the most important diseases. Dr. Baker explained the causation of influenza. He stated that the germs of influenza are generally, or at all times, present, and the germs of pneumonia, tuberculosis, and of the other specific diseases are somewhat widely disseminated, but that there must be certain coincident meteorological conditions to irritate the throat and air-passages sufficiently to let the germ gain an entrance to the body. These meteorological conditions, in this instance, were the excessive prevalence of north and northeast winds, and the excessive amount of ozone during the past three months. The prevention of influenza and of the coincident frequency of other more dangerous diseases has not been possible because of ignorance of the causes. Now the causes are known, and the study of the measures for the prevention can begin.

How to procure more thorough disinfection after contagious diseases was brought up by Dr. Hazlewood, also by a letter from Dr. Nicholson, of the Upper Peninsula, and by other correspondence of the office of the Board. It seems to be plain that if the bill now before the Legislature (Senate bill 257, House bill 640), making a small appropriation to enable the State Board of Health to send an inspector to the localities where one is most needed, to aid in the final disinfection after cases of infectious diseases, shall become a law, the spread of those diseases can be very greatly lessened, and hundreds, and possibly thousands, of lives can be saved in Michigan every year.

The Death-rates of European Cities.—The death-rate per thousand, for the year 1890, in Berlin, was 21.6; in Paris, 24.5; in Vienna, 24.6. Of twenty-two of the larger European cities, Stockholm had the lowest rate, 19.6; then followed London, 20.3; Christiania, 21.1; Brussels, 21.5. The highest rate existed at Munich, 30; Budapest, 31.4; and Moscow, 40.3.

THE seventeenth annual session of the Mississippi Valley Medical Association will be held at St. Louis, October 14, 15 and 16, 1891. An invitation to attend the meeting is extended to the members of the medical profession.

Dr. Samuel O. L. Potter, M.R.C.P.—Dr. Potter, of the Cooper Medical College of San Francisco, has lately had conferred upon him the degree of Member of the Royal College of Physicians of London. Professor Osler, of Baltimore, and Dr. Robinson, of San Francisco, are said to be the only other Americans holding the degree.

Lehigh Valley Medical Association.—The eleventh annual meeting of the Lehigh Valley Medical Association will be held at Mauch Chunk, June 25, 1891. Dr. Howard A. Kelly, of Johns Hopkins University, will deliver the annual address. His subject will be "Injuries to the Vaginal Outlet."

Washington State Medical Society.—The second annual meeting of the Washington State Medical Society was held at Seattle, May 6th, 7th, and 8th.

The President, C. K. Merriam, of Spokane, read the Annual Address. Dr. E. E. Heg, of North Yakima, delivered the address in Anatomy; Dr. H. P. Tuttle, of Tacoma, the address in Physiology; Dr. N. Fred. Essig, of Spokane, the address in General Surgery; Dr. E. L. Smith, of Seattle, the address in Abdominal Surgery; Dr. J. B. Wintermeuth, of Tacoma, the address in Surgery of the Brain; Dr. C. H. Willison, of Port Townsend, the address in Genito-urinary Surgery; Dr. J. J. McKone, of Tacoma, the report in Obstetrics and Gynecology; Dr. T. V. Goodspeed, of Seattle, read a paper entitled "Do Maternal Inpressions Affect the Fœtus in Utero?" Dr. J. W. Waughop, of Steilacoom, on "Treatment of the Insane;" Dr. W. J. Redpath, of Steilacoom, on "Analgesia of the Insane;" Dr. G. S. Armstrong, of Olympia, "On the Existence of an Intellectual Centre;" Dr. C. W. Sharples, of Seattle, on "Increased Reflexes and Allied Phenomena;" and Dr. A B. Kibbe, of Seattle, on the "Importance of Free Nasal Respiration."

The following officers were elected for the ensuing year:

President, Dr. H. C. Willison, of Port Townsend.

Vice-Presidents, Dr. G. W. Libby, of Spokane, and Dr. H. P. Tuttle, of Tacoma.

Secretary, Dr. Elmer E. Heg, of North Yakima.

Treasurer, Dr. James B. Eagleston, of Seattle.

The next meeting will be held in North Yakima, on the second Wednesday in May, 1892, and continue for three days.

Massachusetts Medical Society.—The one hundred and tenth anniversary of this Society was held in Boston, June 9th and 10th. The programme included papers by Drs. Pierce, of Bernardston ("Typhoid Fever"); J. A. Jeffries, of Boston ("The Bacillus of Typhoid"); Withrington, of Roxbury ("Bright's Disease"); Thorndike, of Boston ("Catheter Fever"); F. H. Williams, of Boston ("How Shall We Nourish in Acute Disease?"), and many others. The Shattuck Lecture was delivered by Dr. Edward Cowles, of Somerville, and the annual discourse by Dr. James B. Brewster, of Plymouth.

The New Hampshire Medical Society will hold its annual meeting and celebrate the centennial anniversary of its organization at Concord, June 15, 16, and 17, 1891. An interesting programme has been arranged. In addition to the regular business proceedings, and the reading of medical, historical, and biographical papers, there will be an excursion to Alton Bay and an anniversary dinner. A cordial invitation of attendance is extended to the medical profession.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 2 TO JUNE 8, 1891.

By direction of the Secretary of War, the leave of absence on surgeon's certificate of disability, granted SAMUEL M. HORTON, *Major and Surgeon*, in S. O. 49, March 4, 1891, from this office, is extended three months on surgeon's certificate of disability.——Par. 6, *S. O. 129, A. G. O.*, June 4, 1891.

By direction of the Secretary of War, VAN R. HOFF, *Captain and Assistant Surgeon*, is relieved from duty as a member of the Board of Medical Officers to which he was assigned by Par. 6, S. O. 78, April 7, 1891, from this office, and will, upon the completion of the duties assigned him by Par. 6, S. O. 110, May 14, 1891, from this office, return to his proper station, Fort Riley, Kansas. —Par. 11, *S. O. 126, A. G. O.*, June 3, 1891.

By direction of the Secretary of War, Par. 1, S. O. 74, May 22, 1891, Department of the Columbia, transferring JOHN D. HALL, *Major and Surgeon*, from Fort Canby, Washington, to Fort Sherman, Idaho, is confirmed.—Par. 4, *S. O. 126, A. G. O.*, June 3, 1891.

By direction of the Secretary of War, the extension of leave of absence on account of sickness, granted HENRY P. BIRMINGHAM, *Captain and Assistant Surgeon*, in S. O. 108, May 12, 1891, from this office, is further extended to June 21, 1891, on surgeon's certificate of disability.—Par. 6, *S. O. 125, A. G. O.*, June 2, 1891.

With approval of the Secretary of War, leave of absence for three months, to take effect on or about June 15, 1891, is granted DAVID L. HUNTINGTON, *Major and Surgeon*.—Par. 2, *S. O. 124, A. G. O.*, June 1, 1891.

KEAN, JEFFERSON R., *Captain and Assistant Surgeon*.—Is granted leave of absence for one month, to take effect after the return of Robert H. White, Major and Surgeon, to duty at Fort Myer, Virginia.——Par. 1, *S. O. 123, A. G. O.*, May 29, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 6, 1891.

GRAVATT, C. U., *Surgeon*.—Detached from Naval Hospital, Yokohama, Japan, and ordered home.

ROGERS, FRANKLIN, *Surgeon*.—Detached from special duty at Norfolk, Va., and ordered to Yokohama Hospital.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JUNE 6, 1891.

FESSENDEN, C. S. D., *Surgeon*.—Granted leave of absence for thirty days, June 6, 1891.

IRWIN, FAIRFAX, *Surgeon*.—Leave of absence extended seven days, June 4, 1891.

MEAD, F. W., *Surgeon*.—When relieved at Chicago, Ill., to proceed to Washington, D. C., and report to the Supervising Surgeon-General for duty, May 29, 1891.

MAGRUDER, G. M., *Passed Assistant Surgeon*.—Granted leave of absence for five days, June 1, 1891.

YOUNG, G. B., *Assistant Surgeon*.—Leave of absence extended fifteen days, on account of sickness, June 6, 1891.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment, provided that the request for reprints be noted by the author at the top of the manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

RARE COMPLICATIONS OF TYPHOID FEVER.

BY H. A. HARE, M.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA; PHYSICIAN TO ST. AGNES HOSPITAL,

AND

ARTHUR J. PATEK,

STUDENT OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

WHILE we are aware that the general subject of typhoid fever is one about which little that is new can be said, in view of the host of able contributions which have already been made, we have thought that some peculiar phases of this common disease which we have encountered during the past few weeks were sufficiently unusual to warrant a report, both interesting from a clinical point of view and useful by reason of the addition made to the statistics regarding the complications of enteric fever.

The first cases of which we shall speak presented acute mania ushering in the attack. The histories are as follows:

Annie M., aged twenty-four years, was admitted to St. Agnes Hospital, March 18, 1891. She had been feeling badly for some time, but until four days previously had been able to do her work. On the 14th she had severe headache, vomited a little, suffered from pain in the stomach, and had some diarrhœa, these symptoms being followed on the subsequent day by not very profuse epistaxis. She walked a considerable distance to the hospital, and on her admision at 10 P.M. her temperature was found to be 105°. The resident physician found that her tongue was thickly coated, dry and brown. On the next day, when seen by us in the wards, the tongue was unusually clean, even for that of a healthy person. The patient was delirious, and so violent that it required four or five persons to keep her in bed. The temperature, after an unusually prolonged and severe struggle, was found to be 106°. At this time every symptom of typhoid fever was completely masked by the mania. The bowels were moved, and the passages were of *normal consistency and color*. The urine was somewhat scanty and high-colored, and the pulse full and strong. There were no rose spots or other enteric symptoms. At the end of twenty-four hours the patient, still being in a condition of wild mania, was removed to a cell, the impression being that it might be a case of hysterical mania with hyperpyrexia. Twenty-four hours later the mania had disappeared, and the typhoid symptoms once more reasserted themselves; the delirium became more quiet and muttering, and she was taken back to the wards. During the following week she was constantly delirious, and frequently maniacal, although there would be short momentary intervals of sanity. During this time a large number of rose spots appeared on the abdomen and chest, the tongue became heavily and typically furred, the temperature followed a characteristic course, the typhoid odor was present, and an occasional nose-bleed helped to confirm the diagnosis of typhoid fever. The patient rapidly became worse, and died thirteen days after admission, without becoming sane, except for the brief intervals named.

The second case is as follows:

Mr. A., living in Milwaukee, aged thirty-four years; married; one child. A sister died of convulsions, of unknown nature, but a short time before the onset of his illness. Family history otherwise negative. At the age of seventeen the patient, according to the statement of his physician, had an attack of typhoid fever, attended with as much, if not more, delirious excitement than this, the second attack. The history of the case begins with the circumstance that Mr. A. was nursing his wife, who was down with a mild attack of typhoid. The patient's first complaint was of headache and insomnia. The visiting physician, seeing him on the following day, ordered him to bed, recognizing the case as one of typhoid fever, rather because of the existence of a like case in the same house and from the mere complaint of malaise, than from any symptons particularly characteristic of the disease. The patient obeyed the instructions of the physician, and went to bed, still complaining of insomnia. Hardly had he fallen into mild slumber when, not more than an hour later, he suddenly awoke, delirious, and grew steadily more so. During the following night he became maniacal, rushed to the room of the nurse (she had been procured since the husband's illness), burst open the door, threw the nurse to the floor, and assaulted her in a most violent manner, kicking and striking her, and accusing her of wishing to harm his wife and child. The nurse finally managed to escape, and ran for the physician, who lived across the street. In the meantime the patient jumped through a window leading to a small balcony over the front portico, and leaped to the ground, where he was found a few moments later by the physician. Strange to say, the man suffered little injury, being slightly bruised by the fall, and somewhat cut by the glass; but stranger still was the fact that he was now quite rational, telling the physician all that had transpired, and what he had done. The patient was again put to bed, now apparently quite comfortable. The physician left him to see the wife in an adjoining room. Hardly, however, had he gone

when Mr. A. suddenly sprang from the bed, rushed into the kitchen, where he seized a large knife, and then rushed back, bent upon assaulting the physician. He was, however, overpowered, and again forced to bed. He now rested comfortably, and when seen the following day was doing well. That evening a condition of hyperpyrexia suddenly intervened, and in a few hours the patient was dead.

The interesting features of these cases are that the enteric fever was ushered in by mania. As is well known, it is not uncommon for typhoid fever to be followed by nervous or mental disorders of a more or less persistent character, but it is exceedingly rare for the attack to begin as it did in the cases here reported. Liebermeister, in his article on typhoid fever in Ziemssen's *Cyclopædia*, states that it is by no means rare to see psychical disturbances which do not depend upon any demonstrable lesion, and which generally are of favorable prognosis. In these cases, however, the mental disorder is a *sequela*, not an early symptom, and the condition is to be separated from ordinary delirium. Although Liebermeister gives no statistics as to these complications, and makes little reference to cases such as we have described, he uses these words:

"At the height of the disease, however, the development of such symptoms, or of any uncommon brain symptoms, must be looked upon with alarm." In Hutchinson's article in Pepper's *System of Medicine*, *post*-typhoidal mania is fully discussed, but nothing is said of *pre*-typhoidal mania. Niemeyer does not mention such a complication.

The following cases, which we have found in the literature of the subject, are of interest. Murchison[1] reports the case of a German who was much excited over the Franco-Prussian War. After about four days of discomfort and malaise, he suddenly passed into a state of acute maniacal delirium, requiring two men to control him. There was an absolute refusal of food, a temperature of 102°, with a dry tongue and rapid pulse, slight diarrhœa, and no spots. The patient was subdued by large doses of chloral, and the fever ran its course. The same author also states that in several instances he has known acute mania to develop on the first day of an enteric fever, and that under these circumstances the case is very apt to be mistaken for insanity.

J. C. Wilson[2] asserts that delirium may be an early symptom of enteric fever, and quotes Riberalba, who reported four cases which were delirious on admission to the hospital. Louis saw two cases which were delirious on the first night of their illness. Bristowe has also reported a case in which maniacal delirium existed on the second day. Mottet mentions an instance of typhoid fever complicated with mania to such a marked extent that the patient was placed in an asylum before the true nature of the ailment was discovered, and Henrot and Bucquoy have seen the disease ushered in with the delirium of grandeur. Finally, Daly[1] records an instance in which aggressive mania came on on the fifth day, following a condition of stupor.

From a careful examination of a large amount of literature, we are convinced that the prodromal mania in enteric fever is most rare and, when it occurs, is almost always fatal, while the mania which is in the nature of a sequela may be looked upon as devoid of immediate or remote danger to mind or body. We have also asked a large number of physicians as to their experience, but the reply has been that they have never met with pre-typhoid mania.

Passing from the consideration of this complication, let us call attention to a much more common, but still a rare, accident in the course of this disease. We refer to *erysipelas*. According to Liebermeister (loc. cit.), this complication occurs generally during convalescence and *seldom at the height* of the disease, and this writer also believes it may be a dangerous factor. In 1420 cases of typhoid fever in Basle, erysipelas appeared ten times, and all of the ten recovered. These were all cases of facial erysipelas. Two others developed the disease about bed-sores. In other words, erysipelas occurred in a little less than 1 per cent. of these cases. Griesinger[2] states that it occurs in about 2 per cent.

The following cases occurred within a period of six weeks of each other in the wards of St. Agnes Hospital. The first was separated from the second by an interval of five weeks, and the second from the third by less than a week. They were all in the same ward, but occupied beds at least twenty feet apart. The first case is as follows:

Maggie T., aged twenty-two years, was admitted December 16, 1890, with a history of chronic suppuration of the middle ear. She was treated at the dispensary and rapidly improved, being discharged on December 23d. On January 8, 1891, she was readmitted with well-defined symptoms of a mild attack of typhoid fever, which ran a short course, the patient being discharged on January 30th. On February 2d she entered the house, complaining of pain in the abdominal region and in the knees and elbows; the pains were not very severe, but the joints were somewhat swollen; the tongue was brown and dry, and all the symptoms, such as the stools, the rose-colored spots, the characteristic temperature and appearance of the patient, pointed to a second attack of typhoid fever, although at first the case was treated as one of rheumatism. The temperature did not exceed 103°, and the patient

[1] THE MEDICAL NEWS, 1882, xl. p. 68.
[2] Infectionskrankheiten.

went through a moderately severe attack of typhoid fever without complication, except for very marked enlargement of the glands of the neck, which was relieved very promptly by the use of an ice-collar. On March 5th a well-defined erysipelatous swelling appeared over the left side of the face, about the temples and malar bone, and gradually extended over the entire face and part of the scalp. The eyes were completely closed, and the lips very much swollen. The mouth was very painful, being covered with sordes to such an extent that it was impossible for the tongue to be protruded, and it was almost impossible for food to be taken. The throat was very dry, and a spray of listerine was used as a mouth-wash. The ordinary treatment for typhoid fever was at once withdrawn, and the patient was put on 30 drops of the tincture of chloride of iron, three times a day. Under this treatment she improved, and by March 16th all inflammation had entirely disappeared, leaving only some swelling, which, in the course of the next two weeks, entirely passed away. The patient during this time continued to manifest symptoms of typhoid fever and was unable to leave her bed on account of this disease for three weeks after the erysipelas had disappeared. Total recovery eventually took place.

The second case was that of A. E., a female aged twenty, who was admitted to the wards with all the early symptoms of enteric fever, which developed into a moderately severe attack, but was without any extraordinarily severe symptoms. It was estimated that at the time the erysipelas developed she was in the third week of the typhoid fever. At the onset of the erysipelas there was a chill, followed by a rise of temperature of 2°, and followed, after the use of a cold bath, by a fall to the temperature course previously pursued. The erysipelas began about the bridge of the nose and extended rapidly over the entire face back to the ears and to the margin of the hair, whence it ceased to spread. The eyes were closed and the lips much swollen. An examination of the serum withdrawn by a lancet showed the characteristic streptococci of erysipelas. Under the use of large doses of tincture of the chloride of iron and an application of ichthyol ointment, recovery rapidly took place. The mouth was unusually foul and dry, but no delirium was present. We could not notice that the complication in any way increased the gravity of the case.

The third case is as follows: A woman, aged nineteen, a Swede, was admitted in the early stages of typhoid, which ran a mild course, devoid of delirium or any symptoms of importance, except that on an afternoon about the middle of the third week of her illness she developed a sudden rise of temperature to 104°, followed at once, on the use of cold bathing, by a fall to 98°, with loss of the pulse at *both* wrists. As a precautionary measure, she was treated as if suffering from intestinal hæmorrhage, and soon rallied, developing during the next twelve hours a typical patch of erysipelas on the right side of the nose and over the malar bone. There was no further disturbance of the typhoid temperature, and the disease remained limited to that side of the face. The patient was treated with iron and ichthyol.

By far the most exhaustive study which we have found concerning erysipelas as a complication of typhoid fever is that of Gerente.[2] According to this authority, the complication comes on in one of every sixty-one cases, which would give a much higher percentage than that of Liebermeister or Griesinger. Gerente states that females are more commonly affected than males, which is a curious fact, because males are more exposed and more frequently have typhoid fever. In regard to the period of the disease at which erysipelas, as a rule, appears, Gerente states that it is generally after the twenty-first day, and he also believes that some epidemics of typhoid are peculiarly liable to this complication. The following conclusions of Gerente, however, embody most of his statements:

1. Erysipelas of the face is rarely met with during the course of typhoid fever. I have found it in 64 out of 3910 cases, which is about 1 to 61. These figures are derived from the following statistics:

	Typhoid Fever. Cases.	Erysipelas. Cases.
Chomel	130	4
Louis	134	3
Forget	92	1
Jenner	65	2
De Larroque	105	4
Zuelzer	84	3
Liebermeister	1420	10
Zuccarini	480	18
Griesinger	500	10
Murchison [1]	900	9
	3910	64

2. Outside of the question of contagion, it appears to be most frequent in the grave, adynamic forms of typhoid and in those of long duration; it appears to be most frequent in lymphatic subjects.

3. While observed at all the stages of typhoid fever, erysipelas shows itself especially and almost exclusively during the last period and during convalescence.

4. Under these circumstances erysipelas produces a marked amelioration in the general as well as in the local symptoms.

5. The appearance of facial erysipelas in the course of typhoid fever is of grave prognosis (16 deaths out of 36 cases); this gravity lies less in the erysipelas, which most frequently is benign in itself, than in the poor general condition of the patient, the secondary infection being an indication of this condition.

6. The complication consists in a simple coinci-

[1] Thèse de l'École de Médecine, 1883–84, t. i.

[2] The number of Murchison's cases is not strictly correct.

dence favored by debility, the result of the primary and principal disease.

We think the statement that erysipelas seriously influences the prognosis in all cases too sweeping. Thus, there are cases on record in which the onset of the acute disease has not in any way retarded convalescence. If the disease becomes phlegmonous, the prognosis is, of course, very grave, but if the inflammation is capable of undergoing resolution the prognosis is good.

The question as to the path by which the contagion finds entrance has been much discussed, but the opinion of Griesinger is generally accepted. He believes that the germs gain entrance by means of the inflammation of the frontal or sphenoidal sinuses, and also when ulceration of the buccal mucous membranes exists. Zuelzer also points out that in his own cases and in those of Zuccarini the erysipelas started in the stomatitic spots and ulcerations in the mouth.

In all our cases the patients complained very much, both before and after the attack of erysipelas, of the soreness of their mouths.

The following cases which have been reported in addition to the three of Gerente are interesting:

Armieux[1] reports the case of a soldier, in whom typhoid symptoms set in on September 18, 1881, with pain in the head, vertigo, abdominal tenderness, pain in the right iliac fossa, and an elevated temperature. On October 4th, a complication arose in an otorrhœa, which, by the 22d, was growing steadily worse, so that the patient's condition was critical. Now, facial erysipelas made its appearance, beginning in the auditory canal. Early in November osteitis of the humerus set in, and the patient died on the 9th of November.

Thielman[2] reports the case of a man, aged thirty, brought into the hospital in an unconscious condition. The right ear, eyelids, nose, greater part of the face and forehead were covered with an erysipelatous eruption. The tongue was dry and brown, there was pain in ileo-cæcal region, and the liver was painful and enlarged. The fever was recognized as typhoid and the patient put upon calomel. The patient was in a delirious condition, but on the following day there was a slight remission, and he became partly conscious. The erysipelas was seen to be spreading further over the face, but leaving its original seat. There was delirium the following night and semi-consciousness. Desquamation set in on the right side of the face, the eruption extending on the left. The pulse grew stronger, but the tongue was still brown in the centre. The patient was noticed to be troubled with occasional cough, and the respirations were somewhat more frequent. Examination showed a hypostatic congestion of the lungs. The condition became critical, but was relieved, and the patient gradually improved, being dismissed as cured on the thirty-fifth day after admission.

M. Berthoud[1] reports the case of a soldier who had typhoid fever of a meningeal type. The typhoid fever was declining, but convalescence was tardy, and his general condition was unsatisfactory. At this time the scrotum became tumefied and red, the redness spreading to the inguinal regions, while the general condition became very poor. The scrotum was triple its natural size, red, moderately warm, tender, not very painful, but œdematous, the redness extending to the right and left inguinal regions, as far as anterior superior spinous process, and also to the internal aspect of the thigh. The skin in these parts was swollen but soft, and the color persisted on pressure. On the next day there was no amelioration of the symptoms, but a very small area of necrosis appeared on the scrotum, which was treated by the application of the cautery. On the following day the necrosis seemed to be arrested and the scrotum reduced in size. The general condition, however, remained alarming. Six days later the patient died, after a subdelirium of four hours. The autopsy showed that the iliac and renal veins were involved in a plastic and suppurative inflammation, a case of erysipelas of the veins. The conclusion reached is that the redness of the skin and infiltration were due purely to mechanical causes, viz.: the stagnation of blood.

Freudenberger[2] has recorded two cases, in one of which erysipelas appeared suddenly on both ears in the course of typhoid fever, without unfavorable symptoms. On the following day a chill and rapid advance of the disease took place. The typhoid fever was now considered as declining, but the prognosis grave, because of the erysipelas. In the second case facial erysipelas suddenly appeared during convalescence from typhoid fever, although the temperature was already quite low. The fever became high again, but was easily influenced by antipyretics. The pulse was 140.

Potain[3] reports a case of erysipelas coming on during convalescence from typhoid fever, which was accompanied by a severe chill and fever. The erysipelas began in the pharynx and palate and did not affect the tonsils. On the next day the inflammation appeared at the corners of the mouth and on the face.

Finally, Martinez[4] reports the following cases:

A girl, twenty years of age, belonging to the lower class, of lymphatic temperament, with very irregular menstruation, which was often almost absent, was taken ill with typhoid fever. The symptoms were obscure at the onset of the disease, but the most prominent manifestation was an erysipelatous inflammation of foot and leg. On the fourth day the erysipelas was marked, there was great fever, cephalaglia, and other typhoid symptoms, such as

weakness, gurgling in the right iliac fossa, dryness and tremblings of the tongue, sordes on teeth, great stupor, delirium, and a frequent and small pulse. Death took place after some days.

Whether the erysipelatous trouble had anything to do with the causation of the typhoid symptoms or not Martinez does not state, but he mentions the case of another woman in whom an extensive erysipelatous inflammation of the face and scalp produced cerebral symptoms, fever, etc., but they were not so pronounced as to be confounded with those caused by true typhoid fever, as in the present instance. In this case the patient recovered.

SIMPLE MELANCHOLIA AND ITS TREATMENT.[1]

BY A. B. RICHARDSON, M.D.,
LATE MEDICAL SUPERINTENDENT, ASYLUM FOR THE INSANE, ATHENS, OHIO.

MELANCHOLIA is mental pain. It is a condition of emotional depression. It is the antithesis psychically of mania and emotional exaltation. Not all conditions of emotional depression, however, are melancholia, nor does melancholia include all forms of mental pain. "Man is prone to evil as the sparks fly upward" and evil brings pain. It is only when mental pain exists without adequate cause, or when the degree in which it exists is out of proportion to the exciting cause, that it can be called melancholia. Melancholy is physiological; melancholia is pathological. Both are mental pain—the one has a physiologically justifiable origin; the other is always dependent upon disease.

Melancholia is the simplest form of mental disease. It is the usual form of mental disease in the incipient stage, though this stage may be very brief, and is often known to none but the unhappy victim. Melancholia shades off into melancholy by imperceptible gradations, and the dividing line between them is often ill-defined and uncertain. The first indications of mental disease are usually only removed from the normal mental functions in slight degree, and are usually such as are consciously recognized by the patient himself. This recognition and the accompanying anxiety give rise to a feeling of depression which can justly be called melancholy in the first instance, but which usually has or soon acquires some of the elements of the pathological form. In many instances this stage of primary depression is only transitory, and as the consciousness of the patient becomes more disturbed he passes rapidly into a condition of exaltation. In others, however, the depression only deepens as the disease extends its limits and the mental pain becomes more intense and more irrational—more out of proportion to any possible justifiable cause.

In its incipient stages melancholia is usually simple; that is, a simple emotional depression without well-formed delusions. I have seen cases, however, in which the first symptoms noted by others than the patient himself were hallucinations of some special sense and the resultant delusion of persecution or of a pursuing foe. Simple melancholia may exist as such for a considerable time, without progressing into the forms pathologically and symptomatologically further removed from melancholy, but as a rule the progression into some one of these forms is somewhat rapid and does not occupy more than a few weeks. Even in the simplest forms we see the tendency to the development of delusive ideas. There is an ill-defined impression of impending evil, a subjective sensation of weakness, want of self-confidence, a sense of unworthiness, and a disposition to become irritated by trifles, to be annoyed and disappointed by insignificant occurrences, often rapidly following delusions of threatening want or of loss of family, of the commission of the unpardonable sin, of eternal condemnation, or of persecution by general or specific enemies. There is no other form of mental disorder so insidious in development or so delusive as to its terrible consequences and results.

The chief symptom of melancholia is the disorder of consciousness. There is a diminished intensity of the object-consciousness and a heightened subject-consciousness. The patient loses interest in business affairs, neglects obligations and the ties of family, and is occupied more and more with the subjective sensations and impressions of impending evil. The former is the negative aspect of the disease, while the latter is its active phase. Melancholia cannot be said in every instance to be a form of insanity, though it usually is. There are cases in the incipiency of which there is an ill-defined feeling of depression which overpowers the patient, of which he is fully conscious, but against which he is powerless to offer any resistance. Griesinger (*Mental Diseases*, p. 210) says of this form: "The melancholia which precedes insanity is distinguished from the mental pain which is experienced by healthy persons by its excessive degree; by its more than ordinary protraction; by its becoming more and more independent of external influence, and by the other accessory affections which accompany it."

With the disorder of consciousness which accompanies the more advanced stages, there is a coloring of Nature which affects the whole environment of the patient. This emotional state gives a dark and gloomy interpretation to all about him. He sees everything from an unfavorable standpoint.

[1] Read before the Southwestern Ohio Medical Society, at its semi-annual meeting, April 3, 1891.

For him all Nature is unpropitious and wears her darkest frowns. There is a difficulty in concentrating the attention on anything external to himself without unusual effort, and "there is a want of vigor in the representation of the environment" (Bevan Lewis, *Mental Diseases*, p. 117). As the same author also expresses it, in the same connection, "there is a state of cerebral torpor in the physical substrata of object consciousness and a state of cerebral irritation in the physical substratum of subject-consciousness."

Melancholia assumes different forms in different individuals. The causes for this variation, I imagine, are about as follows: (1) the varying influence of individual cerebral structure and the resultant individual temperament; (2) the extent of the diseased process; and (3) the varying implication of the different parts of the cerebral structure. As has been already stated, that form which is least removed from physiological depression is simple melancholia. The physical disorder is least advanced in these cases; it is less extensive and the prospect of recovery is much better. Nearly all cases of the simple form recover, if discreet treatment is commenced in time. In those cases, however, in which the simple form is but a transitory stage in the development of the more severe varieties, the prognosis is less favorable, and the results of treatment more unfavorable.

The first symptom is usually an irremediable fatigue, a tired feeling, which is not removed by the periodical rest which the individual formerly found sufficient. There is a jaded feeling, and it requires a constant effort to keep the attention fixed on the subject in hand. The affections also become changed; there is no pleasure in family or friends; courage is lessened; there is greater irritability; more impatience at restraint, and religious belief even brings little solace. Sexual desire is lessened and the ability to gratify it diminished; the appetite is dulled, and there is often an uncomfortable feeling after eating. The bowels are usually constipated, the tongue coated, and the various secretions diminished in quantity. Sleep is usually disturbed, and insomnia is often one of the early and most troublesome symptoms. If these indications are heeded, and rest, change of scene, freedom from causes of worry, and nutritious food in abundance are secured, improvement usually begins in a few weeks or months, and continues until the former state of health has been restored. If these steps are not taken, the condition has a tendency to progress and develop into the more severe forms. In some cases this primary stage is transitory, and in spite of treatment the disease rapidly progresses into the more permanent and more serious varieties. The symptoms then become more severe; the disturbance of health is more pronounced; the reason is more in abeyance or more perverted. The morbid fancies gradually become more fixed and more clearly defined. Gloomy fears pervade the mind. The thoughts are fixed on self and with the rise in intensity of subject-consciousness there is a fading out of the normal significance and importance of the outside world. In many cases there is increasing suspicion, and evil is ascribed to the action of everyone. In some instances there is a remarkable paralysis of volition, and hours may be consumed in forming a determination to excute the simplest and most unimportant duties. The memory is usually not much impaired, but there is great difficulty in controlling and concentrating the attention. Suggestions of suicide, as a relief from the horrors of the situation, are frequent. They should be constantly borne in mind, and their presence suspected in every case of depression. They are often present when least expression is given to them, and the silent determination is by far the most dangerous. The only safe rule to adopt is to view every melancholiac as a possible suicide, and to direct the treatment accordingly.

It is not my purpose to go into detail in the description of the more pronounced forms. It is with the disease in the incipient stage that the general practitioner has to deal, and its symptomatology and treatment are most important to him. As the delusive ideas become more fixed, they assume innumerable forms and, according to the conceptions of different authorities, give rise to many clinical varieties. A large group of delusions relates to the bodily functions; every possible as well as impossible form of bodily disease may be the subject of such a delusion. To cases of this class the name of *hypochondriacal melancholia* has been given. The delusions not infrequently have a basis in actual disease. Delusions concerning the stomach and bowels often have their origin in dyspeptic disorders or some organic abdominal disease. When the delusion has a more general character and is permanent, engrossing more or less completely the patient's thoughts, the condition is called *delusional melancholia*. When the motor functions are more prominently involved there is greater restlessness, and *motor melancholia* or *jactitating melancholia* is the name applied. If accompanied by mental excitement approaching delirium, the condition is called *frenzied* or *delirious melancholia*. If there is torpor of the intellectual functions, it is *stuporous melancholia*, and in marked cases *melancholia attonita* of the French; in the profounder disturbances of the motor functions there may be convulsive seizures giving rise to an *epileptiform* variety. Another variety which is sometimes mentioned is *organic*

melancholia, in which there is evidence of localized or gross organic lesion of the cerebral tissue, but it may well be doubted whether such a distinction is wise, for in reality all forms depend upon organic change of some kind in the cerebral tissue, at least for the time being.

The chief primary and determining cause of melancholia, that which gives direction to the diseased process, and also determines the character of the mental symptoms, is to be found in the peculiarities of the structural arrangement of the elements of the cerebral convolutions. The cells are more than ordinarily sensitive; that is, they respond more readily than usual to impressions. Their receptive capacity is increased beyond the average; the individual feels intensely; his affection-capacity is excessive. Comparatively slight causes produce marked variation in his emotional state. He passes from one extreme to another under slight exciting cause. There is also, more or less marked, a morbid temperament, which predisposes to mental pain; there is a weakened resistance and a tendency to lose the normal sense of well-being from slight causes, either from within or without. This temperament and this predisposition are strongly hereditary, and, according to some authorities, more so in the male sex from the mother, and in the female sex from the father.[1] In such cases there is also a tendency to depression after acute bodily diseases, fevers, pulmonary and cardiac affections. In such predisposed persons there is also often a want of proper adjustment among the mental faculties. They are, on the other hand, sensitive, neurotic, sympathetic or melancholic, impressible, and with weakened resistance, yet possessed of such active energy, such ambition, or such strong volitional control that they keep the flagging powers in activity until the danger-point is reached, and a less ambitious individual or one of weaker volition would have heeded the warnings of Nature and have yielded to the demands of exhausted tissues. Though this is often the gift of genius, it is a dangerous power, and in its possession the safety of the mental autonomy is often jeopardized.

Of exciting causes it is unnecessary to speak further than to say that they are as various as the evils to which flesh is heir. They are such as directly produce exhaustion of the cerebral elements by undue drain upon their resources, or interfere with their proper nutrition. Pathological depression is rare in well-nourished brains. Perversion of nutrition is the rule. The sources of this perversion or interference are three-fold. There may be such disease of the bloodvessels as incapacitates them for the proper performance of their functions, and starvation of the cells thereby results; or the nutritive elements of the blood may be deficient in quantity and quality; or lastly the blood may carry to the cells material which acts as a poison to them; and thus destroys their energizing capacity. Whatever the cause, the actual result is that the cerebral cells are impoverished and are thrown into disorder because of their poverty. It may be that their reparative power is naturally deficient, and that a comparatively slight burden is sufficient to exhaust them. Some types of brain-cells are essentially short-lived and have but little reserve power. They are constantly put upon the strain by their everyday routine of work, and any slight excess may result in disaster to them.

While there is occasionally some difficulty in diagnosticating the existence of melancholia, because it shades off so imperceptibly into mere depression, it is a form of mental disorder in which the symptoms cannot long remain concealed. There is usually less difficulty in the examination of such a patient than in many other varieties of insanity. The patient is nearly always conscious that he is not well, and will admit the fact. His description of his symptoms is usually a reliable guide to the discovery of his mental derangement, but he almost invariably attributes them to erroneous causes. There is seldom much difficulty in getting the patient to talk, and in the examination of the insane one of the most valuable qualifications is to be a good listener. Let the patient do the talking, and, as far as possible, confine your own remarks to such as will draw out his peculiarities. There are usually some physical symptoms which are valuable aids in diagnosis. Digestive disorder is frequent. There is often loss of flesh, and there are the general evidences of impaired nutrition. Examine thoroughly for hallucinations and delusions. These always indicate a more serious malady, and one which is less likely to be transient. Hallucinations of smell are thought to be especially of unfavorable omen, and after them those of hearing. Delusions are unfavorable indications in proportion to their prominence and the degree in which they dominate the reasoning powers. Those of self-condemnation and future punishment are most likely to lead to suicidal attempts, while those of persecution and suspicion are more productive of homicidal outbreaks. All such delusions should be carefully noted, and the true significance attached to their presence. The profession is scarcely alive to its responsibilities in this regard. Take no risks. It is far better now and then to needlessly restrain a patient for a few weeks than to permit the continuance of the daily record of suicides and homicides from unheeded indications of danger with which

[1] Clouston: Mental Diseases.

the daily press now teems. It does not follow that hospital restraint is always required, but efficient means should be taken to secure the patient's safety, and if this cannot be done outside of a hospital, then to one he should go.

The pathology of melancholia in its earlier and simpler forms is not such as admits of satisfactory ocular demonstration. It is chiefly seen in perverted function and evidences of collateral physical disturbance. The essential feature in it is the impaired and perverted nutrition of the cells of the cerebral cortex. This may be primary, dependent upon causes which act directly upon the cells in modifying their molecular arrangement, by overstrain, or work of kind and quality beyond their capacity of safe performance; or secondary, produced by disease of other tissues or other organs, the healthy activity of which is necessary to their proper nutrition. This disease may be in the cerebral blood-vessels, in the digestive tract, in the liver, the kidneys, the lungs, the heart, or, in fact, to a greater or less degree in any tissue of the organism. Diseases of the digestive organs and of the cerebral vessels are the most frequent. The brain cells do not show the gross lesions of alcoholic insanity, paretic dementia, or of many other forms of mental disorder, nor is the destructive change so rapid. There are not the evidences of violent perturbations in the adjoining tissues, so usually found in maniacal states. For this reason melancholia offers a better prospect of improvement, after a prolonged continuance of the disordered state, than do most of the other forms of mental disorder. I have known a not small number of cases to recover completely, or nearly so, when the disease was of several years' duration.

The treatment of melancholia is a complex question, and cannot be stated in general terms. There is no disease in which the individuality is so dominating as in insanity. Every case is a separate study, and the treatment should be adjusted to the peculiarities found in each. The first consideration is usually that of safety. What has already been said in that connection will point the way. In every case have in view the possibility of suicidal or homicidal impulses, and search for them. If the depression is profound, or there are present delusions of persecution or self-condemnation, great care should be exercised in providing efficient supervision. Cases of the agitated form are less liable to such impulses, except in the rather rare cases in which this class of delusions is also present. Care should be taken in the apathetic form that such accidents do not happen, for the stupor and consequent silence may conceal dangerous delusions, which may unexpectedly give rise to dangerous impulses. Change of environment is advisable in nearly all cases. This is more universally true than in cases of exaltation. The painful mental state in which the patient lives is connected largely with the circumstances of his environment and removal to new surroundings and the starting of new lines of mental activity thereby is an important condition of successful treatment. The particular nature of this change, the kind of selection which is made, must be determined by the situation and peculiarities in each case. In one, removal to a hospital may be best and the only thing practicable. In another, a stay in the country, removed from all forms of irritation, and with but little society other than the required nurses, may be most advantageous. In still other cases, the removal to busier surroundings and to a more active life may prove best. Changeable climates, with low barometer and moist atmosphere, are to be avoided. Tact should be used in selecting the proper kind of companions. Too much attention and too great a manifestation of sympathy may prove as injurious as neglect or harshness.

Having chosen the most favorable environment practicable, selected the most judicious companions available, and made certain that the safety of the patient is insured, the next consideration is the daily line of conduct which should be prescribed. Many of these patients have led sedentary lives and have neglected the cultivation of their muscular system. In such cases, carefully adjusted and methodical exercise of the muscular system will be of advantage. Walks in the open air, gymnastics, massage, baths with friction afterward, with a complete cessation of all mental activity as far as possible, constitute the proper regimen for these. Such treatment will tend to divert the blood-current to other regions, and thus relieve the passive congestion which is frequently the accompaniment of the impairment of nutrition of the brain-cells, and prevents the proper supply of healthy blood, while it also contributes to the enriching of that fluid by removing waste-products and stimulating the assimilative processes. In the motor forms, exercise is likely to be injurious, and rest and quiet should be secured instead. In all, any prodding of the mind to intellectual effort is to be discouraged and avoided. As the mind shows capacity for healthy exercise, it should be led into pleasant paths in which exercise will be amusement, and where, as far as possible, the mental landscape will be at variance with that which developed the depression and the melancholic fancies. All these are most important requisites to successful treatment; and a companion with tact, experience and the proper breadth of intelligence is worth more than all the articles of the materia medica.

After rest and properly regulated and selected exercise comes the question of nutrition. This is a broad field, and should be carefully studied in each

case. Clouston's "gospel of fatness" in these cases is of incalculable advantage. Encourage assimilation by every possible means. Give the most nutritious diet and in quantity as large as can be utilized by the system. Don't be afraid of the amount consumed. It cannot be too great. Stimulate the secretion of the digestive fluids. Carry off the waste products promptly and thoroughly, and then see that the brain is given the opportunity to utilize the material furnished it. Encourage sleep by every means within your power, and never curtail the amount. Remember that it is advantageous in proportion to its approach to the natural variety. The stupor of many narcotics, particularly in large doses, is not sleep, and gives the brain no opportunity to obtain nutritive supplies. This is the great purpose of sleep, and is not accomplished by simply creating a condition of unconsciousness by the circulation of a drug through the brain. Hypnotics are only of value to adjust the conditions and start the process, leaving Nature to perform the actual work. Use hypnotics sparingly and as a last resort. Remove as far as possible all the obstacles to natural sleep, and test first the influence of change of environment, new forces and new lines of mental activity. They will often work wonders, when, if hypnotics have been given, the effect is likely to be wrongly attributed to them, and their use continued to the detriment of the patient. Of the many in use, perhaps paraldehyde is the least depressing and the least injurious, though difficult to administer and most unpleasant. The bromides and cannabis indica are useful in the more active forms. In the very excited cases a combination of the alkaloids of hyoscyamus with morphine, given by preference hypodermatically, I have found invaluable in controlling the motor irritability and conducing to natural sleep. Chloral and sulphonal are usually too depressing in their after-effects to be of advantage. Strychnine, arsenic and phosphorus are of use, as the system can take care of them. Iron is often useful in anæmic states. The bowels should be kept freely open and stomachic tonics used judiciously. Remember that the brain is in direct communication with every portion of the animal economy, and that for its healthy action the condition of no other organ can be safely neglected.

A CASE OF PUERPERAL SEPTICÆMIA.

BY JOHN T. BINKLEY, M.D.,
OF TACOMA, WASHINGTON.

ON February 22d, at 7 o'clock A.M., I was called to attend Mrs. B., aged thirty-six years. She had borne four children and had aborted four or five times by self-induction. She then desired another child, but, aborting twice from habit, she consulted me. I succeeded in carrying her through to term.

When I reached her bedside I found her in the first stages of labor, the os slightly dilated and soft, a head presentation, and every indication of an easy labor. I left the house, made a few calls, and returned at 9 o'clock. Pains were recurring a little more frequently, and the os was the size of a silver dollar. At 11.30 the os was well dilated and the head in the vagina. The pains now became less frequent, the head did not further descend, and complete uterine inertia followed. At 2.30 I urged the necessity of applying the forceps, and the delivery was easily accomplished inside of twenty minutes. I soon delivered the placenta by expulsion, apparently intact. There was no hæmorrhage and no perceptible abrasion of the continuity of the parts, and I congratulated myself upon the result. I told the nurse I would call and use the catheter in the evening, but on my arrival I found the patient had arisen and urinated.

Early the next morning I was called to the hospital to assist in an amputation of the thigh. I found a case of gangrene, and was excused, but the "Esmarch" slipped during the operation, and I helped control the hæmorrhage until it was readjusted. I immediately washed my hands thoroughly in bichloride solution, left the hospital, changed all my clothing, and called to see my patient. I found her condition splendid and I gave her a vaginal douche at 3 P.M. But I was soon summoned by telephone and found her just recovering from a severe rigor. I waited one hour, her temperature reaching 100½°. I then gave her another douche, after which she was comparatively comfortable. I learned that many women of the neighborhood had called, and knowing that she was exceedingly nervous and excitable, I concluded she had had a nervous chill. I ordered her four five-grain capsules of quinine to be given within the next twelve hours.

The following morning the nurse's report showed the evening temperature 102°; morning, 101⅘°; pulse ranging from 100 to 120. I found the stomach irritable, a little abdominal tympanites, and pain in the right hypochondrium, radiating into the right thigh. I ordered twenty grains of antipyrine to be administered, gave her another uterine douche and an enema, the bowels moving freely with the escape of much gas. The temperature fell and the patient rested well until evening.

On February 25th, the third day, the evening temperature was 101°; pulse, 118. The tympanites was more marked, and the pain returning, I gave quinine, antipyrine, a vaginal douche, and a turpentine enema. The patient passed a bad night, the temperature on the fourth day being 101⅘°, and the pulse 84. She had been vomiting and was very restless. I gave her a douche and inserted a rectal tube. In the afternoon there was complete anorexia, and the morning symptoms were all exaggerated. I then requested a consultation with Dr. W. We gave a uterine douche, 1:6000 bichloride solution, but nothing came away, and we found nothing to justify the condition. There was no perceptible abrasion in the vaginal tract; the os felt intact; there was no odor and no soreness to the touch. We turned our attention to the symptoms and prescribed: tr. nucis

vom., ʒj.; tr. bellad., ʒij.; tr. menth. pip., ʒjss.; sulph. magnes., ʒiv.; elix. simpl., q. s. ad ℥iv.—M. Sig.: ʒj. every two hours. We also ordered an enema of turpentine, a milk diet, and the water to be drawn every eight hours.

On the fifth and sixth days the symptoms were about the same, the tympanites being controlled by keeping a rectal tube inserted above the sigmoid flexures. Milk was not well retained, and I ordered it partially digested with Fairchild's peptonizing powder, after which it was well borne.

The seventh day the tympanites was enormous, the pain unbearable, much vomiting and headache, the pulse 88, and the temperature 102°. Dr. W. was again called in, and deciding the treatment should be on the expectant plan, we gave one-half grain morph. sulph. et atropia sulph. grain $\frac{1}{100}$ hypodermatically at 10 P.M. The patient slept ten hours, awaking in the morning much improved, the bowels moving naturally.

From this to the thirteenth day there was but little change; the temperature did not go above 102°; the pulse not over 104.

On the fourteenth day the pulse was very weak; there was vomiting, diarrhœa, and night-sweats. I gave bismuth and bicarbonate of soda and milk by the rectum, with sulphate of atropia hypodermatically for the night-sweats.

On the fifteenth day I consulted with Dr. W. The pulse was 92 and weak; the temperature 100⅘°. I had come prepared to curette and douche the uterus, and to this Dr. W. agreed. Under anæsthesia, I curetted thoroughly and was quite surprised at the amount of small bits of broken-down tissue that were brought away. I then douched with water that had been boiled, applied pure carbolic acid thoroughly to the uterus through a Wylie's applicator, and gave the patient milk and brandy per rectum. The temperature rose in one hour to 104°; the distress was marked, but controlled with hypodermatic injections of morphine.

On the sixteenth day all symptoms were much improved; the patient was transferred to a new bed, put upon tonic treatment and soft diet. She gradually improved until the twenty-fifth day, when I discharged her.

Though the most rigid antiseptic precautions had in this case been observed throughout, there is every reason to believe that in some way or other my patient was infected through my unfortunate connection with the above-mentioned case of gangrene. The more I see of such cases, the more I am convinced that curetting in such cases need not and should not be delayed, because, when done carefully and under antiseptic precautions, it can do no harm and may do a vast amount of good.

I may doubtless be criticised for the free application of carbolic acid to such a large absorbing surface, but I am upheld by Dr. C. C. Hunt, of Dixon, Ill., who has treated successfully a number of cases of puerperal septicæmia in this manner, as reported by him in an excellent paper read before the Illinois State Medical Society, at Jacksonville, Ill., in May, 1889.

SECONDARY CARCINOMATOUS DEPOSITS IN ASSOCIATION WITH SCIRRHUS OF THE BREAST: WITH REPORT OF A CASE.

BY WILLIAM MARTIN, M.D.,
OF BRISTOL, PA.

SECONDARY carcinomatous deposits occur during the latter stage of the disease, forming in all parts of the body, but principally in internal organs. The most important of the changes which take place in carcinoma is fatty degeneration, which always occurs, to some extent, in all varieties of carcinoma. It is usually most marked in the encephaloid, but the more rapid the growth the earlier does the retrogressive change occur. Mucoid and colloid degeneration, with the formation of cysts from blocking of the ducts of the mammary gland, as well as hæmorrhage and pigmentation of tissues, may occur as secondary changes, whilst calcification or ossification are rarely found.

In all the varieties of carcinoma the tendency of secondary growths is to reflect the peculiarities of the primary. Exceptionally, in scirrhus, the growths in internal organs differ somewhat from the primary, in that they are softer and more vascular, resembling the encephaloid, to which variety they are regarded as belonging.[1] Although more rarely than in other parts, we do find that deposits take place in the osseous structures, the long bones being most liable to the invasion: foremost among these is the femur. The deposit is usually an infiltration, although it may be tuberoid. In the latter form the morbid mass is either solitary, or consists of several small nodules of irregularly rounded or oval shape, each about the size of a hazlenut. The infiltration usually or always begins in the cancellated structure, and is diffused through into the areolar tissue. The bone is seldom much altered in size or shape, but is liable to undergo rarefaction, and to be fractured at the seat of the disease. This tendency to fracture is very great. Fracture may be caused by the most trivial circumstance, such as turning in bed or muscular contraction.

The diagnosis of this secondary infiltration in the femur is evident from the subjective symptoms. The peculiarly constant, dull, heavy pain referred to the seat of the deposit, with occasional sharp, lancinating pains in the limb and body, increased almost beyond tolerance by the slightest pressure upon the part, are pathognomonic, as there is usually no history of traumatism to account for the degree of disturbance. As the slightest motion of

[1] Green's Pathology.

the part or pressure upon it elicits the most excruciating pain, the patient, as a protection from injury, usually flexes the limb, using the knee as a support for the bed-clothing.

The abdominal complications may also be marked, as will be seen in the following case, which the writer saw during latter stage of the disease, in consultation with his father, Dr. William L. Martin, to whom he is indebted for the report of the earlier history of the case.

Hannah H., about forty-three years old, married, the mother of four children, all living, presented a tumor in the right breast, which had been noticed for about two months, and which seemed to increase quite rapidly in size. Upon examination the tumor was found to be hard and mobile, occupying about one-quarter of the whole mammary gland, with the nipple somewhat retracted and drawn to one side. No lymphatic involvement was apparent. The diagnosis of scirrhous carcinoma of the breast was made, and an operation advised. The entire breast, together with the axillary glands, were removed by Dr. John H. Brinton. The patient made a good recovery from the operation, and in about three weeks returned home. She apparently remained physically well, but in the following spring noticed some hardened nodules around the cicatrix and in the axilla, which were removed a few days later. During the following fall she gave birth, at term, to a male child, of medium size and feeble vitality, which died a few months later from pulmonary disease. In a little less than a year from the primary operation the third was performed, all the cicatrices and underlying secondary growths being removed. It became necessary to repeat the operation in the fall of the same year. The fifth operation was performed nearly two years later, when a large mass of carcinomatous tissue was removed, and the axilla cleaned out. In the fall of the following year new growths in the axilla, with the cicatricial tissue and part of the pectoralis major were excised. In addition to these six operations there followed two minor excisions, the last being performed only a few months prior to her death, which took place less than six years after the primary operation.

Microscopical examination of the removed tissue conclusively showed the nature both of the primary and secondary growths.

The first operation was the most important, and the case illustrates to what degree life may be prolonged by early and thorough operation. As the tumor was unusually rapid in its growth the patient most probably would have died within a year from the time it was first noticed had nothing been done, while as the result of operative interference the patient lived for nearly six years after the first operation. During all this period, until within a short time of her death, she remained comparatively well, being able to attend to her household duties, although readily fatigued.

With some emaciation and tympanites, she also complained of a peculiar pain in the hip-joint, which she thought rheumatic, having noticed it but a short time before death. Two weeks before her death, while attempting to cross the room, she tripped and almost fell, with severe pain in the thigh near the joint, which caused her to take to her bed. The pain remained constant, and became an urgent symptom. Upon examination no fracture could be detected. It was thought that the peculiar pain was caused by secondary deposits in the neck of the femur. The limb was kept carefully protected in a comfortable position of slight flexion. Despite the greatest care, just before death a fracture at the neck of the femur took place, most probably from the muscular contraction, as no other cause could be assigned.

During the last week of life other symptoms became marked, and required constant attention. Of these dyspnœa was prominent, and was so decided as to necessitate a constant change of position, semi-recumbency being the most comfortable. In addition, there were moderate emaciation, the peculiar characteristic pallor of the face, tympanites, nausea and vomiting—the last more properly retching, at times very little matter being ejected, except when something had been taken into the stomach a short time previously. Pain was constant and severe, requiring anodynes frequently given hypodermatically, but subsequently not yielding to these means. Diarrhœa appeared during the last week. There was slight œdema of the lower extremities. The symptoms pointed to secondary involvement of the abdominal viscera, but a post-mortem examination was not permitted.

CURVED NASAL SEPTUM: A SUCCESSFUL METHOD OF OPERATION.[1]

BY CHARLES A. TODD, M.D.,
OF ST. LOUIS, MO.

THE conflicting views as to the best method of remedying curvature of the nasal septum by operation afford proof that surgeons have not yet satisfied themselves upon that point. But the problem demands solution, since by blocking the respiratory channel, the deformity gives rise to serious disorders that are sufficiently familiar.

The curvature is usually most pronounced in, if not confined to, the cartilaginous septum, though it often enough involves the osseous part as well; as Zuckerkandl points out, it is the anterior two-thirds of the septum that are affected, the posterior part of the vomer rarely swerving from the vertical.

The first operation to straighten the septum, with preservation of its integrity, was devised by the English surgeon, Adams, who forced the septum into place with flat-bladed forceps and then retained it in position with nasal plugs until consolidation was supposed to have taken place. This method does not seem to have been generally adopted; indeed, we hear nothing more of it and it is not

[1] Read before the St. Louis Medico-chirurgical Society, March 17, 1891.

likely that it ever produced satisfactory results for reasons presently to be stated. Then it was suggested that the cartilaginous septum be incised with cutting forceps of various styles, the sections forced into position and maintained by plugs of various devices. In a recent English work, the old operation of bodily cutting out the most convex portion so as to leave a free communication between the nasal passages, is mentioned with a degree of approval.

Many surgeons, doubtless, have tried different operations, only to find the obstinate cartilage twisted back into its undesired position a short time after removal of the retaining-plugs. The difficulty lies in this simple fact, that the septum-cartilage is highly elastic, and when merely incised and bent into position, if left to itself, is pretty sure to work gradually back; the cicatrix is stretched and the old condition is reëstablished. As to the operation of excision and leaving a hole in the septum, this is contrary to Nature's method and ought not to be regarded as a legitimate procedure. A perforated septum is likely to give rise to constant trouble; the mucus collects and dries upon the margin, forming a troublesome crust; as this is picked off erosion follows, etc. The patient must constantly use unguents or some substitute to keep the edges free. In common with the usual experience, I had not found operative measures satisfactory and have avoided dealing with such cases until last December, when three pronounced cases came under my care. In these, I determined to depart from the customary methods and make a double operation to overcome the tendency of the sections of the incised cartilage to return from their median to their abnormal position. After making the stellate incision with the well-known Steele forceps, I cut across the base of the most refractory segments with a curved knife; this second cutting was made while a finger was held in the opposite nostril, so that the mucous membrane on that side should not be injured, the knife cutting through the cartilage to the mucous membrane. This scheme proved fully successful, the deformity not being reproduced, except in one instance in which the patient returned to his home in the country while the parts were still unconsolidated, and then, contrary to directions, wore the plug only part of the time; he wrote that his nose was again bad—as might well be expected. When last seen, his septum was in particularly good condition. I doubt the expediency of making the secondary incision at the time the first is made with the forceps, as sloughing might follow such extensive interference with the circulation as would be occasioned. Under cocaine, the knife may be easily applied a few days afterward, according to the appearance of the wound. The cuts should be made so as to allow the parts to yield at once under touch of the probe; any less decided result will not insure against subsequent trouble.

I have tried to remedy the deflection in the bony septum by using, after the Steele forceps, one of my own invention, which instead of a stellate knife carries a number of conical pegs; this forceps, when applied, crushes the spongy bone, and by twisting tends, without much injury of the mucous membrane, to break it up sufficiently to enable the surgeon to rectify the position. It has seemed to me that some good was effected in this way. The principle is reasonable. Naturally when there is much thickening of the septum, such excess of tissue must be cut away. It will sometimes be found after rectifying the nasal cartilage that the passage posteriorly is blocked by outgrowths or simple thickenings of parts; these can now be reached and, according to their nature, removed with knife or saw.

ORIGINAL LECTURES.

OVARIOTOMY FOR CYSTIC TUMOR—THE RADICAL OPERATION FOR CANCER OF THE BREAST.

Abstract of a Clinical Lecture delivered at the New York Hospital.

BY W. T. BULL, M.D.,
ATTENDING SURGEON.

GENTLEMEN: The first patient I present to you is a married woman, about thirty years old, who was admitted to the hospital with an enlargement of the abdomen, which had been noticed for a year. Although the enlargement has attained considerable size, the general health is evidently unimpaired. The patient only complains of the weight of the tumor and of pain upon exertion. Palpation of the abdomen readily elicits fluctuation, while a previous examination has failed to detect disease of the uterus. I shall at once pass to the consideration of the proposed method of treatment—*i. e.*, the removal of the tumor by operation. Briefly, the operation will consist in making an incision through the abdominal wall, large enough to admit the hand, and laying bare the surface of the cyst. The existence of adhesions to the abdominal wall will be ascertained by passing a sponge-forceps or sound over its surface. By means of a trocar, the fluid will be evacuated; and then the pedicle, which is usually continuous with the broad ligament, will be ligated and the sac removed. The first incision exposes the aponeurotic layer; the second passes through the linea alba and the subperitoneal fat. Having controlled all bleeding by the application of pressure-forceps and ligatures, the peritoneum is opened and at once the cystic tumor bulges into the wound. The fluid contents having been evacuated by means of a trocar and canula, the greater portion of the sac is brought outside of the wound, and a free opening made with scissors. Fortunately, there are no adhesions to interfere with our emptying the cyst

in this manner, which prevents the contents from running into the abdominal cavity. By passing the hand into the abdomen, the omentum is found adherent over a small area of the upper surface of the cyst. The omentum is separated and ligated with silk, and the sac is drawn out further. The hand is passed into the interior of the sac and detects a second cyst within, which is torn through and its contents allowed to escape. The fluid is darker in color and thicker in consistence than that contained in the other sac. With the hand the cyst is found to fill the pelvis and to be continuous with the broad ligament of the left side and firmly adherent to the posterior surface of the uterus. The left ovary is merged in the sac. The pedicle is only a fold of broad ligament. It is to be tied with a double "chain-ligature" of strong silk, and the sac, after being separated from the uterus, removed with scissors. This step is tedious, and I encounter much troublesome hæmorrhage, which will be gradually controlled by silk ligatures and the thermo-cautery. Having left a sponge temporarily in the left side of the pelvis, I turn my attention to the right ovary, and here I find another ovarian tumor, small in size, with very thin walls. It is desirable that this be removed without rupture of its wall and consequent escape of its contents; but in order to be prepared for such an accident, I shall introduce a large sponge deep down in the pelvis, so as to limit as much as possible the discharge of the contents of the cyst. (The rupture of the cyst proved to be unavoidable, so that after the removal of the sponge, the pelvic cavity was flushed with hot water by means of a funnel and tube.) As there is still a little bloody oozing from the posterior surface of the uterus, I shall place a rope of iodoform gauze in contact with this surface, and in order to be informed as to the recurrence of the bleeding a glass drainage-tube will also be inserted. (The peritoneum was sewed up separately with a catgut suture, and over it the aponeurosis united with catgut and the skin with silk. The external dressing consisted of iodoform and sublimated gauze, held in place by broad strips of adhesive plaster, and over this absorbent cotton so placed as to avoid injurious pressure on the drainage-tube.)

During the next twenty-four hours, at intervals of two or three hours, the condition of the pelvis will be investigated by carefully introducing to the bottom of the well formed by the drainage-tube a small syringe to which a piece of soft catheter is attached, and withdrawing whatever fluid may have accumulated. If no further hæmorrhage occur, the tube will be withdrawn at the end of twenty-four hours, and the gauze after forty-eight hours. If there should be much bleeding, the wound would be reopened and the bleeding-point ligated. If this were not possible, the cavity of the pelvis would be stuffed with iodoform gauze, enclosed in a "handkerchief" of the same material. (Recovery ensued without a complication. The sinus left after the withdrawal of the tube and gauze closed at the end of five weeks.)

The next patient is a woman, fifty-four years old, with

A TUMOR OF THE RIGHT BREAST,

which has been growing steadily about two years. A few months ago the skin began to ulcerate, and since then she has had occasional sharp, lancinating pains, which have become more severe as the ulcerative process has progressed. The general health is good. There is no material increase in the size of the breast—in fact, it appears reduced in size. The nipple is not retracted, as it often is in cases of this kind, but it is not so freely movable as in health. The upper half of the breast is abnormally hard, and the ulcer feels almost as hard as a board. The base of this ulcer is sloughy; the secretion is moderate; and there is an area of inflamed and congested skin at the periphery. The tumor and ulcer are characteristically carcinomatous, the points already noted serving to render the diagnosis quite simple. At a previous examination there seemed to be a slight enlargement of the axillary glands, and although this is not evident at present, we should not on this account be led to confine our operative measures to the breast itself. The duration of the disease in the present instance should induce us to remove the contents of the axilla; but it is a wise precaution to observe in all cases, even when no glands are felt.

To deal with this form of malignant disease radically, one must remove the diseased organ and the overlying sound skin, the fascia of the pectoralis muscle and the contents of the axilla. Do not pay too much attention to the question of securing flaps to cover the wound completely; the main thing is to remove the disease thoroughly. I wish to call your attention to the characteristic gray color, as well as the hardness of the carcinomatous tumor which I have just removed. In prolonging the incision into the axilla, you should follow the border of the pectoralis muscle, stopping at the line of the arm. Having reached the edge of the pectoralis minor muscle, divide the fascia, retract the edge of the muscle, push the fat away, and look for the axillary vein. Continue the dissection to the apex of the axilla, pushing with the handle of the scapel or blunt scissors the fat containing the glands away from the vein and the wall of the chest. Notice that I have exposed an intercosto-humeral nerve, the division of which sometimes gives rise to disagreeable numbness on the inside of the arm. The small arteries and veins are easily seen and clamped before division. I do not yet feel any enlarged glands, but I remove the fat *en masse*. A close examination reveals several small, hard masses, which, on section, are found to present the same characteristic appearance noticed in the portion of breast already removed. This plan of removing the whole chain of glands with the fat *en masse* is preferable to the older method of incising the fat and searching for the enlarged glands; glands which are only slightly involved are thus not overlooked, and at the same time the danger of discharging some of the contents of these glands into the wound is avoided. Having searched carefully with my finger between the two pectoral muscles, to assure myself that there are no diseased glands there, I introduce a rubber drainage-tube into the axilla through an opening made below the main wound, and then bring the flaps together by sutures, taking care, in this case, not to secure complete coaptation, lest by so doing the sutures exert too much tension and give rise to sloughing. All fluid should be carefully squeezed out of the wound, and then by the skilful application of compresses the cavity may be completely obliterated. The whole upper extremity is carefully bandaged to the body so as to secure rest during the process of healing, which is usually unaccom-

panied by fever or much discharge, and ordinarily requires the patient to be confined to the house for ten days or two weeks.

You have seen the operation successfully performed, and may naturally inquire, Is it likely to cure the patient of the disease? I feel constrained to answer in the negative. The reason is, that the disease has already existed for so long a time. If we expect to cure cases of carcinoma by operation, we must adopt operative treatment at a much earlier period. I think we can all accomplish much good by instilling into the minds of the laity a correct notion as to the good results likely to follow early operations for carcinoma, as well as by encouraging them to seek advice much earlier in regard to all abnormal growths, whether apparently benign or malignant. As the average duration of life in this form of cancer of the breast, without operation, is about three and a half years, this patient would be likely to live about one and a half years more if not operated upon; but on account of the pain and discharge from the ulcer, her existence would be a distressing one. With the operation, these features are removed to a later period, and she may enjoy life with no appearance of disease for a number of months. The disease will most likely recur in the scar, or it may appear in some internal organ, as the liver. In either event the operation prolongs life, delays the progress of the disease, and relieves the patient at once of a painful growth. In some instances removal of recurrent growths is advantageous. The cicatrix should be inspected at frequent intervals, and any small, hard nodule appearing in it excised at once. This can be done with cocaine-anæsthesia. I recall two patients, both living at the end of six and ten years respectively after excision of the breast for carcinoma. In both cases several of these little secondary growths have required removal. (The wound healed without complication in two weeks. The axillary drain was removed on the third day.)

CLINICAL MEMORANDA.

CATLIN'S METEOROLOGICAL PAIN-PHENOMENA.

BY S. V. CLEVENGER, M.D.,
OF CHICAGO.

AMERICA has good reason to be proud of the good work of Dr. S. Weir Mitchell in many directions, and he has added to his fame by starting Captain Catlin upon a scientific investigation that will prove of inestimable value to neurology.

Nearly twenty years ago I essayed some observations and tabulations similar to those of Captain Catlin, when I was connected with the meteorological department of the United States Signal Service. Other work interfered with the completion of my calculations, and since the publication of the Captain's synopsis in your journal of May 2d I can clearly see where previous efforts at establishing the relationship of pain and atmospheric conditions have been so very faulty. Observers have generally sought causes in hygrometrical conditions alone, in barometrical fluctuations, in ozone quantities, in wind directions, or in thermal conditions, and have been compelled to rely upon the statements of others as to the time when pain was greatest and least. In Catlin's case, the sufferer himself being the observer and a competent scientist, we for the first time have the advantage of reliable information upon this important subject.

Unless one has undertaken a systematic series of meteorological observations he cannot appreciate the enormous amount of work involved therein, and it is to be hoped that our Weather Bureau may take proper cognizance of Captain Catlin's work and incorporate it in the general meteorological literature, so that these researches may be built upon by future observers. By studying, as the Captain has done, the entire range of phenomena and their association with pain, certain very definite deductions are gained, and single factors, such as moisture, sunshine, etc., can then be properly assigned their modifying influences.

Pain predictions may some day be announced by the Signal Service, if it can be found that a useful purpose can be subserved thereby, particularly if Catlin's observations result in methods of mitigating the agony that so many of the limbless suffer. And why may not prevention follow next upon the knowledge of the cause? It would be well to thoroughly try the possibility of neutralizing such causes of pain, no matter how troublesome the process may be at first, for simplification of means would surely follow any success. Captain Catlin and Dr. Mitchell would be most competent to discuss this next phase of their researches, and it is hoped that they may find the time to do so.

A CASE OF VARICOSE VEINS OF THE BROAD LIGAMENT.

BY W. REYNOLDS WILSON, M.D.,
OF PHILADELPHIA.

THE patient, Mrs. C. B., aged thirty-five, was operated upon at the Lying-in Charity on April 27th. Both ovaries were removed on account of the following symptoms: She had suffered for a long time from pelvic pain, backache and hæmorrhage, continuing, on an average, for two weeks from the beginning of each menstrual period. She had been compelled to pass most of her time in bed. She had had six children, and, since the birth of her last child, three miscarriages.

When first admitted to the hospital, the patient presented the following conditions: She was suffering, to an extreme degree, from the symptoms described above. Locally, the os was deeply lacerated bilaterally, an extensive cicatrix evidently being the result of a former unsuccessful operation. The uterus was enlarged, movable, and in normal position. There was a movable tumor, the size of a walnut, to the right of the uterus, very sensitive on pressure. The left broad ligament was tense, but no distinct tumor could be made out.

At the time of the operation the right ovary was found to be cystic, the tube normal. The left ovary was also cystic, but not so much enlarged as the right, the tube on this side being also normal. In the left broad ligament there was a plexus of enlarged veins. On examination *in situ* they were three-eighths of an inch in diameter, tortuous, and evenly dilated in their whole extent; no knotty appearance was observed. This condition existed in the left ligament alone, the absence of adhesions admitting of a careful inspection of both liga-

ments. A double ligature was introduced between the ramifications of the dilated veins, and, after emptying the veins by pressure, tied on either side.

This case is similar to those reported by Dudley (*New York Med. Journ.*, xlviii., 147), Hirst (THE MEDICAL NEWS, lvi., 538), and Kelly (*Johns Hopkins Bulletin*, 1889–90, 223), and may be considered in connection with an article by Malins on "Varicose Veins of the Broad Ligament" (*Amer. Journ. of the Med. Sciences*, 1889, xcviii., 340). It is remarkable that Tait, in a paper on the "Pathological Importance of the Broad Ligament" (*Edinburgh Med. Journ.*, 1889–90, xxxv.), in writing of pelvic hæmatocele and intra- and extra-peritoneal hæmorrhage from a rupture of the veins of the broad ligament, fails to allude to a varicose condition of these veins as a distinct pathological condition, except in connection with hæmorrhage due to a sudden arrest of menstruation where the veins are acutely distended.

The case I report is also of importance in illustrating the occurrence of varicose veins (most frequently) in the left ligament. They occur on the left side of the female for the same reason as in the male—namely, for the reason that in both sexes the spermatic vein on this side enters directly into the renal vein and at right angles to it. There is no doubt that the symptoms were consequent to this pathological condition. In reference to this Kelly writes: "Whence the pelvic pain arises in these cases it is impossible to say; it is equally impossible to say that these great distended vessels may not play a very important part in the production of the pelvic and lumbar malaise." Those who have worked upon this subject agree in the propriety of operating for the ligation of the veins when the ordinary palliative treatment has proved unsuccessful; the future of the case reported will, I hope, confirm this decision.

1633 LOCUST ST.

CURRENT LITERATURE.

OPERATIVE TREATMENT OF TUBERCULOUS NEPHRITIS.

MADELUNG'S experience is, under certain conditions, in favor of operation. The main obstacle to a more general application of surgical therapeutics to tuberculous nephritis is the difficulty, on the one hand, of making a positive diagnosis; and, on the other hand, of locating the lesion positively on the right or left side. The most positive proof of tuberculosis in the genito-urinary organs, tubercle bacilli in the urine, is difficult or impossible of establishment. The attempts to separate small numbers of bacilli from a larger quantity of urine have not yet led to practical results. More promising as a means of diagnosis appears to be the inoculation-test from suspected urine on animals; but it is objectionable that the length of time required for the development of general secondary miliary tuberculosis is at least four weeks. In cases in which bacilli were found, Madelung experienced great difficulty in excluding tuberculosis of the bladder. Dysuria and strangury may be referred to a diseased kidney. Inspection by the cystoscope, which has proved valuable in other affections, gave uncertain pictures. Digital palpation of the female bladder has several times been followed by permanent paralysis of the sphincter vesicæ muscle.

If the diagnosis of tuberculous nephritis has been positively established, difficulty may be experienced in determining which of the two kidneys is affected, or whether both are diseased. Cases have occurred in which the kidney, from the subjective symptoms, the palpable tumor, etc., suspected to have been affected, has been found, post-mortem, much less involved than its fellow on the opposite side, which was not enlarged and in which pain had been moderate, or severe only for a short period. In such cases, and in those rare ones in which one kidney is congenitally absent, the removal of the only renal organ must inevitably be fatal. The author reports a case which strikingly illustrates the possibility of such an error. He holds that even Thornton's method of exploratory abdominal incision and direct palpation of the suspected kidney gives no positive clue in locating the affection. Catheterization of the ureters has been proposed as another means of diagnosis. To facilitate the introduction of the catheter the author in two cases made a supra-pubic incision, as in lithotomy. The openings of the ureters were easily located, but he failed to introduce anything larger than a fine probe. Madelung disputes the diagnostic value of nephrotomy. The exclusion of disease in one kidney by draining off the urine of the suspected organ through an opening made into it, and finding the urine free from pus, is possible only in cases of unilateral non-tuberculous pyelitis or pyo-nephrosis, but usually not in tuberculous unilateral nephritis. It remains doubtful whether the fistulous opening reaches the pelvis of the kidney, since, to accomplish this, a more or less thick layer of kidney-substance has to be perforated, as when the kidneys are tuberculous the pelvis is usually not much, if at all, dilated. If only one calyx is reached, or an abscess in the kidney-substance be found, the object of the operation (to drain off the urine by another channel and prevent its escape by the ureter) will not be attained. According to Madelung, the most certain way to establish the diagnosis is to expose the kidney and examine its condition. If the latter does not account for the gravity of the signs and symptoms present, extirpation should not be performed. Since, then, initial stages of the disease cannot positively be diagnosticated, and since it scarcely admits of doubt that spontaneous recovery may take place in case of the small foci of tuberculous ulceration, the operation seems indicated only in the later stages of the disease, in which spontaneous recovery cannot be expected.

With the present means of diagnosis the object of the operation must be to remove inflammatory products which cannot be spontaneously eliminated, and thus to free the patient from unspeakable suffering. Manifest tubercular disease of other organs, except advanced cystitis, is no contra-indication to the operation.

On the principles laid down, Madelung performed nephrectomy in four of twelve cases of undoubted tuberculous nephritis. On the ground of

his own experience and on that of most other writers he disputes even the palliative value of nephrotomy.

He considers the extra-peritoneal method of operation alone admissible, and advises a free exposure of the organ to facilitate the removal of fragments of tuberculous tissue, as portions of a cyst wall, of the pelvis, and the ureter. He prefers the lateral oblique incision, joining with it, if needed, above or below, transverse incisions running toward the spine. To prevent slipping of the ligature it was found advantageous to allow a small piece of the kidney to remain, to be subsequently removed. The ureter is severed as low as possible, and the deep wound is closed with catgut sutures. Tampons of iodoform-gauze were used to fill the cavity. The wound healed kindly, but fistulous tracts remained for three-fourths of a year and one and a quarter years respectively, but finally also healed. Madelung believes that the convalescence of his cases was materially aided by continued internal treatment with creasote.

Little can be learned from the literature regarding permanent cure by this operation. Madelung collected sixty cases, reported since 1872, most of them from American and English literature. Eleven cases died immediately after the operation, and five in the first five months subsequent to the operation. The number of cases reported as permanently benefited is very small. Bardenheuer has obtained the best results. Four cases of nephrectomy, though operated on at an advanced stage of the affection, with the vitality considerably reduced, were living at the time of his communication, free from suffering, and in a condition justifying the hope of a permanent cure. It is a peculiar fact that the quantity of urine voided, increased shortly after the operations.

The author then adds a detailed report of the four cases of nephrectomy and one of nephrotomy in which nephrectomy was performed later on by Prof. Thierfelder. They were all women, in the second or third decennium of life, all permanently confined to bed, and in such a condition that death seemed imminent.—*Archiv für klinische Chirurgie*, vol. xli., No. 2.

CASE OF HÆMOGLOBINÆMIA AND HÆMOGLOBINURIA FOLLOWING INTRA-UTERINE USE OF CARBOLIC ACID.

RICHARD KRUKENBERG reports the case of a woman, twenty-eight years old, who had borne three children and was under observation for threatened abortion. After a chill, an embryo of two months and part of the membranes were cast off. The patient was pale, completely conscious and without special complaint. The pulse was 96 and regular, respiration not accelerated; the heart showed signs of a compensated mitral insufficiency. Chloroform was given, and the uterus curetted; about one and a half tablespoonfuls of membranes were removed, one little piece being greenish-gray. The uterus was then washed out with a 2.7 per cent. solution of carbolic acid, Olshausen's modification of Bozeman's catheter being used. The eyes of the catheter became plugged with particles of tissue. About one quart and a quarter of the fluid was injected, when the pulse became small, and then ceased. The douching was immediately stopped, the uterus expressed bimanually, and the woman, who was pale and cyanotic, placed horizontally. The pulse, when it returned beat 100–112 per minute, two strong beats being followed by a weak one. Artificial respiration was necessary. The pupils were small and did not react; the extremities were flaccid, without tremor or spasm. The lungs became œdematous. After the deep coma had lasted two hours, it yielded gradually to the employment of powerful analeptics and irritants to the skin; but the intellect remained clouded. The patient muttered unintelligibly, was restless, breathed stertorously, and presented a pale, cyanotic face, covered with cold sweat. Two hours after the douching the bladder was emptied of five fluid-ounces of urine, dark blood-red in color, resembling raspberry juice. It smelled of carbolic acid, and after being filtered had a specific gravity of 1021. The fluid contained albumin, peptone, and 0.262 per cent. carbolic acid, estimated as tribromphenol in the acidulated distillate of the urine. The normal quantity of carbolic acid in the urine, according to J. Munk, is 0.0034 per cent. Spectroscopic examination demonstrated the presence of oxyhæmoglobin, with characteristic absorption bands in yellow and green. The reaction of the fresh urine was acid, the specific gravity when unfiltered, 1024. On boiling, and with addition of acetic acid, there was a blackish-brown precipitate, which after standing a day filled one-third of the glass. Hæmin crystals were obtained from the sediment, and Heller's test for blood gave a positive result. The sediment also contained red blood-cells, epithelium, no casts, but golden-yellow clumps, partly firmly granular and partly homogeneous.

About four hours after the abortion the patient regained consciousness, complained of great weakness, and with difficulty expectorated a profuse, frothy mucus. During the night she had a brown stool, and urine involuntary passed. She was delirious, and so restless that the moist pack ordered for her had to be removed. Toward daybreak it was noticed that she was very much jaundiced. The urine (one-half to three-quarters of a quart) was raspberry-colored, but unfortunately was thrown away. On the following day, the temperature was 98°, the pulse 110; there was sensitiveness over both kidneys and the spleen; the spleen was enlarged. The patient complained of headache, great weariness, loss of appetite, and frequent desire to urinate, with pain on micturition. A day later considerable swelling of the liver was detected. The jaundice continued, with the diffuse catarrh of both lungs. There were slight chills. The jaundice slowly disappeared, the catarrh persisted, the swelling of the spleen increased, while signs of peritonitis and of œdema were entirely absent. The urine contained a few red and numerous white blood-cells, much-clouded kidney epithelium, very few epithelial casts, but extraordinarily numerous and large hæmoglobin cylinders, yellowish-red to

golden-brown in color. The patient died in coma, following a uræmic attack. The highest temperature observed was 102.1°. The pulse shortly before death remained under 100.

The following symptoms were prominent: 1. Oliguria (seven ounces of urine in twenty-four hours as the maximum), which increased almost to complete anuria. 2. Complete anorexia; violent vomiting, which made nourishing in the usual way impossible; the vomitus smelled decidedly ammoniacal. 3. Brownish, scanty discharge of foul odor from the vagina.

The autopsy confirmed the clinical diagnosis. The author reviews other cases that have been reported, and expresses the opinion that the symptoms produced were due to a specific toxic action of the carbolic acid, which decomposes the hæmoglobin and the red blood-cells. Krukenberg, nevertheless, concludes that when the necessary precautions are used, carbolic acid is the most serviceable intra-uterine antiseptic, and the one to be preferred to all others. —*Zeitschrift für Geburtshülfe und Gynäkologie*, Bd. xxi., Heft 1.

DISTURBANCES IN METABOLISM FOLLOWING LONG-CONTINUED CHLOROFORM NARCOSIS.

CHRONIC chloroform poisoning has been noted by Casper, Langenbeck, and Behrend, but their cases have attracted but little attention. Nothnagel, in 1866, experimented upon dogs, and after death was able to demonstrate fatty degeneration of the heart and liver.

Professor A. Kast and Dr. B. Mester refer to these early cases and to Nothnagel's experiments, and also to the much more recent experiments of Ungar, Strassmann, and others. One of them had previously investigated the influence of chloroform narcosis upon the excretion of chlorides in the urine. The chlorides were found to be increased, the animals exhibited a series of disease symptoms, and failed in nutrition and weight, in spite of the fact that both before and after narcosis they were kept upon meat food freed from chlorine. The inference is that chloroform effects a toxic disturbance of nutrition.

Kast and Mester, struck by the analogy of the excretion of the chlorides as an after-effect of chloroform-narcosis to the chlorine tissue-change in other severe disturbances of metabolism, turned their attention to the excretion of the sulphurous substances in the urine. They examined the urine of fifty or sixty women shortly after chloroform narcosis in the Freiburg gynecological clinic, and that of ten other patients from the surgical clinic. The urine was examined qualitatively and quantitatively for sulphur compounds. About thirty control tests were made. Unoxidized sulphur was found to be increased largely. This is regarded as showing the profound effect of prolonged chloroform narcosis on the metabolism of albumin. As to the duration of this metabolic change, the urine showed the lead reaction for sulphur in one case as early as an hour after the chloroform narcosis, which had lasted two hours; usually it is detected on the second day, and in one case it was present on the fifth day. The duration of the increased excretion of sulphur-holding substances coincides pretty accurately with the duration of the well-known reducing properties of chloroform urine.

As to the nature of the sulphur compound, Kast and Mester believe it to be cystin, or a body resembling it.

Urine, under the influence of chloroform narcosis, becomes highly acid, due apparently to the considerable quantities of chlorine, which occurs in the form of hydrochloric acid.

The conclusions of Kast and Mester are as follows:

1. Chronic chloroform poisoning, that is to say, the toxic action of large doses of chloroform, given either internally or by prolonged inhalation, is recognizable both in animals and in men.

2. It manifests itself by a fatty degeneration of the the organs. There is a lessening of the body weight, an increased excretion of chlorine (Kast), and of oxygen (Strassmann), showing an increased consumption of albumin in animals. In man, as the result of prolonged chloroform narcosis, a sulphur compound, resembling cystin, is thrown off in considerable quantity. There is also a constant and more or less considerable urobilinuria.

3. In relation with the form of excretion of the received chloroform stand—(1) the reducing property of the urine through the formation of a glycuronic acid combination, and (2) the considerable increase in the acidity of the urine following chloroform narcosis.—*Zeitschrift für klin. Medicin*, Bd. lxxx., Hefte 5, 6.

LEUKÆMIA IN AN INFANT.

ORTNER (*Jahrbuch für Kinderheilkunde*, Bd. xxiii. Heft 3, 1891) reports the case of a female child, eight and one-half months old, always pale, who was seized, four or five months before coming under observation, with diarrhœa and vomiting, followed by emaciation and increasing pallor. For two months a progressive increase in the girth of the abdomen had been noticed, especially marked at its upper part and on the left. The mother of the child had borne nine other children, of whom six had died at ages varying from eleven to eighteen months, with symptoms of gastro-intestinal catarrh, all having been pale, feeble and rhachitic. There had been no miscarriage or premature labor. The first child, fifteen years of age, presented evidences of past rhachitis. While nursing the second child, together with another infant, two ulcers formed on one of the nipples, but no secondary phenomena were observed. The strange child was said to have had a cutaneous eruption and died before it was a year old. The mother's own child presented nothing abnormal. The third child, born twelve months after the second, died when it was twenty-one months old, it was said, with an enlarged spleen. Of the remaining children, the sixth and eighth, six and four years of age respectively, were living, but anæmic and presenting evidences of rhachitis.

The child was small, poorly nourished, pale, the

skin wrinkled, the temperature normal; pulse, 128; respiration, 28. The fontanelles had not closed and the occiput yielded to pressure. The prominences on the cranial bones were marked, the teeth were absent, the epiphyses of the long bones were thickened. There were no evidences of syphilis. The area of hepatic dulness extended two fingers' breadth below the costal margin in the nipple line. The lower border of the right lobe of the liver was palpable. The spleen was perceptible as a palpable tumor, extending almost to the crest of the ilium and the median line. The lymphatic glands in the groins, the axillæ, the supra-clavicular fossæ and behind the angles of the jaw, were firm, but not much enlarged. No parasites or ova were found in the stools. The red blood-corpuscles were pale, small, ill-shaped and not disposed to form rouleaux. There were 2,495,000 red and 166,000 white corpuscles to the cubic centimetre, 1:15. The hæmoglobin was estimated at 55 per cent. The eye-grounds were anæmic. Treatment by inhalations of oxygen was instituted. The spleen and the lymphatic glands increased in size. Two months after admission to the hospital, lobular pneumonia developed, together with submucous and subcutaneous hæmorrhages, and death resulted in a few days from collapse.

The autopsy disclosed, in addition to the evidences of rhachitis, lobular pneumonia, parenchymatous nephritis and fatty degeneration of the heart, decided enlargement of the spleen, slight enlargement of the liver and swelling of the mesenteric, inguinal and axillary glands. Sections of the spleen showed irregular extravasations of blood and the presence of an excessive number of lymphocytes, with an increase of the cellular elements of the Malpighian bodies. The cortex of the kidneys contained numerous areas of small-celled infiltration; the vessels were distended with blood; there were changes in the glomeruli and tubules. There was an abundance of cells in the cortical follicles of the mesenteric glands, the lymph sinuses being crowded with round cells. The follicles of the small intestine were enlarged.

THERAPEUTICS OF ERYSIPELAS.

GOTTSTEIN refers to a communication of his published in the *Therapeutische Monatshefte*, March, 1889, in which he adduced proof that, contrary to the accepted opinion that antiseptics dissolved in fat lose their activity, corrosive sublimate in combination with lanolin preserves its disinfecting properties. Wenderoth has compared the effect upon anthrax bacilli of a mixture of sublimate, lanolin, and vaseline, and of one containing sublimate and olive oil. The proportions of the former were as 1 to 1000. The sublimate and olive oil destroyed the anthrax bacilli in a time between thirty-three minutes and two hours, while the sublimate and lanolin accomplished the same result in from nineteen and a half to twenty-six and a quarter hours; as it takes so long, however, it cannot be reckoned among the active disinfectants. Moreover, it was found by Wenderoth that an older mixture loses its strength in course of time; it may be that the bichloride becomes decomposed gradually into calomel.

These results of Wenderoth in part conflict with those of Gottstein; the latter suggests that the reason may be found in the different management of the experiment.

Wenderoth's experiments in the treatment of erysipelas with sublimated lanolin are more important and of general significance. The erysipelatous portions of the skin, and also a part of the skin bordering upon them, were generally covered twice a day with a thick layer of the sublimated lanolin, over which cotton is laid. There was no internal treatment, except the administration of wine. Of the ten cases treated by Wenderoth in the manner described, all but two were characterized by the limitation of the erysipelas to the affected parts, and by a short duration. In one of the two exceptional cases, the erysipelas had attacked both arms, and the general symptoms were severe. On the seventh day there was a decline. In the second case, in spite of the treatment, the erysipelas extended beyond the buttocks, and was checked on the thirteenth day with injections of corrosive sublimate.

Gottstein has treated a case with the sublimated lanolin. The patient was a woman fifty-six years old, who had suffered severely several years before, and for a long time, with facial erysipelas. She was taken ill with high fever and severe general symptoms, such as delirium. The next day there was erysipelas of the right side of the face and a temperature of 103°. The sublimated lanolin was energetically applied. The next day the temperature was 100.5° and the erysipelas was subsiding. On the third day the temperature rose again to 102.3°, owing to involvement of the scalp. On the fourth day the temperature fell to 97.4°, and convalescence began. The patient was out of bed in eight days from the beginning of the attack.—*Therapeutische Monatshefte*, April, 1891.

A CASE OF PURULENT PERITONITIS CURED BY ABDOMINAL SECTION.

HENOCH (*Berlin. klin. Wochensch.*, January 26, 1891) has reported the case of a girl, four years old, without hereditary taint, admitted to his clinic with vomiting, colic and diarrhœa, which had existed for a month, and a temperature of 101.8°. In a few days the abdomen became distended; the pallor and emaciation increased. The child lay still, with the legs drawn up, movement giving rise to pain. A little above the umbilicus, fluctuation was detected over a limited area. Percussion dulness was more extended. The diaphragm and the heart were displaced upward. By an exploratory puncture a little thin pus, containing no bacilli, was removed. Through an incision, an inch long, between the umbilicus and ensiform cartilage two quarts of thin pus, mixed with coagula, were removed, and drainage provided. Uninterrupted recovery ensued. Henoch did not believe the peritonitis tuberculous, not only from the failure to find bacilli but also from the acuteness of the attack and the rapidity and completeness of recovery.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

SATURDAY, JUNE 20, 1891.

THE ANTAGONISM BETWEEN MICROÖRGANISMS AND THE TREATMENT OF INFECTIOUS DISEASE.

THE first attempt to diminish the virulence of pathogenic microörganisms by the antagonistic action of other microörganisms was made by PASTEUR, who, by inoculating fowls with the virus of chicken-cholera, rendered them resistant to anthrax. FEHLEISEN, NEELSEN, CANTANI, PAVONE, PRIMROSE-WELLS, BABTCHINSKI, HEER, and others have since adduced a number of experimental and clinical facts which are rather favorable to the therapeutic application of the antagonism between microörganisms. An analogous antagonism is seen in the higher forms of vegetable life, as evidenced by the crowding out of some plants by the growth of other varieties and the tendency of forests to present more or less uniformity of kind, in spite of the fact that the soil may be quite as fertile for one variety of forest-growth as for another. The subject has received attention at the hands of BOINET (*Bull. Gén. de Thérap.*, September 30, 1890), who has studied the action of the yeast of beer upon the development and virulence of the bacilli of typhoid, of anthrax, and a number of other pathogenic bacteria. Observations were made upon tube-cultures of the microörganisms, and were to a certain extent supplemented by inoculations of animals with the mixed growths. Culture of the yeast grown with typhoid bacilli caused a notable alteration in the morphology of the latter, the individual bacilli growing to abnormal lengths, with a tendency to a wavy outline; these peculiarities were also apparent in subsequent generations. Anthrax bacilli suffered little change, except possibly a diminution in length. Both in culture and inoculation experiments the presence of the yeast appeared to exert an exaltative influence on the bacillus pyocyaneus, increasing its rapidity of growth and its virulence in the body. While it cannot be said that the experiments of BOINET have yielded any positive results clinically, it is certain that the association of yeast with pathogenic microörganisms does not heighten their virulence, while there is evidence of a diminution of activity of the infectious agent. For example, while ordinarily in anthrax the liver is found to contain large numbers of bacilli, but few could be found in the livers of animals dead after inoculation with the mixed growths. In typhoid fever, more positive favorable results were obtained in 1888 by HEER (*Deut. med. Zeitung*), who succeeded in modifying the diarrhœa by the internal administration of commercial beer-yeast. He also records having favorably influenced patches of thrush and diphtheritic deposits by local applications of yeast suspended in glycerin.

The antagonistic action of microörganisms among themselves is frequently witnessed in the laboratory, although in these attempts at isolation by natural selection absolute purity of growth is rarely obtained, because the necessary conditions are wanting. Clinically, little study has been devoted to the results of the coincident occurrence of infectious diseases to determine whether the intensity of one or the other is diminished or exaggerated. In WOODWARD'S study of the relations of the malarial and typhoid infections, as presented in the medical records of the late war, it is recognized that malarial infection modified the severity of the attack as well as the mortality of typhoid fever, as compared with the course and termination of the ordinary type of typhoid fever as seen during the same time and under the same external conditions. Moreover, in the absence of knowledge of the nature of the antagonistic influences, the clinical and experimental value of alcohol—a product of microörganismal activity—in the suppression and extermination of infectious agents may be cited in justification

of the line of thought suggested. It is not at all impossible that substances analogous to alcohol may be produced which, if properly understood and employed, may have a wider field of applicability in the control of disease. It is possible that the overpowering of one bacterial growth by another is due to the elaboration of some such controlling agent, although the same result may be due to excessive growth and the effects of crowding. Whatever the method, this suggestion offers a line of study promising to be of no little importance in combating disease. The modification of a severe type, rendering it less severe, if not eradicating it entirely, cannot but lead to the most positive and widespread benefit, especially in the management of epidemics. Non-pathogenic microörganisms, as those contained in the yeast employed by HEER and BOINET, should first be studied. The results may only partially succeed in diminishing the virulence of the graver infections, but even the negative knowledge thus derived is not unlikely to prove of value in relation to exposure to infection; positive results would in the highest degree be satisfactory to those who strive to attain the ideal in the management of infectious diseases—that is, their eradication.

THE CART BEFORE THE HORSE.

IN his "Plea for the Scientific Study of Insanity" (*Brit. Med. Journ.*, May 30, 1891) DR. TUKE tries to rally the materialists for another charge against the strongholds of the well-entrenched enemy. "All insanities are symptoms of morbid conditions of the brain," is the text of the discourse. But the author's bitter complaint against the indefiniteness attending all research into the etiology of depraved mental states will hardly be overcome either by the histological or the gross anatomist. It will be a long day or two before the microscope or the dissecting-knife reveals the supposed lesions of mental disorders. It is superb effrontery to claim as scientific only the investigation that starts out with the assumption that function is the product of structure, when the developmental history of every organ and every organism in the world is a crying demonstration that function always precedes structure. It takes tendency and purpose, or, in other words, mentality, a long time to create its instruments that we call organisms, and then the gentlemen who loathe teleology gather about the mechanism and say that the tool made the toolmaker. Before founding the pathology of mental disease upon a crude bit of dogmatic deduction the would-be psychologist should answer two questions: 1. Is the pseudopod of an amœba an organ or not? and, whether the question be answered affirmatively or negatively, 2. Does the pseudopod create the desire of locomotion or does the desire create the pseudopod?

A SIGNIFICANT QUESTION.

THOSE who have been given to thinking that women are incapable of competing with men for the highest intellectual acquirements and prizes have been repeatedly startled during late years to learn, especially from England, of the astonishing success of young women in competitive examinations in fields of study and research deemed especially preëmpted by the masculine mind.

There have been few young modern medical students who have given more brilliant promise of future fame than DR. ADELE MCCULLOCH KNIGHT, of South Australia. Honors, prizes and distinctions came to her as if spontaneously. She has just died at Vienna at the age of twenty-five. One cannot help wondering if, under the intense stimuli of a noble ambition, a laudable rivalry, and a fervent love of science, such mental development or acquirement is not the sad evidence of the prodigal expenditure of a life's vital revenues in a few brief, splendid years.

In one of the great cities of the Eastern United States it is a subject of common and eulogistic remark that the course of study is more thorough and the examinations more rigorous in the Women's Medical College than in the other prominent and dignified colleges for men. "In a competitive examination the girls will whip the boys every time." But among these noble girls has there not possibly been over-strain? Does there remain the strength to wrestle with Life?

COMMISSIONS BY DRUGGISTS TO PHYSICIANS.

ACCORDING to the President of the California State Medical Society the sentiment of self-respect and professional honor among apothecaries and doctors must in California, and especially in San Francisco, be at low ebb. It appears that the most impudent boldness in percentage-giving and taking is very prevalent. Prescriptions are sealed in

envelopes, telephoned directly to the drug-store, or written in cipher, outrageous prices being demanded from the patient in order to pay the doctor from 30 to 75 per cent. It is hard to believe that men can stoop to such wretched practices. In the Eastern cities, if the custom exists at all, it is well concealed or so sugar-coated that it becomes a far more delicate proceeding. Essentially, of course, there is no difference in morality between taking an expensive Christmas present and having in the druggist's shop a lock-box of which the physician alone has the key, and in which is deposited a dollar for each prescription received. It is gratifying to know that with us even the complimentary gifts are rarely offered or received. We have heard of a druggist who was greatly surprised to find himself credited by a hospital report as the donor of much fine cologne and toilet sets galore. The doctor had considered himself as only the transfer agent.

THE LONDON HOSPITALS AND CONVALESCENT HOMES.

FROM the *Lancet* Hospital Sunday Fund Supplement we learn the extent of the medical charitable work done in the care of the sick of the great metropolis. During the year 1890 the average number of beds daily occupied was 6143, and the total number of in-patients received was 78,033. The number of out-patients' visits reached the enormous total of 1,158,026. This entire work was done at an expense of $3,031,290. An interesting and peculiar phase consists in the convalescent homes, of which some 15,000 patients enjoyed the benefits. It is a matter of regret that in the United States we have nothing corresponding to this excellent system. A patient lingers on during the long weeks of slowly increasing strength, in close intimacy with all forms and degrees of illness about him, depressed by unpleasant sights and sounds, at a time when the condition of the mind must powerfully exercise an influence upon nutrition and the restoration of vitality. A change to more agreeable surroundings would often be of double service to the over-crowded hospital and to the convalescing patient.

THE SHEPPARD ASYLUM.

THE second largest private bequest ever given to found a hospital for the insane was that of MOSES SHEPPARD, of Baltimore, who in 1857 left $560,000 in trust to establish an institution for the care and treatment of members of the Society of Friends who might become insane. The trustees out of the income have expended about $880,000 in the purchase of some 377 acres of land near Baltimore and in the erection of three fire-proof buildings, each 365 feet long, from 75 to 200 feet deep, and from two to four stories high, fitted with the best modern improvements as to ventilation, heating, water-supply, etc. The original endowment fund, despite these outlays, has even been increased, and the asylum will be supported by the interest of $600,000 in well-invested securities. DR. EDWARD M. BRUSH, at present of the Pennsylvania Hospital for the Insane in Philadelphia ("Kirkbride's"), has been selected superintendent. DR. BRUSH is an alumnus of the Buffalo Medical College, graduating in 1874. As a specialist he is well known to the profession, and will bring to his new field of labor a well-trained mind and a rich experience that fit him exceptionally well for the great work he has to do.

THE DOCTOR IN THE DRAMA.

IN the new play, *Margaret Fleming*, lately produced in Boston with so much interest and success, it is pleasing to find the family physician, in a typical American home, represented as having so dignified and honorable a function. According to the playwright, he adds to his titular duty that of the old-time spiritual and moral adviser. He is the family friend, pointing out the path of duty, and encouraging the weak and erring to walk in it. Since MOLIÈRE, the doctor in the play and in real life has greatly changed both rôle and character. It becomes a question if the parson has indeed been so derelict in duty that the medical man must also assume a part of that worthy's office in addition to his own. Between city and suburban practice there is, doubtless, a difference in this respect. In village and rural life hundreds of families have no warmer or truer friend than the family doctor. The business necessities and manners of the city practitioner may bring greater rewards of certain kinds, but ——.

A NOVELIST'S ANATOMICAL KNOWLEDGE.

THE critics are advising that brilliant cometary novelist, RUDYARD KIPLING, to be a little more careful about his anatomical facts before writing his next story. One of his heroes is reported as being permanently blinded by a sabre cut on the forehead, which *injured the optic nerve*.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting of April 6, 1891.

THE PRESIDENT, WILLIAM HUNT, M.D., IN THE CHAIR.

DR. JOHN H. BRINTON presented

A TUBE FOR THE REMOVAL OF FRAGMENTS OF BONE IN LITHOLAPAXY

—a modification of that of Otis. After crushing a stone there is often difficulty in removing the fragments, partly due to the character of the tube employed. In the tube demonstrated the curve at the end was so adjusted that the instrument is flat in the bladder while the bulb is perpendicular. The tube is provided with a stylet which completely closes the fenestra.

Dr. Brinton also showed a modification of Thompson's crusher. The blades are so arranged that when the stone engages, it slips up toward the bend of the blades where the force can be most advantageously applied. The blades are short, so that the instrument can readily be turned in the bladder.

DR. JOHN B. ROBERTS related that, in one case, after breaking the stone and washing out considerable of the débris there remained a portion of the stone, which was very hard. Exerting a good deal of force on the screw, he stripped off the thread of the instrument, and, having no other lithotrite at hand, he was compelled to make an incision to deliver the remainder of the stone. In another case, there were many fistulæ in the scrotum, and one in the penis in front of the scrotum, as a result of rupture of the urethra. After opening the fistula, and introducing a sound through the urethra, a good-sized stone was detected in the bladder. The ordinary operation of lithotomy was then done, and the stone removed. The complication had not been suspected either by the patient or his physician.

DR. JOHN B. DEAVER showed a stone weighing 420 grains, removed from a child three and a half years of age by supra-pubic cystotomy. The stone was too friable for removal with the forceps, and was brought to the opening in the abdomen by a finger introduced into the rectum. The child made an interrupted recovery, and was entirely well in three weeks. At the end of two weeks the urine was passed through the urethra. The bladder wound was not closed.

DR. W. W. KEEN stated that air for injection into the bladder may be readily sterilized by passing it through a a mass of cotton placed over the end of a Davidson's syringe.

DR. NEILSON read a report of

TWO CASES OF EXTENSIVE COMPOUND DEPRESSED FRACTURE OF THE SKULL,

published in THE MEDICAL NEWS of May 30, 1891.

DR. W. W. KEEN stated that the two cases reported illustrated the results to be attained by modern methods of treatment. The introduction of the finger between the dura and the bone in searching for bleeding vessels is, of course, new. It was Dr. Keen's practice not to ligate any vessels whatever in the scalp. Hæmostatic forceps were applied and removed one by one, and the point of hæmorrhage inspected; if bleeding continued the hæmostatic forceps were replaced. Sutures were carefully introduced at these bleeding-points, the flaps were brought together, and in this way the hæmorrhage was controlled. The conditions were different when there are bleeding vessels in the dura of the brain. In such case ligatures are absolutely necessary. In the dura the circular Hagedorn needle is the best to control the hæmorrhage. The rat-tooth forceps is to be recommended for lifting the membrane. The dural vessels occasion no difficulty; the vessels of the brain are more troublesome. It is to be feared that if gauze packing be permitted to remain for eight or twelve days, it may give rise to irritation of the brain, while any advantage to be gained by pressure will be had in two or three days at the longest. Drainage is to be judiciously employed in cases in which there are bleeding-points not absolutely secure; but in ordinary operations upon the brain, after arresting the hæmorrhage, Dr. Keen has discarded drainage without resultant harm. In one case a little puffiness was noticed ten days after the operation. The introduction of a probe and the separation of the scalp were followed for four or five days by a discharge of dark, tarry-looking blood—undoubtedly the remains of a liquefied clot, which had given rise to a little local irritation and elevation of temperature. As an illustration of the possibility of danger, in another case in which the skull was a half-inch thick, drainage was continued for three days, and the tube removed; hernia cerebri was nevertheless threatened.

In any subsequent case in which it became necessary to remove a portion of the dura leaving an opening in it, Dr. Keen proposed to take a portion of the scalp sufficiently large to close the dural opening and secure it in such a way as to overcome the tendency to hernia cerebri.

DR. NEILSON concluded by stating that the criticism of Dr. Keen was based upon a misconception. The time at which the iodoform gauze was removed was from the fifth to the eighth day, not from the eighth to the twelfth. His experience had been wholly with cases of severe injury, in many of which the brain was lacerated, and in these cases drainage seemed safest, as a provision for the escape of blood and other fluids.

Adjourned.

Meeting of May 4, 1891.

THE PRESIDENT, WILLIAM HUNT, M.D., IN THE CHAIR.

DR. JOHN ASHHURST, JR., reported a number of cases in which he had performed

OPERATIONS UPON SOME OF THE LARGER NERVES.

In several cases he had sutured nerves as a primary operation. In one case of excision of the elbow-joint, the parts were so distorted and matted together that section of the ulnar nerve was unavoidable. The cut ends were immediately sutured, and the patient recovered with a limb as useful as if the nerve had not been divided. We are all familiar with the advantages of suturing nerves as a primary operation, but there is still doubt on the part of some surgeons as to the advantage of secondary suture. In the case of a young man, in whom the median nerve and the tendon of the flexor carpi radialis

muscle had been divided by a wound received some months previously, with paralysis and trophic changes, the ends of the nerve were freshened and brought together with catgut; the divided tendon was also united. The hand was dressed in the position of extreme flexion. The wound healed without complication and the function of the part was restored. An interesting point was that the restoration of function began at a period earlier than at which we could ordinarily expect to have regenerative changes take place. It is possible in cases in which secondary suture has been attended by such a favorable result, that the preceding degenerative changes, which take place principally in the proximal ends of the nerve, have gone on until they are already so far advanced that the subsequent regenerative changes commence so soon as the restoration of continuity is established. Whatever the explanation, it is a fact that the function of nerves is sometimes restored at a very early period.

In cases in which, on account of loss of tissue or retraction, it is not possible to bring the ends of the nerve together, various other means have suggested themselves. One is to unite the distal end of the divided nerve to another nerve. Another plan is to split the cut ends of the nerve in such a manner that they may be spliced by turning down a section from the proximal portion and uniting it with a section turned up from the distal portion. Still another plan is the introduction of a graft of nerve from an amputated limb or from a lower animal. One other ingenious plan is to introduce a decalcified bone tube between the ends of the nerve; it has been found that by doing this, the nerve tissue may be prolonged in the calibre of the tube. An analogy to this can be found in sponge-grafting. As is well known, by introducing properly prepared sponge, a wound can be induced to fill up by granulation more rapidly than otherwise. The influence appears to be mechanical, a skeleton being furnished on which the granulations can spread. This operation might be resorted to in any case in which nerve-grafting was required, but in which a natural graft was not available.

Dr. Ashhurst then spoke of cases in which operations had been performed for the removal of tumors from nerves. Two cases of the so-called "painful subcutaneous tubercle," believed by the majority of writers to be a true neuroma, were entirely cured by operation. The large majority of cases of neuroma in stumps are fortunately not painful, but when they are, and the pain can be localized in a single nerve, excision may be resorted to. He had recently had occasion to remove a large neuroma of the kind called "false neuroma," from the popliteal nerve. The tumor was as large as a hen's egg and situated between the branches of the nerve in such a way that it was a matter of some difficulty to remove it without partial division of the nerve itself. The patient made a complete recovery. One point of interest as regards these tumors is as to the diagnosis. They can be moved readily from side to side, but not longitudinally.

Dr. Ashhurst reported eight cases of nerve-stretching, or as the French call it, elongation of nerves. In three cases the musculo-spiral nerve was stretched, having been exposed just above the bend of the elbow. The first case was that of a middle-aged woman with traumatic neuralgia. The operation gave entire relief, but only for a time. Afterward, the pain recurring, neurectomy was performed at her own request. She was permanently relieved of pain, although, of course, paralysis of the parts supplied by the radial nerve resulted. The second case was one of tetanus in which the musculo-spiral and median nerves were stretched, but without benefit. The third case was one of traumatic paralysis. In a case in which the median nerve was stretched for traumatic neuralgia the operation was successful. After stretching nerves, the parts around the wound are for a few days extremely tender. Such was the case in this instance, but the neuralgic pain did not recur so long as the patient was under observation.

Upon two occasions Dr. Ashhurst had stretched the nerves of the brachial plexus. In a case of so-called "concussion" of the brachial plexus in a sailor, there was not only brachial paralysis but also intense neuralgia of the upper extremity. The plexus was exposed in the axilla, and the six principal nerves were stretched. The patient was much relieved by the operation. There was certainly less pain. In another case, in a young man of rather deficient mental powers, there was a history of intense neuralgia of the arm, resisting all medical treatment, and said to have followed a twist of the arm some years before. The patient experienced great relief from the operation and considered himself almost entirely well. In two cases, Dr. Ashhurst had stretched the sciatic nerve for sciatica. One was in a neuralgic female, and although the pain was relieved on the affected side it recurred in the course of the nerve upon the opposite side. This bears out the observation of other surgeons that in cases of idiopathic neuralgia there is not so much to be hoped from the operation of nerve-stretching as in traumatic cases. In a second case, the patient considered himself much benefited by the operation.

It is interesting to observe the profound shock to which stretching of large nerves gives rise. In cases in which, for instance, the sciatic nerve is stretched, the patient suffers from shock to a degree out of all proportion to the severity of the proceeding. This tends to confirm the view that the influence of nerve-stretching is not only local, by breaking up interstitial adhesions, but that it also operates upon the central nervous system, and in some cases is reflected to the corresponding nerve of the opposite side. In the operation of stretching or elongation of nerves, the amount of force to be applied should be sufficient to lift the limb from the bed. The nerve is first drawn upward, then downward; then the whole limb is, for a few seconds, lifted and suspended by the nerve. Such an amount of force is safe in dealing with such nerves as the radial, the ulnar, the median, or the sciatic, but would not, of course, be safe in dealing with very slender nerves. After the operation, the nerve should be restored to its place, and primary union of the wound encouraged.

Neurotomy, or simple section of a nerve, is not often employed at present, since its effect is only temporary, the ends of the cut nerve usually reuniting at an early period. Neurectomy, on the other hand, in suitable cases, may be properly resorted to with considerable freedom. In one case referred to, in which elongation had failed, a portion of the musculo-spiral nerve was excised; a permanent cure was obtained. In four cases Dr. Ashhurst had resected

portions of the inferior dental nerve for neuralgia; in three of these the results were perfectly satisfactory. In one instance only temporary relief was afforded; in this case it was noticed at the operation that the nerve was enlarged and apparently inflamed. The patient returned a year afterward, when the lower jaw was found to be the seat of an extensive epithelioma, a sufficient explanation of the origin of the neuralgia. This case is interesting as illustrating the fact that malignant disease may give rise to rational symptoms before the physical signs of its presence can be detected. At the time of the operation there was no reason to think that the patient had a malignant growth.

In a case of painful convulsive spasm of the trapezius muscle in a middle-aged woman, Dr. Ashhurst resected the spinal accessory nerve. The operation effected a temporary cure. After a time the spasm returned, but was not so painful as prior to the operation. This is the usual history of such cases. The operation is, however, justifiable, though the result be but temporary.

Resection of the superior maxillary nerve has been performed in a number of cases, and in some with good results. Dr. Conner some years ago collected thirteen cases, in seven of which the pain recurred after a shorter or longer interval, while two of the others had not been under observation more than one year. Dr. Dennis has more recently collected a larger series of cases, in which more or less benefit resulted in sixteen out of twenty-one. The operation is a proper one in suitable cases. It consists in shaving off the nerve beyond the ganglion of Meckel. The suggestion has been made that the Gasserian ganglion should be removed. This has been done by Mr. Rose by removing the upper jaw and trephining over the foramen ovale. In this case destruction of the eye followed, and enucleation became necessary. The patient recovered from the operation, and at the end of six months was still free from pain. In the discussion which followed the reading of Mr. Rose's paper, the suggestion was made that possibly all the good attained might have been accomplished by excision of the upper jaw without opening the skull. So many branches of the nerve would have been severed in this operation that it is probable that relief, at least for a time, would have been given. Such an operation would be analogous to that suggested by the late Dr. S. D. Gross, who found that neuralgia of the alveolus in edentulous persons was relieved by removal of the alveolus itself. Dr. Ashhurst had himself employed this procedure in two cases with satisfactory results. The operation consists in simply laying open the soft parts, and with gouge-forceps cutting away the alveolus. Somewhat analogous, too, are those cases of neuralgia of the metatarso-phalangeal articulation relieved by excision of the joint, which Dr. Morton has reported. In the same way it is conceivable that, ingenious as was the operation of Mr. Rose, the same result might possibly have been secured by removing the upper jaw.

Dr. Abbe has extended the ordinary operation of neurotomy for cervical neuralgia, in one case, by removing the vertebral laminæ and cutting the roots of the nerves. The wound healed, but the patient was not relieved of the pain. Another operation consists in freeing the nerves from external pressure. It is now a good many years since Ollier relieved a patient by removing a mass of callus which pressed upon a nerve. This operation has been repeated a number of times. Sometimes the pressure was due to a cicatrix and sometimes to bone. In the case of a child on whom osteotomy had been performed by another surgeon for bow-legs, it was noticed sometime after the operation, when the parts were entirely healed, that the toes of the right foot were drawn down, apparently from paralysis of the extensors. Subsequently an ulcer had formed on the end of the great toe. The flexor tendon of the toe had then been divided and a splint applied. Afterward the patient dragged the foot when he walked; very slight pressure caused sloughing. Three months subsequently, when the patient came under the care of Dr. Ashhurst, the great toe of the right foot could not be raised, and blisters were constantly forming on the toe and heel; the tibialis anticus did not respond to electrical stimulation. It was suspected that the anterior tibial nerve might have been divided in the original osteotomy, but this did not seem likely, because the symptoms had not developed until two months after the operation. Exploration showed that an exuberant mass of callus had formed, pressing upon and binding down the anterior tibial nerve. On cutting down and freeing the nerve, it was found that in the open wound the muscles responded to galvanism. The incision was closed, and soon afterward a fair response to the galvanic current was noted. The patient progressed to recovery without any further trouble, the paralysis gradually disappeared, and the trophic changes were entirely removed.

In the case of a man in whom fracture of both bones of the left leg had been followed by marked bowing outward, there was great pain at the seat of the fracture, and in the ankle, referred to a spot one and one-half inches external to the spine of the tibia. Cutting down upon the tibia, an enormous mass of callus was found, and cut away with great difficulty. The nerve was pressed upon and displaced by this mass. The patient is still under treatment, but has had no pain since the operation; there is every reason to hope that he will recover with a useful limb. These cases are particularly interesting, because in them good can be accomplished without concomitant evil. In neurectomy there is always a risk that the operation will impair the utility of the part, even if it gets rid of the pain.

DR. THOMAS G. MORTON reported a case of

FRACTURE OF THE PATELLA, IN WHICH THE FRAGMENTS WERE APPROXIMATED BY CATGUT; RECOVERY WITH OSSEOUS UNION AND UNIMPAIRED FLEXION AND EXTENSION.

H. F. D., thirty-two years old, fractured the patella by falling from a car, striking the flexed knee upon the ground. There was considerable pain and intra-articular effusion. The limb was placed upon a straight posterior splint and cooling lotions were applied. Five days later a vertical incision six inches in length was made in the median line directly over the patella, exposing the fracture, which was found to be nearly transverse; between the broken surfaces were shreds of the torn extensor tendon, which would have formed an effectual barrier to the apposition of the fragments by any external apparatus. After being drilled in three places, the fragments

were closely approximated and secured by large catgut tied over the upper surface of the patella. A gut drain was inserted and brought out at the upper end of the wound, which was closed by interrupted gut sutures. The limb was again placed upon the straight splint and elevated. The subsequent history was uneventful: there was not an untoward symptom. The dressings were changed four times—first on the seventh day, when the wound was found entirely closed; on the forty-seventh day the patient walked out of the hospital, the limb being protected by a posterior splint. At this time, four years after the accident, there is perfect bony union; flexion and extension are absolutely normal; the patient does not experience any difference in the usefulness of the two knee-joints.

DR. THOMAS G. MORTON also reported a

PECULIAR AND PAINFUL AFFECTION OF THE FOURTH METATARSO-PHALANGEAL ARTICULATION.

The patient, M. M., was twenty-two years old; at the age of fourteen he first experienced pain in the right foot; after some time the left became similarly involved. From that time to the present there have been daily paroxysmal attacks of pain. The suffering has at times been almost unbearable; it generally seemed to be produced by wearing shoes; the pain was confined to the joints of the fourth metatarso-phalangeal articulation of both feet. Removal of the affected joint of both feet was followed by complete relief.

This peculiar and painful affection of the fourth metatarso-phalangeal articulation is not uncommon, but has not received the recognition it deserves. Periodical pain is the only symptom; the suffering is very often almost intolerable. The affection is strictly local, and may be mild or severe. It commonly follows a sprain or twist of the foot or results from pressure of the shoes; it often appears without apparent cause; sometimes both feet are involved.

The occurrence of neuralgia may be understood by a reference to the anatomy of the parts. The metatarso-phalangeal joints of the first, second and third toes are almost on a direct line with each other, while the head of the fourth metatarsal is from one-eighth to one-fourth of an inch behind the head of the third, and the head of the fifth is from three-eighths to one-half an inch behind the head of the fourth; the joint of the third, therefore, is slightly in advance of the joint of the fourth, and the joint of the fifth is considerably behind the joint of the fourth. The fifth metatarsal joint is so far posterior to the fourth that the base of the first phalanx of the little toe is brought on a line with the head and neck of the fourth metatarsal, the head of the fifth metatarsal being in apposition with the neck of the fourth. Lateral pressure brings the head of the fifth metatarsal and the phalanx of the little toe into direct contact with the head and neck of the fourth metatarsal, and the extremity of the fifth metatarsal rolls above and under the fourth metatarsal.

The mechanism of the affection becomes apparent if we consider the nerve-supply of the parts. The branches of the external plantar nerve are distributed to the little toe and to the outer side of the fourth; deeply lodged between these toes are numerous branches of the same nerve, which may be unduly compressed or pinched by a sudden twist of the foot.

Great comfort, often entire relief, is afforded by the use of a soft, narrow flannel bandage, which should firmly cover the anterior portion of the foot, so as to give steadiness to all the toes and which should be tight enough to prevent any rolling or movement of the joints. A suitable broad-soled shoe, laced in front, should be worn. In many cases, however, no treatment except excision of the irritable part will be of any service, and the excision of the joint of the toe, which is readily performed and quickly recovered from, will insure a complete and permanently good result.

DR. CHARLES W. DULLES reported a case of

RARE LUXATION AT THE ELBOW.

G. C., a slight woman, twenty-two years old, fell to the floor by the tipping over of the loose seat of a chair on which she was sitting, injuring the left elbow. Assisted to her bed, it was found that there was a luxation at the elbow. Ether being administered, a dislocation of the radius forward, upward and inward, and of the ulna backward, upward and outward was made out, as manifested by the following signs: the outline of the olecranon was apparent and the process could be felt projecting backward and outward on the radial side of the humerus above the outer condyle; the head of the radius was felt, and its outline was distinctly seen resting against the humerus on its ulnar side above and in front of the internal condyle. The width of the injured elbow was increased to about double that of the sound one, and the arm was semi-flexed, with the forearm so over-pronated that the surface of the dorsum was turned toward the chest. It is well known that the forearm is strongly pronated in simple dislocation of the ulna backward and of the radius forward, which itself is a rare luxation; but in the case reported the forearm was actually twisted on its long axis, and the radius could be felt resting against the humerus above the internal condyle, on its ulnar side. The arm below the elbow was numb, and the patient suffered great pain at and above the elbow, as far as the head of the humerus.

Reduction was effected by placing the patient in the recumbent posture. Standing on her right side, the upper arm was so grasped that the humerus was firmly held near the elbow, and the forearm was flexed and rotated strongly outward until the head of the radius was opposite the external condyle; then the forearm was extended, drawn downward, and strongly drawn upon while being flexed again, when the ulna jumped into its proper place with an audible sound. All the motions at the elbow joint—flexion, extension, pronation and supination—were made, and the humerus, as well as the radius and ulna, were examined from end to end for evidences of any as yet undetected injury which might exist; but none was found. An external rectangular splint, padded with fine carded wool, was then applied and fastened to the arm, forearm and hand to the middle of the fingers. A sling completed the dressing.

The patient made an uneventful recovery, and in a few weeks could use the arm quite well. Two months after the date of injury, the condition of the arm was almost perfect, the only variation from the normal exercise of every motion being a very slight impairment of the power of flexion, so that the left wrist could not be brought as near the shoulder as the right, about half an

inch. This slight imperfection was ultimately overcome.

DR. DULLES also reported a case of

DANGEROUS SPLINTER-WOUND OF THE ORBIT.

A small boy, about ten years of age, had protruding about one-fourth of an inch from the upper right eyelid, the butt of a splinter of wood about one-third of an inch square. A short time before, while playing with some comrades, the boy had run toward a post-and-rail fence, and had squeezed rapidly between two of its rails. Immediately afterward he cried out with pain, and his comrades found that he had run a splinter "into his eye."

On examination it was found that the splinter had apparently passed through the eyelid and the inner and upper part of the eyeball, and was firmly imbedded in the bony wall of the orbit. Its direction was downward, backward and toward the median line.

After gaining the child's confidence, the fixity of the splinter was tested with the fingers and with a pair of dressing forceps. With neither of them was it possible to move the splinter. With a pair of carpenter's pliers, firmly grasping the splinter, the head steadied with the free hand, traction was carefully made upon the splinter in a line with its long axis. Torsion or rotation was avoided, in the hope of bringing away the entire splinter. I had to apply considerable force, and the splinter broke. About an inch and a half came away, leaving an unknown quantity behind.

In conference with Dr. Agnew it was concluded, from a study of the direction of the splinter and the anatomy of the parts, that the splinter might have reached the upper part of the nasal fossa. After etherizing the patient, with a pair of dressing forceps search was made high up in the nose, on a level with the inner canthus. Here a portion of the splinter was felt and grasped, and with some effort a piece of wood about two-thirds of an inch long was dislodged and brought out of the nose. On washing it, it was concluded that it could not be the entering end of the splinter; so the forceps was again introduced, and another piece, which seemed to be imbedded in the septum narium, was worked out in an opposite direction from that used in removing the former piece; on washing it and adding it to the two other pieces, it was thought the entire splinter was secured. The nose was then gently washed with a solution of borax in warm water, and the operation was completed.

The patient was put to bed with the eye lightly bandaged, after an examination which permitted the hope that the splinter had passed over the eyeball without seriously injuring it.

There was no fever and no suppuration. The wound united by first intention, and in a few days the boy was up and apparently perfectly well.

The entire splinter was about two and a half inches long and tapered from one-third of an inch square at the largest part to a point.

DR. J. HENRY C. SIMES read a paper upon

THE REMOVAL OF THE OVARIES AND TUBES,

and reported two cases. Both presented analogous symptoms demanding operation, which was, however, followed by dissimilar symptoms.

Mrs. X., twenty-seven years old. The family history was good. She had had no serious sickness; menstruation began at thirteen years of age; she was always regular and did not suffer more than usual, never going to bed. She was married at twenty-one years of age, but had had no children and no miscarriages. Her health remained remarkably good until three years ago, when she first experienced pelvic pains and tenderness over the region of the left ovary; at the same time there was a very profuse discharge of a "yellowish-greenish matter," which has continued more or less since. Shortly after the attack of pelvic pains she began to have difficulty at her menstrual periods; there was considerable pain, and the flow of blood was much increased. The latter gradually increased to such an extent that she was compelled to remain in bed a week or ten days at each menstrual period. She became much reduced in health, unable to leave her bed, and was steadily losing ground; the profuse hæmorrhage, which occurred at each menstrual period, was fast exhausting her, and she was willing to submit to any treatment which offered a chance of relief. In consideration of the previous history and treatment, there only remained the removal of the ovaries. The ovaries with their tubes were removed, some difficulty being experienced in the separation of the organs on account of dense adhesions to the pelvic fascia. The tubes were enlarged about three times their normal size; the ovaries, to the naked eye, presented nothing pathological. The uterus was very firmly bound down by adhesions. Owing to the hæmorrhage, due to the tearing of the numerous adhesions, it was thought best to insert a glass drainage-tube.

The second case was that of K. Y., twenty years old, unmarried. There had been previous good health, until two or three years ago, when there occurred an attack of pelvic pain, accompanied with vaginal discharge. Subsequently, there was painful and profuse menstruation, which continued to increase in spite of medical treatment, until the patient became exhausted. The ovaries and tubes were removed. The adhesions were less extensive than in the first case, and there was not the same difficulty experienced in the removal of the organs. The bleeding not being so great, it was not thought necessary to employ a drainage-tube. The removed ovaries presented nothing abnormal macroscopically; the tubes were increased to about three times their normal size.

In the subsequent history of these two cases it is to be noted that, although the symptoms were in both quite analogous, and the operation presented local conditions apparently similar in both, yet the course of the cases and the symptoms which developed during convalescence were very dissimilar.

In the second case reported, nothing unusual occurred —in fact, the patient made a rapid and satisfactory recovery, not only from the operation, but also from the symptoms for which the operation was performed. More than two years later she was in excellent health. Menstruation had not returned.

In the first case the drainage-tube was removed on the third day after the operation; the wound healed kindly; however, on the fourth day after the operation the patient appeared somewhat excited and evinced a desire to talk; although quite rational, her conversation was a

little rambling. This was thought to be due to the excitement attendent upon an operation done in the general ward of a hospital, and the patient was removed to a private room. Her nervous state, however, did not improve; the following day decided delirium developed. She remained in the hospital six weeks, and during that time there was no abatement in the symptoms. The insanity continued and there was some deterioration of the physical condition. The patient was now taken to an insane asylum. After two months' detention she returned home with her mental faculties completely restored, although still feeling the effects of the severe nervous shock she had experienced. Menstruation returned for the first time, quite profusely, four months after the operation; three months later there was another hæmorrhage, also quite large; and again two months later there was a slight hæmorrhage; since then there has been no more bleeding. Occasionally, a sharp uterine pain is felt; otherwise there are no local symptoms. The physical condition of the patient is good and she is gaining flesh. She states, however, that her mental condition is not what it was prior to the operation; she is not able to think as she formerly did, at times becoming very much confused; there is a great tendency to sleep; she has lost her ambition for work, and is inclined to melancholia, with much depression of spirits; reading soon tires her and she has no taste for amusement.

In comparing these two cases, symptomatically and pathologically identical, the question that naturally arises is this: Why should one case progress to recovery without a single unfavorable symptom and the other develop a most serious complication? It is reasonable to inquire: Is it possible to form a prognosis, when such analogous cases pursue such opposite courses?

In answer to the first question, it is difficult to give any reasonable explanation, except to say it was due to a peculiarity of the patient herself, a so-called idiosyncrasy, which is a confession of ignorance. The slight excess of hæmorrhage in the one case may have been a possible cause for the complication. While admitting this as a possible cause, the excess was so slight it is scarcely probable.

CORRESPONDENCE.

THE OBSTETRIC CLINIC OF THE UNIVERSITY OF MICHIGAN.

To the Editor of THE MEDICAL NEWS,

SIR: Three years ago the Regents of the University made it possible to establish an obstetrical clinic at this University, and since that time not a student has graduated from the Medical Department without having an opportunity for actual experience at the bed-side of lying-in patients, either under the supervision of myself or of my assistant, Dr. Lynds. Notwithstanding our classes are large and the students of the section make at least two examinations during each labor, there has not been a case of septicæmia during the past three years, and the patients have left the hospital each well satisfied with her treatment. The method adopted in the treatment of these cases is as follows:

The house physician keeps a list of the names and residences of all senior students arranged in sections. So soon as a patient is reported by the nurse to be in labor a messenger is dispatched to the members of the section to which that case belongs. If any student of that section has of late been assisting in post-mortem work or has been with scarlet fever patients, etc., some member of another section takes his place. For final preparation the students thoroughly scrub their nails, hands and arms with brushes, soap and water, and then wash themselves carefully with 1 : 1000 bichloride of mercury solution. They are watched by my staff to see that the examining hand does not become contaminated before the examination is made.

In the meantime the patient is given a douche of sterilized water and carbolic acid, the vulva is washed with bichloride solution and all clothes placed about the patient have been sterilized. When ready for the examinations the patient is placed upon the bed, a drop-curtain shielding her from the view of all except the attending physicians. After the presentation has reached the perineum the parts are sufficiently exposed to demonstrate the delivery. The child is washed and dressed by one of the section, under the supervision of a nurse.

After confinement the patient is given douches of warm, sterilized (thoroughly boiled) water, twice daily. Many of these patients are nursed by the students under the direction of the ward-mistress.

J. NELSON MARTIN.

UNIVERSITY OF MICHIGAN,
ANN ARBOR, June 5, 1891.

NEWS ITEMS.

THE Treasury Department has decided that a statue of the late Samuel D. Gross, which the American Surgical Association proposes to erect at Washington, D. C., may be admitted duty-free.

Parkin Prize of the Royal College of Physicians of Edinburgh.—In accordance with a bequest by the late Dr. John Parkin, the Royal College of Physicians of Edinburgh has offered a prize of one hundred pounds sterling for the best essay upon "The Curative Effects of Carbonic Acid Gas or Other Forms of Carbon in Cholera, the Different Forms of Fever, and Other Diseases." The competition is open to all nations. The essay must be written in English, and be received by the Secretary, G. A. Gibson, M.D., not later than December 31, 1892. Each essay must bear a motto, and be accompanied by a sealed envelope bearing the same motto on the outside and the author's name within. The successful candidate must publish his essay at his own expense, and present a printed copy of it to the College within three months after the adjudication of the prize.

Tulane University.—The wife of Dr. T. G. Richardson has donated $100,000 to the Medical Department of Tulane University, New Orleans, for the erection of a new college building.

Milwaukee.—The Milwaukee Clinical Society has changed its name to that of the Milwaukee Medical Society, and is endeavoring to enlarge the scope and

membership of the Society. It has elected Dr. S. W. French as President. Dr. U. O. B. Wingate as Secretary, and a board of thirteen Councillors, who have the general management. It will hold two meetings per month, on the second and fourth Tuesdays, except the months of July, August and September.

Medico-legal Society of Chicago.—At the annual meeting of the Medico-legal Society of Chicago, held at the Grand Pacific Hotel, June 6th, the following officers were elected for the current year: President, Judge O. H. Horton; Vice-Presidents, Drs. D. R. Brower and James Burry; Treasurer, Dr. Joseph Matteson; Secretary, Dr. Archibald Church.

Delaware State Medical Society.—At the one hundred and second annual session of the Delaware State Medical Society, held at Georgetown, June 9, 1891, Dr. Joseph H. Chandler was elected President; Dr. Ezekiel W. Cooper, Vice-President; Dr. William C. Pierce, Secretary; Dr. Oliver D. Robinson, Treasurer. Delegates were elected to the American Medical Association and to the Medical Society of the State of Pennsylvania. Dr. E. E. Montgomery and Dr. Mary Fisher, both of Philadelphia, read papers and were elected honorary members of the Society. The next meeting will be held at Dover.

Illinois State Board of Health and Medical Education.—The Secretary of the Illinois State Board of Health has issued the following circular to the principal teachers and to the educational institutions of the country:

DEAR SIR: There is a demand from medical teachers and young men who intend to study medicine for a literary course preparatory to the study of medicine. This demand has been met by a few of the literary institutions in the United States, and it is hoped and believed that it will be much more generally met during the next two years. The following institutions now offer science courses for students who intend to study medicine, or who intend to teach or otherwise engage in biological work: 1, University of Wisconsin; 2, University of Pennsylvania; 3, Johns Hopkins University; 4, University of Nôtre Dame; 5, Yale University; 6, Cornell University; 7, Princeton University; 8, Lake Forest University; 9, Northwestern University; 10, West Virginia University; 11, University of Kansas.

As must be obvious, such a course should be based on biology, and should include thorough work in this science, as well as in osteology, comparative anatomy and chemistry, with English, French, German, some Latin, clay-modelling, free-hand drawing, mineralogy, mathematics, thorough trigonometry, mechanics, logic, general and pharmaceutical botany, and (in the last year) psychology. It is, of course, understood that botany, being a branch of biology, should have a prominent place in the course.

The catalogues of the universities mentioned contain the lists of studies offered in their science courses.

Such a course should extend over four years. This will involve no loss or waste of time to the student. The Illinois State Board of Health now requires that students of medicine matriculating in the autumn of 1891 or thereafter must study medicine four years and must attend three courses of lectures—no two in the same twelvemonth—in order to obtain a license to practise in Illinois. This rule will apply also in some other States. The Illinois State Board will, however, recognize a thorough course in science, such as indicated above, as equivalent to two years' study and one course of lectures, thus enabling the student to enter the second class in the medical college. This makes the full time of study in the literary and medical schools six years, or two years less than is required of the student pursuing a strictly classical course. Not only will time thus be saved, but the science student will be much better prepared to enter the second course of the medical school than will the classical student to enter the first year.

The Illinois State Board wishes to make up a science course that can be recommended to any college wishing to adopt such a course, and having but little time to study the subject, I desire to enlist your aid and have your advice in the matter, so as to make the course as practical and as beneficial as possible. Will your Faculty, therefore, make out such a course as it thinks best for the purpose, and send it to the Secretary of the Board.

The demand from medical teachers and from students of medicine, having been met by some universities, must be met by all who would continue to hold a high rank as educators of young men for the work of life.

Respectfully, JOHN H. RAUCH, M.D., Secretary.

Frederick P. Henry, A.M., M.D.—The many friends of Dr. Henry will be gratified to learn that at the last commencement of Princeton College the honorary degree of Master of Arts was conferred upon him. The selection is excellent and the honor well merited.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 13, 1891.

ALFRED, A. R., *Assistant Surgeon.*—Detached from Naval. Hospital, Norfolk, and ordered to the "Fern."

STOUGHTON, JAMES, *Assistant Surgeon.*—Ordered to duty at Naval Hospital, Norfolk, Va.

YOUNG, L. L. S., *Assistant Surgeon.*—Ordered to duty at Naval Station, Port Royal, S. C.

HOCHLING, A. A., *Medical Inspector.*—Ordered as a member of Naval Medical Examining Board.

STREET, T. H., *Surgeon.*—Ordered to duty on the U. S. S. "Bennington."

WALES, P. S., *Medical Director.*—Ordered as delegate to represent the Medical Corps of the Navy, to the International Congress of Hygiene and Demography at London, Eng.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment, provided that the request for reprints be noted by the author at the top of the manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

ORIGINAL ARTICLES.

A STUDY OF THE SNOOK-HERR POISONING CASE.[1]

BY GILES S. MITCHELL, M.D.,

PROFESSOR OF OBSTETRICS IN THE CINCINNATI COLLEGE OF MEDICINE AND SURGERY; PROFESSOR OF GYNECOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF CINCINNATI;

AND

JAMES G. HYNDMAN, M.D.,

PROFESSOR OF MEDICAL CHEMISTRY AND CLINICAL LARYNGOLOGY IN THE MEDICAL COLLEGE OF OHIO.

A WEDDING dinner was recently partaken of by sixty or seventy guests at the country-house of the bride's parents, near Louisville, Ky. Within a few hours the great majority of the guests were taken ill, all presenting the symptoms of gastro-intestinal inflammation. Within a few days several died. The lives of others were prolonged for from ten to fifteen days. Six cases finally terminated fatally. The symptoms in all the cases were essentially identical, differing only in intensity. Such an occurrence would under any circumstances have attracted much professional and popular attention, but in this instance it was probably increased by the social prominence of the victims and the number of people affected. Shortly after the repast, the newly-married couple left for the North. When their train reached Cincinnati, three hours later, both were feeling ill; they concluded to remain at a hotel over night, and continue their journey the following day.

Dr. Mitchell was called to see Mr. Snook at 10 o'clock on the evening of April 15, 1891. The patient was partly undressed and reclining on a lounge. He stated that he and his wife had arrived that evening from Louisville via the Shortline Railroad, and that the motion of the train had made him ill. He complained of nausea, abdominal pain, intense thirst and a constriction of the throat. He had vomited several times while on the train, and had had one stool. Upon inquiry as to what he had eaten, he said that he and his wife had attended a reception just prior to starting, and that he had partaken freely of chicken-salad, ice-cream and cake. His wife had eaten but little, and was only slightly nauseated. While giving this recital he vomited quite freely, the vomited matter consisting mainly of water, mucus and bile. The case was regarded as one of ordinary gastro-intestinal irritation, due to the character of the food eaten, and aggravated by the motion of the train, upon which latter point the patient laid particular stress. Although the pain was quite severe, it was deemed best to assist nature in washing out the stomach and unloading the bowel. The patient was given warm water in large quantities to drink, which was immediately vomited; after which one-tenth grain calomel powders were ordered to be taken one every hour, and mustard to be applied over the stomach. Dr. Mitchell then left, promising to return on the following morning. He was again summoned, however, at 2 A.M., and learned that the patient had continued to vomit. He had had three stools, and the pain in the stomach and bowels had become so severe as to be unbearable. A hypodermatic injection of one-third of a grain of morphine was administered. At the expiration of one-half hour the patient had become easy. At 7 A.M. on the following day Dr. Mitchell was informed that the patient had slept some, but he still complained of pain, vomiting and diarrhœa. The pulse was 100, and the axillary temperature 102° F. These symptoms continued throughout the day. Milk and lime-water were ordered; also a siphon of seltzer. These were mostly rejected, while the thirst increased. The calomel was discontinued, and a mixture of bismuth and paregoric was given. In the evening the temperature of the patient was found to be one degree lower. At the morning visit, on this second day, Mrs. S. presented the same symptoms as her husband, but not in so intense a degree. Her temperature, however, was the same as his. During the day Dr. Mitchell became convinced that his patients were not suffering from an ordinary attack of biliousness, and suspicion was aroused that some irritant poison had been ingested. Careful inquiry of the patients failed to furnish any light upon this point, both firmly believing that the motion of the train had produced their illness.

On the morning of the 17th, Mrs. S. had slightly improved, but her husband was worse in every way, save that his temperature had fallen almost to the normal. It continued to fall until late in the evening, when it was found to be subnormal. Dr. Hyndman was now asked to see the case in consultation, and from this time forward he and Dr. Mitchell continued in joint attendance. Mr. Snook was then in a condition of profound collapse. He was cyanotic, his heart's action very rapid and weak,

[1] Read before the Cincinnati Academy of Medicine, June 1, 1891.

the skin bathed in a profuse cold perspiration, and the axillary temperature 96°. Strophanthus was now administered per os. This was selected instead of digitalis on account of the continued irritability of the stomach. Morphine (one-tenth grain doses) combined with atropine was given hypodermatically. Warm applications to the body, in the form of frequent mustard baths, were employed.

During the fourth and fifth days there was improvement, the stools becoming less frequent, but the nausea continuing. At this time we learned of numerous similar cases having occurred in and about Louisville, all traceable to the same wedding dinner. It was ordered that the urine and vomited matters be preserved for us, but, by some oversight, we did not obtain any for examination until the sixth day of the patient's illness. On this day, and upon several subsequent occasions, the urine, vomited matter and mucous excretions from the bowel were carefully examined by Reinsch's method, but the bright copper strip showed no signs of the characteristic deposit of arsenic.

Beginning on the third and fourth days respectively both cases exhibited a decided eczematous eruption over the arms, shoulders, face and upper portions of the chest. In the case of the lady this continued during her entire convalescence, which began about the sixth or seventh day. In the case of Mr. S. the eruption had more of a papular appearance. Under strophanthus, whiskey and a bland diet for the next few days he appeared to improve. His heart's action became stronger, his temperature remained about 100°, and his abdominal tenderness diminished. Diarrhœa and vomiting were almost checked. But the thirst, restlessness, and mental hebetude were quite pronounced. Morphine in small doses was continued. There was also decided subsultus tendinum. His urine, heretofore passed in normal quantity, was found diminished, and had to be withdrawn by the catheter. On the ninth day of his illness but four ounces were secreted. We now resorted to the hot vapor-bath, reinforced by the hypodermatic injection of one sixth of a grain of pilocarpine. The profuse perspiration which followed was accompanied by a marked amelioration of his mental condition. Three injections of pilocarpine were made at intervals of eight hours. At the end of this time the kidneys appeared to have resumed their function and secreted almost the normal quantity; but catheterization was required from this time on.

While Mr. Snook could at all times be aroused without much difficulty, his mind seemed sluggish. About the tenth day epistaxis set in. Though not profuse it reappeared daily for several days. On the twelfth day, having for three days had no stool, he was given a saline cathartic in divided doses. The resulting passages each contained a small amount of bright-red blood, evidently from the lower bowel. From this time on the bleeding continued. Its amount was small, but it was constant, and the patient, though able to answer questions intelligently, did not seem to realize that hæmorrhage was going on. His restlessness continued, interrupted only by very brief naps, and, notwithstanding stimulants, his heart's action grew more and more feeble, occasionally intermitting. These intermissions grew more frequent and the contractions weaker, until the evening of April 30th, the sixteenth day of his illness, when he died.

During the week preceding death Dr. Long, of the Marine-Hospital Service, and on the last day, Dr. P. S. Conner, saw the case in consultation with us. The coroner was at once notified of the death; upon his arrival he decided to order a post-mortem examination and a chemical analysis of the tissues. The following is the pathologists' report to Coroner Bange:

"In accordance with your instructions we have this day, May 1, 1891, made a post-mortem examination of the body of W. B. Snook. The body was that of a well-developed, well-nourished, white, adult male, of the apparent age of about thirty-five years, about 5 feet 6 inches in height, and about 160 pounds in weight. Post-mortem rigidity and post-mortem staining were well marked. On the right arm and left leg were found numerous small elevations of the skin, resembling wheals. On section the subcutaneous fat was found in good quantity. *Pleuræ:* In the right pleura about one ounce of fluid blood was found, with some extravasations of blood under the pleura. The *lungs* were normal, with the exception of slight hypostatic congestion. *Heart:* An extravasation of blood, about the size of a split pea, under the endocardium of the left ventricle, was found. The *stomach* contained about three ounces of reddish, grumous fluid. The mucous membrane was marked by hyperæmia, and there was marked extravasation of blood in its substance. *Intestine:* The small intestine in its mucous and submucous coat contained extravasated blood; the mucosa was very hyperæmic, and the solitary follicles and the patches of Peyer were swollen. The large intestine was also hyperæmic, with swelling of the solitary follicles. The *liver* was somewhat fatty. The *spleen* was slightly larger than normal, firm and hyperæmic. The *kidneys* were fatty, with small extravasations of blood under the capsule and under the lining of the pelves. *Bladder:* Marked extravasation of blood under the epithelium and in the mucosa. The *brain and meninges* were normal.

"In our opinion the cause of death was, in all probability, the ingestion of some irritant poison.

"FREDERICK KEBLER.
"E. W. WALKER."

On May 8, 1891, the following report was submitted to the coroner by Dr. Dickore, the analytical chemist:

"On Friday, May 1st, you sent me for poison-analysis the following parts of the body of the deceased Mr. Snook: 1. The stomach and its contents, in separate glass vessels. 2. The liver, spleen, heart, kidneys, intestines, a piece of rib, etc., in another glass jar; all of which I have carefully examined and analyzed for metallic poisons.

"In the spleen, the liver, the intestines, and the other parts from jar No. 2, separately examined, I have found traces of copper-combinations in sufficient quantity to be separated and to answer all chemical tests for this metal. None of this was found in the stomach.

"The analysis for arsenic by Marsh's method resulted, in the case of the liver, spleen, intestines and stomach, in producing a few little spots on white porcelain, resembling those which arsenic gives by this method; but the spots were not larger than pin-points—only two of the size of small pin-heads—and it was impossible to produce the nitrate-of-silver reaction with them; and as this is the only absolute and true test for this poison, I cannot conscientiously call these little spots a positive proof of the presence of arsenic.

"If any larger quantity of poison had been introduced into the system of the deceased, it must have been eliminated during the sixteen days of his illness by physiological processes and careful medical treatment. Very respectfully, W. DICKORE."

Thus far we have given a full account of the two cases falling under our observation. The greatest interest necessarily attaches to the diagnosis of the cause of these symptoms. The diagnosis, reached by the process of exclusion during the life of the deceased, and expressed by us, was that we were dealing with cases of arsenical poisoning. At the present time, with the additional information before us, derived from post-mortem and chemical examinations, we feel even more confidently than before that our original diagnosis was correct.

A number of explanations offered themselves. Among them were the possibility of the existence of some acute infectious disease, such as trichinosis or typhoid fever, of mushroom-poisoning, or poisoning by tyrotoxicon or other ptomaine, or by irritant minerals, such as arsenic.

The early onset and the great severity of the symptoms, together with the proof that no form of pork was used at the meal, exclude from consideration the possibility of trichinosis. Though the post-mortem lesions, so far as the intestinal tract is concerned, somewhat resemble those of typhoid fever, the almost simultaneous attack of so many persons leads us very quickly to abandon the supposition of typhoid fever, even though we have before us some resemblance to the hepatic, renal and intestinal changes occasionally following the action of the typhoid bacillus, and the resultant chemical changes due to the ptomaines.

The possibility of tyrotoxicon-poisoning naturally suggested itself. Our patients presented the nausea, epigastric pains, vomiting, and purging characteristic of the action of this ptomaine. Their pupils, however, were never dilated, and, instead of subnormal temperature, they presented fever. The lesions found post-mortem also contra-indicate tyrotoxicon-poisoning; according to Vaughan, this ptomaine produces the symptoms without the lesions of gastro-intestinal irritation. Subsequent investigation showed that those wedding guests escaped who partook only of ice-cream and coffee with cream.

Mushrooms cannot be charged with the production of the symptoms, because some of the most severe cases were those of persons who had not eaten any mushrooms.

One of the latest of the many local theories of explanation is based upon the report that, at the time of the wedding, the chickens and turkeys at the bride's home were affected with chicken-cholera, and that some fowls showing evidence of being affected with this disease were used in the preparation of the salad. The report states that parts of these chickens, which were black, were cut off and the remainder utilized. It is difficult under the circumstances to conceive of the possibility of such an occurrence. We are informed by very competent authority that, in this vicinity, chicken-cholera is almost unknown so early as April; but aware, as we are, of the rapidity with which such pathogenic germs may multiply and cause general barnyard infection, we do not care to insist upon this objection. Persons living on a farm and familiar with chicken-cholera would be the first to recognize danger from this source. The further elaboration of the chicken-cholera theory is by no means convincing. We are told that the chicken-salad left over from the wedding was examined (eight or ten days later), and that ptomaines were found. As these investigations were not begun until after the death of several of the persons poisoned, and as the material examined consisted of such remnants of the wedding dinner as were still collectable at the end of a week of warm weather, it is not at all surprising that ptomaines should be present. Being chemical compounds, formed during the putrefaction of organic substances, such ptomaines would almost necessarily exist in the refuse food a week old; but, we are told, these ptomaines were identical with those found in the chickens which died of cholera and in the stomach of one of the victims (who died eight days after the wedding). As to this, we can only state that as far as we are acquainted with the literature of ptomaines, we believe that the ptomaine resulting from the action of the chicken-cholera bacillus has never yet been isolated. There is, therefore, good ground for scepticism regarding this discovery. In the light

afforded by the symptoms, the post-mortem lesions, the chemical analyses, the fact, already mentioned, that up to the present time no such anatomical lesions have ever been observed to follow ptomaine-poisoning, and the utter absence of any reliable experimental observations upon these ptomaines (or their precedent bacilli) in man—we feel justified in saying that the application of the ptomaine-theory to this case is not tenable.

Let us now consider the theory of a mineral irritant. The history of our cases has recorded the occurrence of thirst, nausea, retching and vomiting, epigastric and abdominal pain, tenderness on pressure, severe purging, decided fever, small, irregular pulse, labored respiration, suppression of urine, great restlessness, mental hebetude, eczematous eruptions, epistaxis, hæmaturia and intestinal hæmorrhage. Many of these symptoms were manifested by both, and all by the fatal one, of our cases. No poison but that of a mineral irritant could produce such an array of symptoms and such lesions as have been described. These post-mortem conditions, found by two of the most competent pathologists of Cincinnati, led them in their report to the coroner to state that the cause of death was probably "the ingestion of some irritant poison."

Portions of the liver, kidney, spleen, muscle, brain and bone were submitted to Dr. Dickore for chemical analysis. As stated in his report, Dr. Dickore found decided traces of copper, and lesser amounts of some other substance which might possibly have been arsenic, but which was present in too minute a quantity to be absolutely determined.

It is a well-known fact that copper, like antimony, silver and lead, often remains in the organs for many months after it has been taken. Copper may be taken under so many different circumstances and in such diverse ways, and is, in consequence of its slow elimination, so frequently found in the tissues, as to lead some very able toxicologists to claim that it is one of the normal consistents of the body. It is a well-known fact that copper exists in some edible vegetables, being taken up from the soil in which they grow. Then, too, copper salts are often employed to impart a fine, green color to pickles and other preserved fruits. Its frequent presence in the food and its very slow elimination might possibly account for the discovery of copper in the body of our patient. Its presence should never, however, be supposed to indicate copper-poisoning unless we have the symptoms and pathological lesions which are known to follow its administration in large quantities. These were entirely absent in our patients. The characteristic color of the vomited matter, the jaundice, the green line along the gums, were all absent. On the other hand, there were numerous bloody extravasations in the heart, liver, spleen and pleura, which, according to Tardieu, the greatest French authority, are altogether absent in copper-poisoning.

Copper rarely causes fatal poisoning. Such large quantities are required that the styptic taste would call attention to it, and thus, if homicide were intended, defeat the object. Natural verdigris is undoubtedly poisonous; but the supposition is too strained that, on the occasion of a wedding, unclean copper vessels should be employed, or even, if used, that enough verdigris should exist to poison fifty persons, many of them fatally. It is possible that the poisoning may have been produced by arsenite of copper, the symptoms of which are mainly those of the arsenical ingredient. In this case, however, the analyst would as likely have discovered the arsenical as the cupreous ingredient.

Having, as we believe, excluded all poisons other than arsenic, we desire to take up a few points of interest in connection with this as the probable agent. The late appearance of the pronounced symptoms in many of the cases has been by some considered as excluding arsenic from consideration; but it is recognized by all writers on this subject that there are few poisons which present a wider variation in the time of appearance of symptoms than arsenic. As one of the many instances of this fact we may mention the case recorded by Reese, in which, after a teaspoonful of arsenic had been taken by mistake, no symptoms whatever manifested themselves for six hours. It is true that no arsenic was discovered by ourselves in the tests made of the urine, the vomited matter, and the fæces. For this purpose the Reinsch test was employed, but, as stated in the narration of the cases, our tests of these excretions were not made until the sixth day. During this time vomiting and purging had been profuse and had probably eliminated the greater portion of the poison.

The question will naturally arise, If arsenic were the cause of death, why was it not found in definite quantity in the tissues in our fatal case? We reply that it was simply because the patient was kept alive for fifteen days, and the poison was eliminated by the vomiting, the purging and the excretion of kidneys, possibly the skin, this elimination being accelerated by the hot vapor-bath and the pilocarpine injections. It is a well-known fact that the eliminative functions may in the time alluded to entirely free the system of arsenic. In proof of this we need only cite one of many cases, *e. g.*, that of Dr. Alexander (*Medical Times and Gazette*, April 15, 1857), in which "a gentleman swallowed a large dose of arsenious acid, and after suffering the usual symptoms, died on the sixteenth day. Chemical analysis detected no trace of the poison in any organ of the body, although it was abundantly contained in the

food swallowed by the deceased." Casper says: "Arsenic may be eliminated by the excretory organs to that degree that it may entirely and completely disappear on an average of from one to two weeks. According to some experiments on animals, fifteen grains disappeared completely in three days." Taylor states that in many undoubted cases of arsenical poisoning not a trace of the poison can be found in the stomach or the contents. "It is, further, a well-known fact that if an individual, to whom arsenic has been administered with criminal intent, lives for fifteen or sixteen days, no part of the body may present any trace of the poison."

We are firmly convinced that had an analysis of the tissues been made in those cases in which death took place during the first week, arsenic would have been found and the whole matter long ago have been made plain. Instead of this being done, we learn from the Louisville press that in the case of one of the first to die, a man of high social and business standing, no post-mortem was made and no inquest was held. Instead of the pathologist and analytical chemist, an undertaker was summoned, who proceeded at once to embalm the body with an arsenical fluid. Fortunately, all cases were not handled in this peculiar manner. Scientific interest was not altogether thwarted. The one missing link in this chain of evidence is supplied by the results of the examinations made by Mr. Flexner, a most competent chemist of Louisville, who, with the attending physician, found arsenic (by Reinsch's method) in the urine of two of the non-fatal cases. A single positive observation of this character is of greater value than any number of negative and hypothetical statements.

In conclusion, we would say that at least one of our cases was so marked that, had we seen the arsenic administered, we could have looked for no more pronounced symptoms and no more characteristic pathological lesions. These, considered in connection with the analyses just referred to, in cases having the same origin and many of the same symptoms, leave no doubt in our minds that arsenic was the offending substance.

At this distance so many difficulties and conflicting statements are encountered in our search for the particular ingredient containing the poison that for the present we purposely omit discussion of this feature.

ADDENDUM.—Since presenting the foregoing report to the Academy, the Coroner of Louisville has begun an inquest. The testimony of the father of the bride, at whose home the wedding-dinner was given, completely demolished the chicken-cholera theory. Mr. Herr stated that the chickens and turkeys on his place were healthy, and that not a fowl had died there for years. The chickens were prepared and dressed by a colored woman on the place, and the family had been eating of the giblets for three meals. He stated also that there were no copper vessels on his place. The food was cooked in iron vessels.

ICE-CREAM POISONING.

BY GEORGE S. HULL, M.D., PH.G.,
OF CHAMBERSBURG, PA.

WITH the advent of summer comes the increased consumption of our so-called "national luxury," ice-cream; and, *pari passu*, numerous reports of sickness, sometimes even of deaths, caused by this supposed harmless delicacy. That very many cases of illness are not reported, and on account of hasty and imperfect diagnoses that even more are not recognized, cannot be doubted. The profession has failed to give this important matter the attention it demands.

About four years ago the writer published a report of some experiments he was then performing with a view to ascertain the toxic agent in cases of ice-cream poisoning; since that time he has been following up this line of investigation, and now feels that a fuller exposition of his views may prove of use to the profession.

Previous to the time of the discovery of tyrotoxicon by Dr. Vaughan, cases of poisoning by ice-cream which could not be traced to the criminal introduction of foreign substances, such as arsenic, were thought to be due to the milk having been taken from cows which were diseased, or improperly fed and cared for. But the query would arise: If, from such causes, ice-cream be poisonous, why should not milk, which is consumed so much more largely, cause a far greater amount of illness? The same question comes up when we consider Dr. Vaughan's claim that tyrotoxicon is the cause of the trouble. The eminent professor has not only found the ptomaine in ice-cream which has manifested poisonous effects, but has studied the subject thoroughly, even to the painstaking analysis which proved it to be diazobenzol.

Tyrotoxicon is the product of a peculiar kind of fermentation, but the ferment which excretes it is not precisely known, neither are the conditions which are most favorable to its development matters of exact knowledge. When the microörganism which generates this poison is present in milk at a temperature of 98°, we may look for the production of tyrotoxicon, but we may fail to find it because it is quite ephemeral, breaking up, by further fermentation, into other and probably less harmful compounds. Even following Professor Vaughan's directions, one finds it difficult to make tyrotoxicon; he is taxed to get the milk into the precise condition necessary for the generation of the com-

pound, and, since it is so apt to change into other substances, yet more taxed to know when it is ready for extraction. The fermentation which elaborates the ptomaine would, therefore, seem to be but a fortuitous occurrence, in no wise comparable in constancy to the lactic fermentation. One would infer that tyrotoxicon would most likely be present in milk which has been kept in warm places, in unclean cans, and especially in a vitiated atmosphere; and as these conditions very frequently obtain, why do we not hear of numerous cases of milk-poisoning, and but few of poisoning by ice-cream, instead of the *reverse?* Further, a boiling temperature will not only destroy the ferment, but break up its excretion, tyrotoxicon; and a freezing temperature should certainly not be conducive to the growth and activity of cell life. Many ice-cream mixtures are boiled before being frozen, and, thus sterilized, the chances of fermentation are reduced to a minimum.

Without further argument, it seems obvious that the tyrotoxicon theory will explain but a portion of the cases of ice-cream poisoning, and after eliminating those due to it, and the others caused by the vicious introduction of foreign poisons, we have remaining a large, and I believe a very large, number of cases unaccounted for. To these we now direct our attention.

Granted that the ice-cream mixture, whatever be its composition, is free from any poisonous ingredient, and that it has even been sterilized by heat before being put into the freezer; let us inquire whether there be any possibility of its acquiring poisonous properties while undergoing the process of freezing, or during its stay in the freezer. In short, Is the modern ice-cream freezer, after the innocuous mixture is put into it and the power applied, guilty of engendering in its contents any deleterious substance?

The composite freezer of to-day might be described as an iron paddle coated with zinc, resting upon an iron bottom coated with the same metal, and a surrounding tinned-copper or tinned-iron can. Now, should the zinc or copper, by any chance, be dissolved to any extent by the contents of the can, we must expect serious results. This is the point we wish to consider, and in order to be understood by those who may not be acquainted with the methods we shall pursue, it may be well to begin by instituting a simple comparison. If we expose a piece of wood to the air, it will be very slowly burned (oxidized), but if we make the conditions more favorable by first raising it to an incandescent state, it will be rapidly consumed, giving out a poisonous gas (carbon dioxide), and liberating a force which we call heat; now substitute zinc for the wood, and a dilute acid or a solution of common salt for the air, and we find that the zinc will be slowly burned (chemically combined). But if we make the conditions more favorable by placing with it in the liquid a metal (tin will do), less soluble than the zinc, and bring them into direct contact with each other, or connect them by means of a conducting wire, then we at once have a more rapid combustion of the zinc, which enters readily into chemical combination with the liquid—the result being that a poison, zinc chloride, is generated, and also a force analogous to heat, which we collect and call electricity. As the heat cannot be produced except the wood burn, and the more wood consumed the greater the heat, so neither can the electricity be evolved unless the zinc be eaten up by the liquid, and the more metal dissolved the greater the amount of electricity eliminated. From this we at once conclude that if we can get any electricity from the ice-cream freezer while its contents are being frozen, or before or after, then there must be some chemical action going on between the liquid and the zinc (or, in some kinds of freezers, the copper), by which the metal is taken up and held in solution by the ice-cream, rendering it dangerous to consumers in direct proportion to the amount of metallic poison held in solution. But how shall we tell if electricity is being generated? We determine heat by means of a thermometer, electricity by the use of a galvanometer. The principle of the latter instrument is quite simple: If we take a magnetic needle, bend around it, longitudinally, a turn or more of copper wire, and pass a current of electricity through the wire, the needle will swing to the right or left according to the direction the current is travelling, and the deflection will also be proportionate to the strength of the current developed.

Now we are ready for our crucial test: we are to prove that the modern ice-cream freezer is in reality but a form of galvanic cell, the only difference being that in the cell the current is utilized and the poisonous solution of zinc thrown away, while in the freezer, proper allowance being made for the wide difference in the amounts of zinc dissolved in the cell and in the freezer, the current is wasted and the toxic metallic solution is eaten.

Let us institute a closer comparison: If we put in an acid solution a strip of zinc and one of tin, and connect them by a conducting wire which runs through the galvanometer, at once the needle is deflected, which means that the zinc is being consumed by the acid; so, if we take a tinned can and a zinc-coated paddle in the modern freezer, and instead of letting them be in contact at the bottom, as is the case, lift the paddle a trifle and make the contact above by means of a wire—in order, for the purposes of the test, to get the galvanometer in the circuit—we shall find that on putting into the can

even the purest and simplest ice-cream mixture (cream, sugar, and flavor) there is a deviation of the needle in our galvanometer, telling us that a current is passing, and that it comes from the chemical action between the ice-cream and the zinc, or, in other words, that, however slowly, the poisonous metal is dissolving. Briefly, then, this is what occurs: the zinc or positive element is acted upon by the fluid and a current generated, which passes across the cream to the tin or negative element, then up the wire through the galvanometer and back to the zinc, completing the circuit. The longer the zinc is in the freezer the greater will be the amount dissolved, the rapidity of the solution being directly dependent upon the character of the mixture in the can.

Without introducing lengthy tables, let me summarize a large number of experiments by saying that while pure, sweet cream in the modern freezer deflected the needle of the moderately sensitive galvanometer but 7°, the cream, when sour, swung the needle violently to 90° (*i. e.*, to a right angle to the current). Pure milk registered 40°, and when sugar and corn-starch were added, 45°. When eggs were incorporated the needle moved to 80°. None of the formulæ for ice-cream mixtures failed to show *some deflection*, proving that *all* of them were capable of acting in some degree upon the zinc. When any of these mixtures became sour, or when acid fruits were added, the needle turned rapidly to 90°. If by any mischance salt finds its way into the cream, the deflection is greatly increased on account of the zinc being more rapidly dissolved by the active sodium chloride. The resulting zinc chloride renders the ice-cream so much more poisonous.

The modern ice-cream freezer, therefore, has two fatal defects: first, it has two dissimilar metals, one (the positive element) more soluble than the other (the negative); and, secondly, it has these metals in contact—in other words, it is a galvanic cell in closed circuit. It follows that we have only to put into the freezer some ice-cream mixture, as an electrolyte, in order to get a metallic decomposition and solution, which is proved by the current generated. The amount of poisonous metal dissolved depends upon the character of the mixture used.

Now, what is the remedy? We must conclude that it lies in making the freezer of one metal, and that metal the most insoluble that can be had. Did not cost enter into the consideration of the matter, platinum would make the model freezer. Pure tin, or heavily tinned iron, would be acceptable, while glass, if it could be made tough enough without the addition of lead, arsenic, etc., would be still better. If two dissimilar metals must be used, I would not allow them to be in electrical, *i. e.*, immediate contact. I would also freeze the mixture rapidly and remove the more soluble metal immediately when the cream is sufficiently solid. If ice-cream is made of pure ingredients, even in the modern freezer, provided it has been previously well cleaned and that the paddle is removed so soon as the mixture is frozen, the zinc dissolved will hardly be sufficient to produce symptoms of poisoning even in a large consumer, and yet we know that many people with sensitive digestive organs find ice-cream very frequently disagrees with them. But if the cream is prepared, say for a picnic which is to start early the next day, and if the paddle is left in place all night, so as to re-freeze it in the morning should it have softened through the night, and especially if, as is often the case, the mixture is a cheap one, made of milk, eggs, corn-starch, etc., then we have a first-rate galvanic cell, with its zinc and tin, or, in some cases, copper elements.

As we have seen, the chief mixture is the electrolyte, and the electric action of the whole may, perhaps, be heightened by the presence of some salt added by accident or design. The result will be that the current flows all night—itself doing neither harm nor good to the mixture, but the deadly zinc or copper has all this time been dissolving in the ice-cream. In different cases between these extremes we may have many grades or degrees of solutions of zinc or copper, dependent upon the conditions already mentioned.

Were space at our command we might apply the same character of reasoning to canned fruits, vegetables, etc.

We might sum up the results as follows:

1. If we desire the least quantity of metallic poison in our ice-cream, and still keep in use our modern freezer, we should see that the ingredients are pure, that the mixture is frozen quickly, and the paddle at once removed.

2. The amount of poisonous salts is increased by acid mixtures, especially by the addition of eggs, corn-starch, etc. The addition of salt for flavoring purposes, as done by some manufacturers, becomes criminal, and it is grossly careless to allow any of the salt water from the outside to get into the can. If through fermentation ice-cream should contain tyrotoxicon, then the mixture must be acid, and will, on this account, dissolve still more zinc or copper.

3. The amount of dissolved metal depends upon the length of time the paddle is left in the can, or, if the can have a zinc-coated bottom and tin sides, the length of time the cream remains in it; or the amount of electrical action will again vary if the can be copper coated with tin, and the tin be worn off so as to expose the copper, thus producing local currents and dissolving the copper.

But if the danger element is to be entirely removed from our "national luxury" it is more important

that there be used in the construction of the freezer but *one kind of metal*, and one not easily oxidized. No *dissimilar metals should be in contact in any fluid* for human consumption, especially if the fluid be acid, or contain any saline matter.

THE NUTRITIVE VALUE OF BEEF PREPARATIONS.[1]

BY R. H. CHITTENDEN, PH.D.,
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN YALE UNIVERSITY.

I HAVE been asked to consider this subject mainly from the chemical standpoint and to furnish some information regarding the nutritive value of the various beef preparations which, as concentrated foods, are at the disposal of the physician and the public in general. It certainly is an important matter, one in which we are all interested, for there are many occasions in a physician's practice when it is a question of nutriment rather than of medicine, and we certainly need as definite knowledge of the nutritive properties of the foods we employ as of the medicinal virtues of the drugs of which we may make use.

Let us consider first some of the principles which should guide us in forming an estimate of the nutritive value of a food preparation.

It is a well-understood physiological law that the proteid or albuminous food-stuffs are essential to animal life. They alone contain the peculiar groups of chemical elements necessary for the upbuilding of animal tissues and for the renewal of the worn-out structures of the animal body. The cells and tissues of animal organisms, together with the majority of the animal fluids, are composed in great part, aside from the water they may contain, of albuminous matter or closely allied derivatives. During the life of the organism this material is constantly undergoing decomposition, and to make good this loss new proteid matter must be supplied. An increase in the amount of non-nitrogenous food will not supply the lack of proteid matter, for, as is well known, continued deprivation of the nitrogenous food-stuffs will ultimately result in nitrogen-starvation and death. Hence, no substance can serve permanently as food for the human body unless it contains a certain amount of this peculiar nitrogenized matter in a readily assimilable form. Further, it is not enough that a food contains nitrogen, but this element, to be of use to the body, must be combined in some peculiar way, as in the proteid molecule. Even such closely related nitrogenous substances as collagen and gelatin will not fully take the place of a true proteid, though containing as large or even a larger percentage of nitrogen. This is a point which needs to be emphasized, for we hear so much about the importance of nitrogen in the economy that we are liable to overlook the fact that nitrogen *per se*, or in the majority of its combinations, is valueless; that it is only in one peculiar form that nitrogen can be utilized by the animal organism, viz., in the form of proteid matter.

The proteid food-stuffs may therefore well be called the essential food-stuffs, in distinction from the accessory, as the fats and the carbohydrates. They serve a double purpose in the economy: they not only furnish by their metabolism a considerable amount of energy to supply the general needs of the body, but, as already said, they especially constitute the tissue-building and tissue-restoring foods, and as such are absolutely indispensable to the well-being of the organism.

It has been generally assumed that the animal and vegetable proteids have approximately the same nutritive value. This, however, is probably not wholly true, since there is a noticeable difference in the chemical composition of the two forms—a difference which might well be assumed to have some degree of significance. As a rule, to which there are marked exceptions, vegetable proteids contain somewhat more nitrogen and a correspondingly less amount of carbon than the animal proteids. Now it is well known that nearly all of the nitrogen entering the body in the form of proteid matter is ultimately eliminated as urea, but the amount of carbon contained in the urea is not equal to the carbon contained in the proteid matter ingested; in other words, the proteid food, in serving its purpose in the economy, is apparently broken down into a urea moiety, containing practically all of the nitrogen together with a portion of the carbon of the original proteid matter, while there remains a carbon-containing residue which may be either oxidized at once or stored up in the body as glycogen or fat, for possible future use. Hence, it has been argued that the lower the content of nitrogen and the higher the content of carbon in a proteid substance, the greater its nutritive value.

This view, which in general favors the idea of a higher nutritive value for animal proteids, must, however, be considered in connection with the relative digestibility and assimilation of the two classes. Such experiments as have been tried (mainly upon dogs) appear to indicate that the albuminous matter of muscle-tissue and the proteids of the blood, for example, are more readily digested and absorbed than many of the vegetable proteids, such as the gluten of wheat, and if this should prove to be a general rule it would constitute an additional reason for assuming a relatively higher nutritive value for

[1] Read before the Philadelphia County Medical Society, May 13, 1891.

the animal proteids. There is, further, an additional reason for this generally accepted view—one which is dependent upon the association of the proteid, rather than upon the character of the substance itself. Thus, the most common form in which the animal proteids are taken as food is flesh or muscle-tissue, in which the albuminous matter of the tissue is intimately associated with the nitrogenous extractives contained in the muscle-serum. These latter bodies unquestionably possess stimulating properties, and to this fact is to be ascribed, in part at least, the more invigorating action of the animal diet. Furthermore, the observations and experience of clinicians the world over have clearly pointed to the greater value of animal food in all conditions, either in prolonged illness or in prostration from any cause, when it is necessary to provide nourishment in a form capable of promptly invigorating the bodily powers, and with the least expenditure of energy on the part of the economy.

It has thus come about quite naturally that beef, being, perhaps, the most convenient form of animal material, has almost universally been employed in the preparation of concentrated foods. At first, from lack of knowledge of the true nutritive value of proteids, efforts were confined wholly to the preparation of concentrated extracts of beef, in which practically all of the proteid or nutritive matter of the tissue was rejected as either indigestible or worthless. When Liebig's extract of meat first came into use it was looked upon as containing in a small volume all of the nutritive and valuable portion of the tissue. The chemists and physiologists of that date even went so far as to say that the tastelesss residue, left after extraction of the flesh with hot or cold water, was as worthless as a stone, ignoring the fact that this residue of proteid matter could be digested as well as the fresh tissue, and made use of accordingly. Our knowledge on these subjects has steadily increased since then, and it is now generally known that an extract of beef made after the old plan of extracting the meat with boiling water is practically devoid of nutritive power. This is shown by the chemical composition of such extracts, as illustrated, for example, by Liebig's and Armour's extracts of beef, as well as by physiological experiment. I have recently analyzed these two widely known preparations, and the results fully substantiate the prevalent opinion regarding their nutritive value.

It is unnecessary for our purpose to make any comparison of these two products. They are essentially the same, both being composed mainly of the soluble extractives and inorganic salts of muscle-tissue, the former representing the waste products of muscle-metabolism. The content of nitrogen in both preparations is large, but this nitrogen is not to any extent available for the nutrition of the body. It exists, not in the form of proteid matter, but as a part of certain crystalline nitrogenous bodies soluble in 80 per cent. alcohol. One of the most important of these is creatin, a body always present in extracts of muscle, but which has little nutritive power. Introduced by itself into the animal system, it is neither stored up nor used up, but is simply excreted in the urine, practically unchanged. In the same manner, an extract of beef taken as food fails to show any direct nourishing power; it does not diminish the amount of true food required to keep up nitrogenous equilibrium or to sustain the bodily powers. Further, according to Kemmerich, an animal fed upon an extract of beef alone will succumb more readily than a like animal entirely deprived of food. Hence, the nutritive value of meat or muscle-tissue evidently does not lie in the soluble extractive matters, but rather in the rejected insoluble proteid portion of the tissue. Such extracts, however, are not by any means to be considered as worthless; they have, it is true, little value as foods, but, on the other hand, they are possessed of certain stimulating properties which render them of more or less value as stimulants or restoratives. Among other ways this stimulating action is manifested by a quickened and stronger heart-beat, mainly due, it is said, to the large amount of potash salts in the extract. An extract of beef may, therefore, be likened to an alcoholic stimulant rather than to a food. This, indeed, has for some time been recognized, and hence to supply the demand for a more nutritive product than the ordinary extract of beef there has arisen a class of preparations, under the name of beef juice or meat juice, which are stated to possess the nutritive properties of choice beef to a high degree, as evidenced by the presence of soluble albuminous matter. Such preparations, however, as I have analyzed fail to show in their chemical composition any evidence of great nutritive power. Thus, an analysis of Valentine's Meat Juice and of Wyeth's Beef Juice shows them to possess the ordinary characters of dilute meat-extracts, with a small addition of soluble albumin. This addition, however, is too small to have any practical significance. Certainly a food which contains only one-half of 1 per cent. of proteid matter cannot in any sense be termed a concentrated nutrient. Aside from this small amount of soluble albumin, these preparations are in no wise different chemically from an ordinary extract of beef, except that they are less concentrated.

As illustrations of a somewhat different kind of soluble food, containing considerable soluble albumin, we have Murdock's Liquid Food, and Bovinine, or Bush's Fluid Food. Chemically, these two food products are essentially the same.

Both contain only a small amount of solid matter (16 to 19 per cent.), but this is mostly nutritive, being composed in great part of soluble albumin. The appearance of the products, together with the small amount of mineral matter, and especially the small amount of phosphoric acid, would indicate that they are not prepared from muscle-tissue, but rather from blood. Further, all or nearly all of the nitrogen in these preparations is available for nutriment, as it exists in the form of proteid matter. Thus, in Murdock's Food, if the percentage of nitrogen, 2.29, be multiplied by the factor 6.25, on the assumption that the proteid contains 16 per cent. of nitrogen, the result is 14.31 per cent., just equal to the amount of soluble albumin found. Neither of these preparations is, however, equal in nutritive value to fresh lean beef, unless the soluble character of the albumin should tend to render it more easily available by the system, and thus raise the nutritive value considerably above the point indicated by the percentages of nitrogen or proteid matter.

In Johnston's Fluid Beef, an attempt has apparently been made to obtain a preparation which should possess the stimulating properties of a simple extract of beef and at the same time have the nutritive qualities of the tissue itself. This product apparently consists, as indicated by the analysis, of an extract of beef to which has been added a portion of the insoluble tissue, ground to a fine powder, and the mixture evaporated to a pasty consistency. Apparently, the soluble proteids of the tissue have been coagulated in the process, since the preparation contains no soluble or coagulable albumin. Of dry insoluble matter, the analysis shows 10.02 per cent., of which 9.12 per cent. is insoluble proteid matter. This practically represents the bulk of the truly nutritive matter contained in the preparation. The remainder of the nitrogen-containing substance is soluble in hot and cold water, being composed in great part of crystalline extractives, soluble in 80 per cent. alcohol, although there is likewise present some soluble gelatin or gelatoses, apparently formed by the hydrating action of boiling water on the collagen of the connective tissue. These, however, as previously stated, have little or no real nutritive power.

In any preparation of powdered meat, or of other insoluble proteid matter, there is a great tendency for the nutritive value of the product to be impaired by the long-continued drying to which the proteid material is subjected. The digestibility of the preparation is thereby diminished, and in a corresponding degree its nutritive power. Hence, as you know, in many cases the plan has been adopted of predigesting a portion of the proteid food-stuff prior to its desiccation, by which treatment the proteid matter is rendered partially soluble and diffusible, and hence more readily available, especially for weakened digestive organs. Such preparations, if properly made, must necessarily possess high nutritive value. As an illustration of such a food, I have analyzed a sample of Beef Peptonoids, manufactured by the Arlington Chemical Co., which I understand is prepared from the flesh-forming elements of beef, wheat and milk. At first glance, the small amounts of water and mineral matter in this preparation, together with the large quantity of soluble matter (more than half the water-free substance), are strongly suggestive of possibly high nutritive value. This, however, is at once contradicted by the low percentage of nitrogen, which cannot mean at the most more than 27.6 per cent. of proteid matter. In reality, about three-fourths of this preparation is composed of non-nitrogenous matter, mainly starch and sugar. Of soluble products of digestion—albumoses and peptone, directly available as nutriment—it contains only 7.31 per cent.; of insoluble proteid matter, about 20 per cent., of which certainly a large proportion is in the form of vegetable matter. Hence, as a concentrated tissue-restoring food, it is far below the possibilities. Taking the amount of total proteid matter as an index of its nutritive value, it is about 1.4 times as concentrated as fresh lean beef.

Another preparation of this same order, but which shows a much more promising chemical composition, is Mosquera's Beef Meal, a pre-digested, powdered meat. Its composition indicates that, aside from the small percentages of water and inorganic salts contained in it, the entire product is composed of nutritive matter; in other words, about 90 per cent. of the preparation is nutriment, of which 77 per cent. is albuminoid matter and 13 per cent. fat. Further, of this 77 per cent. of albuminoid matter, 29.43 per cent. is in the form of soluble products of digestion, albumoses and peptone, ready for immediate assimilation. In other words, nearly all of the dry matter soluble in water (31.26 per cent.) is composed of proteid substances directly available for the needs of the body, with a minimum amount of work on the part of the digestive system. That portion of the product insoluble in water is composed almost wholly of albuminoid matter and fat. This albuminoid or proteid matter (47.8 per cent.), however, is, I think, in a form more easily available for nutriment than ordinary dried muscle-tissue. In order to make clear my reasons for this belief, I must digress for a moment to call attention to the character of the digestive ferment employed in the peptonization of the beef-tissue. A short time ago it was discovered that the juice of the pine-apple contained a ferment capable of digesting proteid matter. This fact has, I understand, been made

use of in the preparation of the food-product named, the process consisting essentially in digesting fresh beef with the juice of the pineapple until the proteid tissue is partially peptonized, and then desiccating the product. At present, experiments are being carried on in my laboratory with a view of ascertaining something regarding the chemical and physiological action of this peculiar ferment, which, up to the present time, has not been scientifically studied. The juice obtained from a ripe pineapple is decidedly acid, possessing, on an average, an acidity equal to about 0.3 per cent. of hydrochloric acid. This juice possesses in a marked degree the power of dissolving proteid matters, especially coagulated egg-albumin and blood-fibrin. This proteolytic action is apparent both in an acid and in a neutral fluid, the action being most energetic, however, when the fluid is neutral. Such portion of the albumin as is dissolved is converted into soluble albumoses and peptone, but we have noticed that when an excess of proteid matter is present, this excess, although not dissolved, is plainly acted upon, being disintegrated and giving other evidence of some kind of change which apparently renders it more readily soluble in the natural digestive juices than ordinary muscle-tissue. For this reason I am inclined to the belief that the insoluble proteid matter of the Mosquera Beef Meal is more readily available for nutritive purposes than ordinary desiccated beef.

VENTRAL HERNIA; RUPTURE OF COVERINGS; ESCAPE OF INTESTINES AND THEIR EXPOSURE FOR EIGHTEEN HOURS; RECOVERY.

BY JAMES J. McKONE, M.D.,
SURGEON TO ST. JOSEPH'S HOSPITAL, TACOMA, WASHINGTON.

Mrs. J., aged forty-nine years, mother of one child sixteen years of age, was twelve years ago treated for what her physician called an abscess of the abdominal wall. She was confined to bed for ten months. When she got around again she, for the first time, noticed a hernia. With the exception of weakness from this she suffered no more until the current year, when she noticed the skin over the "tumor" becoming black; she consulted a physician, who told her it was gangrene of the skin, and who applied treatment.

February 10th, about a month later, she fell from a stoop, and the gangrenous tissue gave way for an extent of four and one-half inches, from just below the umbilicus in a direction downward and outward toward the centre of Poupart's ligament on the right side. Through this wound thirty-four inches of the small intestines escaped. The patient walked into the house without assistance and went to bed. Her husband covered the gut with a towel and sent for Dr. Norgren, a Norwegian physician. The latter not being at home, and the husband being unable to speak a word of English, he waited for Dr. Norgren till the following morning, the intestines meanwhile lying on the abdomen covered by the towel.

I was called to the case by Dr. Norgren at 3 P.M. The accident had happened at 9 P.M. of the previous evening, making the time during which the intestines had been exposed eighteen hours. The towel was found adherent to the intestines; after it was carefully removed by irrigation with hot bichloride solution, the exposed coils of intestines were found matted together by recent adhesions, which were easily broken.

The patient's condition was good; the pulse 90 and full; the temperature 100°. Ether was now administered, and examination showed that the abdomen was traversed by thick bands of adhesions, most of which ran between the two widely separated portions of the abdominal fascia. These bands were tied and separated, the abdominal cavity thoroughly irrigated with hot water and the intestines returned. On account of the large amount of gas it was necessary to puncture the gut with a small trocar before reduction could be accomplished. The cavity of the abdomen was again thoroughly irrigated, and the wound closed by a continuous silk suture; after cutting away the gangrenous tissue, which consisted of a strip one inch wide in the whole length of the wound, a glass drainage-tube was inserted in Douglas's pouch and brought out at the lower angle of the wound.

It was impossible to perform an operation for the radical cure of the hernia, as the intestines above and to the right side of the rent were firmly adherent to the inner surface of the integument by adhesions which could not be separated, this integument constituting the sole covering of the intestines, the peristaltic action of which was distinctly visible through the thin tissue. The dressing consisted of bichloride gauze, covered by absorbent cotton soaked in glycerin, the whole being retained by a wide binder.

The patient recovered quickly from the anæsthetic, which was administered by Dr. A. E. Burns, of Brooklyn, and had an almost uninterrupted recovery. The temperature rose to 103° on the fifth day, but promptly subsided after free purgation with sulphate of magnesium. The glass tube, which had discharged quite freely, was removed on the third day, when a rubber one was substituted. After the first day there was scarcely any pain; the patient's appetite returned immediately; she was fed on raw eggs and milk for ten days, when an ordinary diet was allowed. The dressing was removed on the eighth day, and primary union found to have taken place, except in the track of the drainage-tube, in which granulation subsequently took place. The patient is now up and around, and able to attend to her household duties.

This is a most remarkable case. Here is a woman, with most unhygienic surroundings—the shanty in which she lived consisting of one room, which served as bedroom, kitchen, and cellar, lying for eighteen hours with thirty-four inches of her intes-

tines outside the abdomen, and peritonitis well advanced, subjected to the additional shock of an anæsthetic and manipulation, who goes on to recovery with scarcely a bad symptom. That she did not have a fatal traumatic peritonitis is probably due to the fact that continued irritation of the peritoneum for years had made it tolerant of abuse. This may also account for the absence of shock. As to sepsis, I have nothing to say.

PUNCTURED FRACTURE OF THE SKULL, IN WHICH THE SUPERIOR LONGITUDINAL SINUS WAS WOUNDED.[1]

BY WILLIAM J. TAYLOR,
SURGEON TO ST. AGNES HOSPITAL.

FOR the history of this case I am indebted to Dr. John B. Maloney, resident physician.

W. R. J., aged thirty-five years, was admitted to the surgical wards of St. Agnes Hospital, about midnight of June 25, 1890, suffering from a punctured fracture of the vertex of the skull. He was brought to the hospital in a patrol wagon, but walked into the wards. Except for a little anxiety and a disposition to quarrel on not being immediately shown to bed, it could not have been known that anything was wrong.

The man could give no account of the injury, but the police officer stated that he had been struck on the head by a pick, at 1 o'clock in the morning, just half an hour before he was seen by me. He became delirious, spoke of his friends, and did not recognize those about him. At half-past one o'clock he was placed under the influence of ether, and the wound examined.

Two inches from the glabella, and about one-half inch to the right of the median line, was a small wound of the scalp, having an appearance as though made by a pick or other pointed instrument. The skull beneath was punctured, and the bone broken into small fragments, which were driven down into the brain-substance. The opening was just large enough to permit the insertion of the finger. The wound was enlarged with a knife, and the scalp turned back. The edges of the skull were cut away by a rongeur forceps, and the depressed pieces of bone removed. It was then seen that the wall of the superior longitudinal sinus had been wounded by a fragment of bone. The hæmorrhage was profuse. Pressure with forceps controlled the bleeding until a larger opening, two and a quarter inches long by two inches wide, and extending one-half inch to the left of the median line, was made in the bone, thoroughly exposing the sinus, and including the whole area of fracture. The dura was torn and the brain itself lacerated. Blood flowed freely from the small tear in the wall of the sinus, which was about one-quarter of an inch long. Packing would not control the hæmorrhage. The patient having already lost a large quantity of blood, and as the imperfect light made it difficult to see, the opening in the sinus was included in the grasp of a pair of hæmostatic forceps, and the hæmorrhage completely controlled; the forceps were allowed to remain. The dura was freely opened, and the brain examined with the finger. The wound was then carefully disinfected, so much of the wound in the dura as was possible was brought together with catgut sutures, and the whole was packed with idoform gauze.

The patient reacted nicely from the operation. At the end of seventy-two hours the hæmostatic forceps was removed from the wound in the sinus; there was no hæmorrhage that was not easily controlled by a packing of iodoform gauze gently applied. On the third day there were symptoms of intense cerebral irritation, with delirium and restlessness, so that it became necessary to strap the man in bed and give morphine and bromides. For some days he passed both urine and fæces in bed, and was extremely weak. He gradually regained strength, and his mind became clear again. The wound healed by granulation. The patient was discharged from the hospital on August 29th entirely well, and returned to his work.

ORIGINAL LECTURES.

SARCOMA OF THE SCROTUM; VESICAL CALCULUS; CATHETERISM; EXCISION OF BUBO.

Abstract of a Clinical Lecture delivered at Bellevue Hospital.

BY JOHN W. S. GOULEY, M.D.,
VISITING SURGEON.

GENTLEMEN: The case of tetanus which some of you saw last week succumbed on the fourth day of the disease. Opisthotonos was almost constantly present during the last twelve hours of life; but only on two occasions was there any laryngeal spasm. At the necropsy only a few ecchymotic spots in the brain and a very slight effusion in the ventricles were found. The spinal cord was not examined.

The case of tuberculosis of the bladder which I showed you at a previous clinic is progressively failing, and although his bladder is irrigated daily with a solution of peroxide of hydrogen, there is still abnormal frequency of micturition. The testicles also have since become implicated in the tuberculous process. A microscopical examination has confirmed the diagnosis of tuberculosis. Such an examination is capable of rendering valuable assistance in the diagnosis of a not very common condition.

To-day I wish to show you the results of the post-mortem examination in a case of scrotal disease which you saw recently. Microscopical examination corroborated the diagnosis of round-cell sarcoma, or, as I prefer to call it, endothelioma. The patient was a man, fifty years old, having a good family history and no history of venereal trouble, who a year previously was injured by stones falling upon him while working in a sewer. The parts most severely injured were the back and scrotum. The scrotum was swollen and painful for six weeks, but at the end of two months the patient had en-

tirely recovered. About ten months later the right side of the scrotum became swollen and painful, and one month before admission to the hospital, the left side also became swollen. The enlargement was accompanied by pain running up on each side into the groin. The tumor had doubled in size within the last two weeks, and during the same period the patient had lost fifteen pounds in weight. Night-sweats had also become troublesome. You notice the great weight of the tumor, which probably gave rise to the dragging pains in the course of the spermatic cords. On section the right testicle is found to be quite hard, the sarcoma having received an accession of fibrous tissue; it therefore becomes an ino-endothelioma. The left testicle is not so hard as the right. Unfortunately, the necropsy included only the testicles, bladder and kidneys; for there was reason to suspect that the lungs had likewise become involved. The bladder was much inflamed, but the ureters and pelves of the kidneys were normal. The kidneys were the seat of interstitial nephritis.

The case of necrosis of the pelvic bones and stone in the bladder which I showed you recently would undoubtedly be temporarily relieved by the removal of the stone; but the operation would be speedily followed by a re-development of the calculus, which would be repeated so long as there was any communication with the diseased pelvic bones.

Let me now invite your attention to this man, seventy years old, who has cystitis, from prostatic obstruction, and a contracted bladder. He has the appearance of one suffering from some disease of the kidney; he is emaciating rapidly, and has irregular chills, which in themselves are almost pathognomonic of pyelitis. This man has brought a soft catheter with him, but it is far too small to be entrusted to the hands of a patient; it is not only safer but also easier to pass a moderately large instrument. The patient ordinarily should be provided with a No. 9 catheter of the English scale, and he should be instructed to use it, if possible, not more than five times in twenty-four hours. As the last portion of urine flows out through the catheter it is seen to be mixed with pus. As the patient withdraws the catheter he neglects to occlude the distal opening with his finger, and consequently a stream of pus dribbles along the whole length of the urethra.

The next patient comes with swollen glands in the groin. Such a condition is often the result of an injury to the foot, such as a "stone bruise," but it is far more frequently due, as in this case, to infectious matter carried from a chancroid through the lymphatics to the glands. When such a chancroidal bubo has suppurated freely, it is best to make a free incision into it and disinfect the parts thoroughly. Before this stage is reached it is wise to excise the whole mass of glands and endeavor to secure primary union. In doing this, care must be taken that the gland be not broken; for, if this occurs, the whole wound may be converted into a huge chancroid. The operator must also be careful that the fingers are free from sores or "hang-nails," lest his fingers become infected and chancroids develop on them. It is not precisely known what the chancroidal infection is, but it certainly is an essentially local infection, although the same microörganisms are found as are observed in chancres. In performing the operation of excision, a free incision should be made parallel to Poupart's ligament, thus exposing the glands, which are then all enucleated, whether diseased or not. The wound is thoroughly cleansed and its edges united by sutures.

MEDICAL PROGRESS.

On Deaths from Chloroform and Ether since the Hyderabad Commission.—DR. LAURENCE TURNBULL, of Philadelphia, recently read a paper upon anæsthetics before the American Medical Association, of which the following is an abstract:

The history of the First and Second Commissions, and the conclusions which they arrived at.

The opposition to the First by the physiologists and practical administrators of anæsthetics, and the adding of Dr. Brunton to the Second Commission, by the efforts of the editors of the London *Lancet*.

The opposition to the conclusions arrived at by the Second Commission, more especially in England and the United States, until the London *Lancet* advised a more careful study and record of deaths.

With this view, Dr. Turnbull has made a most careful collection of all the deaths both from chloroform and ether, from every available source, assisted by several friends. These 43 deaths have been arranged in a tabular form, giving the name, age, history, nature of operation, anæsthetic used, amount used, apparatus employed, posture, how long under influence, whether heart or respiration stopped first, means to resuscitate, how long continued, post-mortem, cause of death, and reference.

He gives as the result of his examinations a brief analysis of the table as follows:

"The whole number of deaths from chloroform and ether is 43. Of this number 39 were deaths from chloroform and 4 from ether. In 5 cases the cause of death was syncope from chloroform, and in 13 cases the heart stopped first. In 10 cases the respiration stopped first, and in 4 cases the heart and respiration ceased at the same time. In 1 case cyanosis, no pulse. In 12 of the cases it is not stated whether heart or respiration stopped first.

"The cause of death in case No. 37 was due to some peculiar idiosyncrasy. In No. 22 there was paralysis of the pneumogastric nerve, the direct effect of the chloroform, superinduced by efforts at vomiting. After a careful consideration of the report of this case, and as there was cyanosis after vomiting, suffocation was suspected, but this cannot be confirmed, as there was no autopsy. In case No. 20 there was given as cause of death, 'reflex paralysis of the heart,' but there was no post-mortem to confirm this statement.

"There were 21 post-mortems, most of them very imperfect. Nos. 24, 25, 36, and 37 were full and complete, and Nos. 15, 19, 21, 28, and 34 were fairly described in this particular. Many of the cases were very imperfect in their detail, especially those from New South Wales.

"Sufficient cases are given to show the absolute importance of the method of administering chloroform, and to indicate the necessity of the most careful attention to the pulse and respiration.

"The only death from anæsthetics in Philadelphia

during the period stated was one from chloroform (No. 36), while there was not a single death from ether in the numerous hospitals and operations—indeed, we may say, in the thousands of operations.

"The 39 deaths from chloroform added to the 375 collected by us from our work for Dr. H. C. Wood (contained in his address before the International Medical Congress at Berlin) make, up to the present time, 414 cases—the actual number being far greater on account of cases never reported.

"The exceedingly small number of deaths reported from ether demonstrates its great safety; still, it will and does kill, and we notice that the feeble, and persons suffering from malignant disease, are more apt to be its victims (see Nos. 10, 11, and 18). We would advise its use as an anæsthetic, and also would advise a full study and knowledge of the best mode of using it, which we judge is not common in Europe."

Virchow on Koch's Method.—In a recent debate in the Prussian House of Deputies on the granting of additional funds for the Koch Institute for Infectious Diseases, Professor Virchow, among other things, said: "I have never expressed any opinion to my professional brethren on the fundamental value of Koch's method, simply because I do not know how such an opinion can be formulated. I have only communicated a series of personal observations, which have indeed been of service in directing attention to one part of the question, and have especially enforced the need for calm and objective study that is so requisite in these difficult subjects. Dr. Graf [a previous speaker] is still steeped in optimism. He has no right to speak of the importance of the matter until he has proved it, and it is, in fact, not proved. But it would be just as foolish if we, as pessimists, were to say, 'The matter is of no importance whatever; it is only a poison, a noxious substance.' The question has, in fact, been developed in unexpected directions, leading in many quarters to the hope that very striking results can be produced by these powerful measures—a hope which we cannot yet say has been annihilated. As a matter of fact, there is not a single case known in which any form of tuberculosis has been cured by this means. All cases which were for a while regarded as cured have afterward been found to relapse; the improvements were merely temporary, such as often occur under other treatment. On the other hand, there is no doubt whatever, that many serious dangers have been revealed, with regard to which I may claim some merit for myself. Nevertheless, from what I have just said, no doctor who feels called upon to make further trial of the remedy, could by any possibility lay himself open to prosecution. The original trials were, in point of fact, made after results had been obtained in animals, which seemed to justify the expectations that were raised regarding the discovery."—*Lancet*, May 23, 1891.

The Anal Reflex.—RASSOLIMO (*Neurol. Centralbl.*, No. 9, 1891) finds that the anal reflex is exaggerated in neurasthenia, together with general exaggeration of the skin-reflexes; in transverse myelitis, high in seat; and in organic diseases of the nervous system with hyperæsthesia. The reflex is enfeebled or abolished in multiple neuritis, when the sacral plexus is involved; in tabes, when the sphincters are deranged and there is anæsthesia in the region of the anus; in myelitis involving the lower portion of the lumbar enlargement, usually associated with anæsthesia of the rectum, anus and urethra. The reflex is preserved in functional neuroses involving the evacuation of urine, defæcation and the sexual functions.

The Pathological Anatomy of Acromegalia.—At the Tenth International Medical Congress, MARINESCO reported the results of the studies which he, in conjunction with Marie, had made of the pathological anatomy of acromegalia. In the great toe all the structures were hypertrophied, especially the connective tissues. Even the membrana propria of the sweat and sebaceous glands were thickened. The hypertrophy was most marked in the sheaths of the cutaneous nerves, which were degenerated. The changes were less marked in the larger nerves. The bones presented not only columns of hyperplasia, but also true osteogenesis, leading to increased length and thickness. The macroglossia is dependent upon a thickening of the connective tissue and of the muscular bundles of the tongue. The lingual and hypoglossal nerves showed only slight changes—from which it is to be inferred that no relation exists between the hyperplasia of the tongue and changes in the nerves. The cervical sympathetic, especially the lowest ganglion, was decidedly sclerotic. The kidney presented evidences of nephritis, especially cortical. The follicles of the atrophied thyroid gland were hyperplastic and cystically degenerated. The nasal mucous membrane was thickened, its surface tuberculated, the vessels hyperæmic and in places sclerotic and obliterated. These various alterations furnish an anatomical substratum peculiar to acromegalia and distinguishing it from similar affections.—*Münch. med. Wochenschr.*, May 19, 1891.

The Influence of Light upon Pregnancy and upon the Fœtus.—As a result of experiments with mice, VICARELLI (*Annal. di Ostetrica, etc.*, Dec., 1890) found that the absence of light had a tendency to cause early abortion, but did not otherwise modify the course of pregnancy. If the mother was kept in the dark during pregnancy, the development of the offspring was most retarded; the retardation was less decided if, after birth, the offspring were no longer kept in the dark; and least in the case of offspring kept in the dark after birth, the mother having passed pregnancy in the light. The highest degree of development was attained if the mother and the offspring after birth lived in the light.—*Centralbl. f. Gynäkol.*, May 23, 1891.

The Therapeutic Employment of Humon Lymph.—MAGNANT (*Bulletin Gén. de Thérap.*, May 15, 1891) proposes to treat pulmonary tuberculosis and other conditions with subcutaneous injections of lymph obtained from blisters by vesication in persons not affected with the disease to be treated. The fluid is sterilized by exposure to prolonged heat, not above 158° to avoid coagulation, and is kept in tightly stoppered bottles. In a number of cases, including a varicose ulcer of the leg, a diabetic ulcer, an enlarged cervical gland, and two cases of pulmonary tuberculosis, excellent results are reported.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 27, 1891.

PUBLIC BATHS.

As a means of public sanitation, the superiority of the "rain bath" (shower bath) over the tub bath forms the theme of a paper contributed to the *Dietetic Gazette*, for May, 1891, by the accomplished editor of that journal. DR. BARUCH points out that the difficulty of keeping tubs clean is the greatest drawback to the public bath, in which facilities must be offered to large numbers in rapid succession. Another obstacle to be overcome is the large quantity of water needed. In a large swimming-tank privacy is not attainable, and either here or in the tub one is immersed most of the time in soiled water.

These difficulties are very simply and effectually overcome by providing a number of small apartments in which the bather stands beneath an obliquely descending "rain" of warm water. "Imagine for a moment," says DR. BARUCH, "a begrimed coal-heaver attempting to rid himself of the accumulation from his day's labor in a tub bath. It would not be long ere he would be immersed in a concentrated solution of coal dust, unless he had a lavish supply of warm water. Let the same individual enter the bath I propose. Being thoroughly soaped, he stands upon an inclined asphalt floor under a large vase from which with some force a coarse spray is descending. Both hands being as free as in the tub, he may rapidly rid himself of all accumulation, which the descending stream would wash away, flowing at once from him upon the inclined floor and thence into the gutter."

Public baths upon this principle have been in use in Europe since 1883, when one constructed upon LASSAR'S suggestion was practically tested at the Hygienic Exposition held in Berlin. A corrugated tin structure of 40 square metres (48 square yards) area was divided into male and female sections with ten bath-cells, two closets, kitchen, and drying-room. In 1887 the plan was put into operation at Vienna, an old building being divided into seventy-two bathing-cells, furnishing 40 litres (40 quarts) of warm water, soap and towel, for the equivalent of two cents in our money. In Berlin a public bath association has erected a building where baths of various kinds are offered at prices varying from 2½ cents to 12½ cents. In six months 103,000 baths were taken and about $7000 received. In Frankfort, the banker THEODOR STERN opened a public "rain" bath which is a model of its kind, costing $5000. Baths, with soap and towels, are furnished for 2½ cents.

In Göttingen and Weimar these baths have been established in connection with the public schools. The bathing is done during the school hours, by a well-arranged plan of relays, which does not interfere with the instruction. The Director of Schools at Weimar is quoted as follows: "The freshness and pleasure for study after the bath, the cultivation of a desire for cleanliness, the promotion of health in our children, offer such decided results in this arrangement that I cannot refrain from urging other schools to establish similar baths." In many German cities manufacturers have provided shower-bath facilities in their factory buildings for the use of their workmen.

At the suggestion of DR. BARUCH, this method of bathing has been substituted for the plunge-bath at the New York Juvenile Asylum. Sixty-eight sprinklers, twenty inches apart, and connected by pipes near the ceiling, have been erected over the site of the former bathing-tank. The water is heated by admixture with steam. "When the sprinklers are all turned on, the children stand in a shower of warm water flowing upon them with some force. They soap and scrub themselves, while this warm rain rinses them off, and the water flows away at once into the sewer. In ten minutes this batch is clear

and another takes its place. Two hundred and eighty are now bathed per hour, while formerly only eighty could be cleansed in the plunge-bath. The quantity of water is only one-eighth of that formerly used." The Association for Improving the Condition of the Poor is now erecting a building in New York City, in Centre Market Place, upon plans drawn according to DR. BARUCH'S suggestion, to be called "The People's Bath," which will accommomodate 500 bathers daily, and a similar smaller structure will soon be put up in that city by the trustees of the fund instituted by BARON MAURICE DE HIRSCH for the benefit of Jewish refugees from Russia.

We have called attention to this matter in the hope that other American cities, and especially Philadelphia, will promptly fall into line. The free swimming-baths, maintained by public and private benevolence during a few months of hot weather, are good in their way, but the plan advocated in the article from which we have so freely quoted is vastly superior. It would be simply a waste of words to dilate further upon a fact so evident. We trust that some of the many liberal and public-spirited citizens in whom our city takes just pride may be induced to give the subject consideration, and we are sure the medical profession will cordially coöperate in any good plan toward establishing in Philadelphia a "People's Bath."

THE POWER OF WILL IN DISEASE.

AFTER a hundred years of history and education in scientific medicine, and in a country where shrewd common sense has been developed in the most backward-looking mind—at such time and under such circumstances it would have seemed impossible that the incurably sick, the paralyzed, and the maimed should by thousands flock to a priest to be cured of their diseases. The newspapers say the immense depot at Pittsburg has of late seemed like a hospital, filled as it has been with the poor unfortunate invalids seeking FATHER MOLLINGER'S supernatural aid to make them well. The Father anoints and blesses, and the young man who "had not walked since childhood," upon command goes unassisted "from the altar-rail to the rear of the church, to the amazement of the vast audience." Though the report says the great majority are sadly disappointed—even the squarely impossible cannot be done in these times—a number are found that, with functional affections, under strong emotion, exhibit a change, or an increase of strength, so that the belief in "the power" is kept living.

What is it that makes FATHER MOLLINGER, Christian science, faith cure, medical spiritualism, and to some extent homœopathy possible in the nineteenth century? Were there absolutely no element of truth in these reported "cures," even the dullest dupe would come at last to some consciousness of the hocus-pocus. The manure of the soil nourishing these delusions is a truth too often ignored and neglected by scientific medicine. It is the truth of the power of the emotions, of the will—of the spirit, if you please—over the flesh; of life over the beginnings of disease, and even over disease and death itself. Races and nations differ greatly in their power of resisting and overcoming disease, simply by reason of the characteristic attitude of the will and the disposition of the patient toward the physical illness. Just so do all, even brothers, differ in the same way. Thousands are physically sick because mental resolution and spiritual domination is weak and illogical. This is strikingly true in reference to the beginnings of disease. The secret of continuous good health does not always consist merely in physical resistance or robustness, but in sharply conquering the subtle beginnings of corporeal abnormality by pure will-power. There are two homologues of this power that illustrate it exactly. Who has not seen whimsicality, crankiness and oddity by self-indulgence slowly degenerate into monomania, and even into downright insanity? And again, who can doubt that in the commencement many such persons are perfectly conscious of the abnormal tendency, and are, moreover, perfectly capable of *not* doing the ridiculous or self-forgetful things. They are at first driven by no imperious necessity. It is precisely so when one gives way to immoral courses of life. At first the voice of conscience is clear; by and by control is lost and the voice is entirely silent. The analogies obtain in the matter of health. The adage, "Resist the beginnings of evil," holds also here. All disease begins subtly, almost insensibly, as chill, lassitude, malaise, etc. Caught at this stage and fought down by a virile volition, that which by self-indulgence would have proceeded to genuine fever and illness may often be resolved into routine normality of health. A brisk walk of five miles in the teeth of exhaustion and weariness has saved many from severe illness. And so in types of disease that are, if one may so speak, more

organic. The fact cannot be disputed that many who have believed themselves incapable of walking, under powerful emotion their own will being supplemented and "relayed" by that of another, do really find that they can walk a little. Our confutation of the priest's supernaturalism consists precisely in this proved power of the will. Doubtless orthopædic appliances are often given patients who need only resolution, encouragement, and repeated trial in order to develop by exercise the strength that the crutch really conceals or neutralizes. In the sick-room every experienced practitioner knows how much depends upon the *morale*, the resolution of the patient, and how even death and life may depend upon the will. All this, when we read it, seems trite enough, but its significance is lost sight of in the battle of rival theories of disease, and to some it must seem the froth of nonsense. But the practical lesson of the very obvious truth consists in the simple duty of arousing the will to self-confidence and corporeal domination. As has been well demonstrated, the best cure for the most outrageous hysteria is mental and volitional control—supplanting the patient's diseased imagination by a healthy one—true faith-cure in a legitimate and genuine sense. The puppets of fashionable automatonism are prone to run to the doctor for every ache, real or suspected. To indulge them in their folly sometimes seems to the physician not without a certain worldly excuse. But if a higher ethical ruling is adhered to, duty will counsel encouragement of prophylaxis and hygiene; and among the means of forefending disease an energetic domination of will over the body is often the most vital and important.

WAS THE SNOOK-HERR TRAGEDY DUE TO ICE-CREAM POISONING?

WHEN the manuscript of DRS. MITCHELL and HYNDMAN was sent to THE MEDICAL NEWS, the editor, provisionally accepting the conclusion that arsenic was the cause of the poisoning, was struck by the failure to find in the post-mortem investigations definite traces of arsenic, by the improbability of toxic quantities of arsenic having gained entrance to the food by accident, and also by the lack of motive for poisoning.

Remembering that DR. HULL had made some experiments that tended to prove that the modern ice-cream freezer is in reality a galvanic battery, we asked DR. HULL to summarize the results of his experiments and forward them to us for publication. In complete ignorance of the conclusions of DRS. MITCHELL and HYNDMAN—indeed, in ignorance of all the details of the SNOOK-HERR cases—DR. HULL has theoretically and unconsciously established conclusions that may be of service to those investigating these sad cases. The suggestion of uniting the two sets of facts is our own. It will be noticed that the symptoms presented by the patients are precisely those to be expected from poisoning by the salts of zinc or copper; that the discovery of the copper in the post-mortem examinations would be explained, and also the absence of arsenic-findings in definite quantities. Against this possible explanation would, among other things, be the assertion that those who ate only ice-cream had no symptoms of poisoning. In the first place this would need very clear confirmation in order to squarely offset the error certain to arise from the reports of excited, unscientific persons, etc. But a far more important consideration would be one to which DR. HULL does not allude, but one which, we would suggest, may explain how, of two persons eating cream from the same freezer, one might be killed and the other be unharmed. We allude to the improbability of thorough mixture of the toxic agent throughout the whole mass of cream. In a thick, pasty substance like ice-cream the poison deposited at isolated points would not be uniformly disseminated throughout the cream except by very prolonged turning and stirring.

This view, thrown out by us as a mere suggestion, may, to those with closer clinical experience and study of these cases, appear inadequate and worthless, but from this distance, and in view of the impenetrable mystery surrounding the whole affair, it would, at least as a working hypothesis, appear worthy of the consideration of those specially interested.

SUPERCILIARY ENTROPIUM.

EVERYONE has noticed that after the age of forty or fifty there is often, especially in men, an excessive growth of the hairs of the eyebrow. In such cases it will be found that the hairs frequently evince a tendency to curve downward toward or within the palpebral opening. In examining an eye to discover the cause of conjunctival irritation or congestion, the ophthalmic surgeon, in elevating the upper lid, thoughtlessly draws these hairs away with the thumb, or the patient unconsciously raises

the eyebrow the better to expose the globe. In this way conjunctival irritation due to incurvation of the eyebrow cilia may frequently escape the physician's notice. We have seen in private practice three cases of conjunctival inflammation distinctly traceable to this cause. One of these was of peculiar interest, because the irritation was of the conjunctiva of a socket, from which the eyeball had been enucleated. So far as known, this condition has never been described in the literature of ophthalmology. The treatment, of course, suggests itself. In designating this affection *superciliary entropium*, we do not wish to dictate the nomenclature, if a shorter or better term can be found.

SOCIETY PROCEEDINGS.

THE CINCINNATI ACADEMY OF MEDICINE.

Meeting of June 1, 1891.

G. S. Mitchell, M.D., *President*; T. V. Fitzpatrick, M.D., *Secretary*.

DISCUSSION OF A STUDY OF THE SNOOK-HERR POISONING CASE.

PROFESSORS MITCHELL and HYNDMAN submitted a study of the Snook-Herr poisoning case. [See the current issue of THE MEDICAL NEWS, p. 709.]

In the discussion that followed, DR. WHITTAKER said:

As the symptoms read, the differential diagnosis would include the consideration of cholera morbus, typhoid fever, trichinosis, meat-poisoning, mushroom-poisoning, and a mineral poisoning, most especially arsenic.

Cholera morbus might be excluded because of the large number of people affected, but chiefly because of the persistence of the symptoms after the use of evacuants and morphine subcutaneously.

Typhoid fever sometimes begins with gastro-enteric signs so intense as to resemble poisoning, but this is exceptional. It would be impossible to conceive of forty cases all beginning in this way. In the absence of this knowledge the condition of the mind and the course of the temperature would exclude the diagnosis of typhoid fever.

Trichinosis rarely shows signs of such intensity at the outset, and simultaneously in so many persons. Multiple cases of trichinosis have been considered as true cholera, or as poisonings, but not in late years since we have had definite knowledge concerning trichinosis. Characteristic muscle-pains and œdemas at the end of the first week mark this affection.

Mushroom-poisoning also leads to severe vomiting and diarrhœa at periods varying from six to twenty-four hours after ingestion, with subsequent nervous symptoms, and unless the history of the case be clear (no mushrooms eaten, for instance) or fragments of fungi be found in the discharges, the resemblance to arsenical poisoning may be complete. The speaker had occasion, a few years ago, to treat one of his fellows in Cincinnati for fly-fungus poisoning (muscarine) and was impressed by the signs of intoxication which supervened within one hour after ingestion. The patient chattered and raved incessantly, and was in and out of bed in constant excitement which he strove in vain to subdue. Inhabitants of Kamtschatka partake of this fungus purposely to secure this kind of intoxication, and the poor are said to drink the urine of these rich epicures to indulge the same passion. In the case reported the stomach-tube quickly relieved the physician.

Meat-poisoning, which it is now the fashion to call ptomaine poisoning, we know only in connection with pork and veal. Most of the cases thus reported—as at Andelfinger, 444 cases, 10 deaths; Kloten, 657 cases, 6 deaths—on examination turn out to have been trichinosis or typhoid fever. Nevertheless, undoubted cases, independent of these diseases, have been reported. Perhaps the best-observed cases were reported by Gärtner, of Jena: fifty-eight cases in twenty-five families; one death, in a laborer aged twenty-one, taken ill in two hours and dead in thirty-five hours after taking the food. The other fifty-seven cases became sick in from twenty-four to thirty hours and recovered in from a few days to two weeks. The main symptoms were enteritis, prostration, sopor. The discharges were studied bacteriologically with the discovery of a so-called bacillus enteridis, which was cultivated and inoculated in various animals. As a rule the symptoms of meat-poisoning show themselves later than those of arsenical poisoning, sometimes not until the day following the ingestion of the poison. Groenouw confirms the statement of Ulrichs that in all severe cases of meat-poisoning there is both dilatation of the pupils and disturbance of accommodation.

Arsenic shows itself by gastro-intestinal irritation and narcosis. The practitioners in these cases, debarred from tests of the vomited matter at the outset, by the absence of all knowledge of other cases, very properly had the urine (in which arsenic has been detected at any time from five hours to two weeks after it has been taken) examined as soon as suspicion was aroused. Arsenic has been found in the liver four hours after administration and has been wholly eliminated from the body in two weeks. Flaudin found that fifteen grains might disappear wholly from the body of animals in three days. It is pretty universally distributed over the body, including the nervous system and the bones. In his experiments with animals, Scolosohoff found arsenic thirty-six times oftener in the brain and cord than in the liver, and in the muscles four times oftener than in the liver. Rand reports a case of exhumation and examination of the contents of the stomach two weeks after death, with negative results, and a re-exhumation and examination of the soft parts two months after death, with positive results. Sonnenschein found arsenic unequally distributed in the bones, but mostly in the pelvis and adjacent vertebræ. So arsenic has been detected in bodies three, eight, ten, by Altschul fourteen, and by Steinhauser twenty-two years after death.

Inasmuch as the symptoms vary so much that an absolute conclusion cannot be based upon them, or upon the lesions, though both symptoms and lesions read like arsenic in these cases, absolute proof here must rest upon exhumation of the bodies of some of the six victims and examination of the viscera and bones.

DR. G. A. FACKLER agreed with the essayists that the evidence presented in the paper argued strongly in favor of their theory. Although it cannot be positively asserted that arsenic was the toxic agent, still, assuming this to be the case, the appearance of all symptoms can be readily explained. He could not, without exception, agree with the previous speaker as to the discovery of arsenic in bodies of all individuals who had died from the poisonous effects of that drug, even if such bodies be exhumed months after death. It is true that a large number of cases have been reported to substantiate this statement. Yet an equally large number have been reported that would contradict it. We can easily reconcile such apparent contradiction by remembering the fact that arsenic is rapidly eliminated. The first class of cases, then, includes those in which the period between ingestion of the poison and death is brief—too brief to insure complete elimination. The second class, to which the one under discussion belongs, includes those in which considerable time has elapsed after the administration of arsenic until a fatal effect ensues, thus permitting the entire or nearly all of the amount absorbed to leave the body. We must not forget that the toxic effects of arsenic are not due to its direct action upon the tissues. If the agent be injected subcutaneously the same changes will be observed in the internal organs, *i. e.*, the degeneration of glandular organs, submucous structures of the gastro-intestinal tract, manifestations on the part of the pleura identical with those described in the paper of the evening, etc. This action is due to the fact that arsenic, after its absorption, acts alternately as a reducing and as an oxidizing agent, arsenious acid being changed by the absorption of oxygen into arsenic acid; and, again, giving off oxygen, this is changed to arsenious acid. Such changes produce a rapid interchange of oxygen within the protoplasmic structure of the organs in which either of the acids finds entry, and must exercise a destructive action upon them. Thus arsenic sweeps, like a fire, through the organism and, in cases in which life is prolonged, disappears, leaving devastation behind. In these very cases (and the one reported probably belongs to this class) the alterations and degenerative changes produced are of such severe character as to result in a loss of the functional power of the affected organs that must lead to a fatal termination. Exhume such bodies and the closest scrutiny and most accurate analysis of all tissues will not disclose a trace of the poison.

It is true that our knowledge of ptomaines and their action is very meagre. Yet we must not disregard the possibility of their existence. Cases have been reported, especially in Italian literature, in which chemical examination has disclosed the presence of various mineral poisons and alkaloids, and a more careful examination revealed the fact that the symptoms observed antemortem, as also the post-mortem changes, were attributable to the presence of certain ptomaines.

DR. S. P. KRAMER said that he thought that the fact of copper being found had not been sufficiently dwelt upon. Arsenic was rapidly eliminated from the system and copper more slowly; therefore he thought the possible source of poison in these cases might have been the tri-arsenite of copper, or Paris-green as it was more commonly termed, which contained a large amount of copper.

PROF. DICKORE said, in answer to the statement made by the previous speaker in reference to Paris-green, that it contained a larger amount of arsenic than copper, and that the former was more quickly eliminated from the system than the copper. He still thought that the presence of copper might indicate one of the sources of the poisoning. By very careful work he had obtained several little black spots on white porcelain, which looked exactly like those produced by arsenic. Under other circumstances, when no medico-legal question was involved, he would have called these spots "arsenic;" since they were too small to produce all the arsenic reactions he could not make any other report than the one he had given the coroner. Small quantities of arsenic were sometimes found in medicinal preparations, as for instance in subnitrate of bismuth. It would have been interesting to have had the bismuth administered in these cases examined for arsenic. It must also be remembered that arsenic is by no means of uncommon occurrence in some sections of Kentucky, Ohio and Indiana. Most iron pyrites, and the water of some mineral springs, contain arsenic. Traces may enter the human body from such sources. Copper is sometimes found in articles of diet. Cases are on record in which fatal poisoning has happened from eating pickles colored with copper; also from other dishes of acid reaction kept or prepared in copper vessels. The speaker had met a brother of Mrs. Snook who had just recovered from the poisoning, and who said that an aunt who had eaten none of the chicken-salad had become sick and died; another relative had partaken of everything, but had drunk no coffee or water from the silver pitcher on the table; this relative remained well. These facts speak against the theory of ptomaine-poisoning. In the case of the brother of Mrs. Snook, it was stated that the solid parts of his discharges were of a tea-green color; this points toward copper-poisoning. He was under the impression that the water in the silver pitcher contained the poison. He also stated that the taste of the coffee was disagreeable, to such a degree that he could not even yet bear the smell of coffee. The speaker said that in his opinion the mystery was not entirely cleared up. He would recommend that the bodies of some of those who had died first be exhumed and carefully examined; should they all contain copper and arsenic, then Paris-green was the poison; but should they show copper only, or only arsenic, then the one or the other of these metals would be the cause of death. The young man referred to had ulcers of the lips, gums and tongue, such as are result from mineral poisons.

DR. MITCHELL, in replying to a question of Dr. Evans, stated that he had very recently received a letter from Dr. Irwin, of Louisville, who had treated many of these poisoning cases; that up to that date no post-arsenical paralysis had appeared in any of his cases.

DR. HYNDMAN, replying to a remark of one of the previous speakers, warned him that in case any of the bodies now buried should be exhumed and copper should be found on chemical analysis, not to jump to the conclusion that that metal was the cause of death unless found in very large quantity. As stated in the report, copper is so often found in chemical analyses of the body, that it is claimed by some chemists to be a normal constituent.

NEWS ITEMS.

British Medical Association.—The fifty-ninth annual meeting of the British Medical Association will be held at Bournemouth on Tuesday, Wednesday, Thursday and Friday, July 28, 29, 30 and 31, 1891.

An Address in Medicine will be delivered by Thomas Lauder Brunton, M.D., F.R.S., Lecturer on Materia Medica and Therapeutics at St. Bartholomew's Hospital, London; an Address in Surgery will be delivered by John Chiene, M.D., F.R.C.S.Ed., Professor of Surgery at the University of Edinburgh; an Address in Public Medicine will be delivered by Edward Cox Seaton, M.D., Lecturer on Public Health at St. Thomas's Hospital, London.

In the Section of Medicine the discussion on Wednesday, July 29th, on the Etiology and Prevention of Phthisis will be opened by P. H. Pye-Smith, M.D., F.R.S. Speakers: Professor Gairdner; E. Symes Thompson, M.D.; Sir Walter Foster, M.D.; J. B. Yeo, M.D.; J. G. S. Coghill, M.D.; T. W. Blake, M.R.C.S.; R. Robertson, M.B.; M. A. Boyd, M.B.; T. A. Vesey, M.B.; J. Moorhead, M.D.; E. Markham Skerritt, M.D.; A. E. Sansom, M.D. The discussion on Thursday, July 30th, on Lupus will be opened by Dr. J. F. Payne. Speakers: T. Colcott Fox, M.B.; P. S. Abraham, M.D.; J. Moorhead, M.D. The discussion Friday, July 31st, on the Effects of Alcohol will be opened by Dr. Wilks, F.R.S. Speakers: Professor Gairdner; Dr. Ferrier, M.D., F.R.S.; E. Symes Thompson, M.D.; Sir Walter Foster, M.D.; E. Long Fox, M.D.; J. C. Bucknill, M.D., F.R.S.; I. Burney Yeo, M.D.; Isambard Owen, M.D.; E. M. Skerritt, M.D.; J. Moorhead, M.D.; J. Watts Parkinson, M.R.C.S.; A. E. Sansom, M.D.

The following papers have been promised: Clinical Observations upon the Cardiac Bruits of Chlorosis, by A. G. Barrs, M.D.; Cancer and Phthisis occurring in Different Members of the Same Family, by T. W. Blake, M.R.C.S.; (subject unannounced), by J. G. S. Coghill, M.D.; Erysipelas of the Pharynx, by F. de Haviland Hall, M.D.; Some Points in the Treatment of Influenza, by Norman Kerr, M.D.; Differentiation in Rheumatic Diseases, by Hugh Lane, M.R.C.S.; On the Heart Sounds in Pulmonary Phthisis, by R. Robertson, M.B.; Hydrophobia, by T. A. Vesey, M.B.; Consumption—the Conditions of its Cure, by I. Burney Yeo, M.D.

In the Section of Surgery arrangements have been made for the following important subjects to come under discussion: 1. The Value of Professor Koch's Method in the Treatment of External Tuberculosis, to be introduced by William Watson Cheyne, F.R.C.S.; Mr. C. B. Keetley will take part in this discussion. 2. Abdominal Surgery: (i) The Operative Treatment of Peritonitis; (ii) The Treatment of Strangulated Hernia by Median Abdominal Section; to be introduced by Lawson Tait, F.R.C.S. 3. The Present Position of Intra-nasal Surgery; to be introduced by W. J. Walsham, F.R.C.S.

The following papers have been announced: Cancer of the Rectum and its Surgical Treatment, by Alfred Cooper, F.R.C.S.; Notes from an Experience of 100 Cases of Urinary Tuberculosis, by E. Hurry Fenwick, F.R.C.S.; The Limits to the Curability of Scoliosis—A Clinical Inquiry, by C. H. Golding-Bird, F.R.C.S.; On the Treatment of Peritonitis and of Hernia by Abdominal Section, by C. B. Keetley, F.R.C.S.; On the Treatment of Peritonitis and of Hernia by Abdominal Section, by C. B. Lockwood, F.R.C.S.; 1. The Relation of Movable Kidney to Hydro-nephrosis; 2. A New and Certain Way of Obliterating Hernial Sacs and Performing Radical Cure for Hydrocele, by R. Clement Lucas, M.B., B.S.; Intra-nasal Surgery in Relation to Sneezing and Hay Fever, by Greville MacDonald, M.D.; On the Treatment of Peritonitis and of Hernia by Abdominal Section, by H. A. Reeves, F.R.C.S.Ed.; On the Present Position of Nasal Surgery, by Charters J. Symonds, M.S., F.R.C.S., and Scanes Spicer, M.D.; On the Pathology, Diagnosis and Surgical Treatment of Necrosing Ethmoiditis, by E. Woakes, M.D.

In the Section of Obstetric Medicine and Gynecology the discussion on Puerperal Eclampsia will be opened by Dr. Galabin, and discussed by Dr. Braxton Hicks, Dr. Aust Lawrence, Professor Auvard (Paris), Dr. More Madden and others.

The discussion on Uterine Polypi will be opened by Dr. Murphy, and discussed by Dr. Robert Bell, Dr. More Madden, Dr. Godson, Dr. Murdoch Cameron, Professor Auvard, and others. A Demonstration on Frozen Sections of the Pregnant Cadaver will be given by Dr. Freeland Barbour.

The following papers have been announced: The Medical Treatment of Cervical Metritis, by Professor Auvard (Paris); The Treatment of Chronic Disease of the Uterine Adnexa, by Robert Bell, M.D.; Murdoch Cameron, M.D., will show an Improved Crutch for Operations; Eclampsia Occurring in a Primipara aged Fifteen and a Half Years, by D. D. Donovan, F.R.C.S.; Two Additional Cases of Porro's Operation, by Clement Godson, M.D; Early Incision and Drainage in Cases of So-called Pelvic Abscess, by Aust Lawrence, M.D.; On the Treatment of Puerperal Convulsions, by More Madden, M.D.; A Case of Epithelioma of the Perineum Treated by Electricity, by J. Inglis Parsons, M.D.; Midwives Should be Ended, not Mended, and the Public Supplied with Thoroughly Trained Obstetric Nurses, by R. Reid Rentoul, M.D.; A Case of a Rapidly Recurring Uterine Polypus, by William Travers, M.D.

In the Section of Public Medicine the following papers have been announced: Factory and Workshop Sanitary Inspection, by H. W. Langley Browne, F.R.C.S.Ed.; An Outbreak of Diphtheria at Leeds, by Spottiswoode Cameron, M.D.; Diphtheria—the Cause of its Increase and the Means to be Adopted for its Prevention, by Alf. Carpenter, M.D.; The Notification of Diseases Act—Should Measles or Other Diseases be Added to the Number of Compulsory Notifiable Diseases? by Harvey Littlejohn; The Powers Conferred on Sanitary Authorities with Regard to Slaughterhouses, Bakehouses, and Milkshops, by H. Manley, M.D.; Vaccination—What Constitutes Efficient Vaccination? by H. May, L.R.C.P., and C. E. Underhill, M.D.; The Duty of the Medical Officer of Health with Reference to the Examination of Notified Cases of Infectious Disease and the Sanitary Inspection and Disinfection of Premises, by B. H. Mumby, M.D.; The Discharge of Town Sewage into the Sea Near Watering-places and Seaside Health Resorts, by Louis Parkes, M.D.; The Influenza Epidemic and its Distribution in the British Isles, by Frank-

lin Parsons, M.D., V.P.; The Water Supply of Rural Communities where (*a*) Streams, (*b*) Ponds, or (*c*) Shallow Wells are Relied On, by J. C. Thresh, M.D. (Chelmsford), and E. F. Willoughby, M.D.; It is Imprudent and Inexpedient to Treat Scarlet Fever and Diphtheria in the same Isolation Hospital, by Wm. Thursfield, M.D.; The Disposal of the Dead, by Sir T. Spencer Wells, Bart., and J. Comyns Leach, M.D.; The Communicability of Tuberculous Diseases from Animals to Man, by G. Sims Woodhead, M.D., and Professor McFadyean (Edinburgh).

In the Section of Psychology the President, P. Maury Deas, M.B., will deliver an address, to be followed by a discussion. Dr. T. Clifford Allbutt, F.R.S., will open a discussion On the Proposed Hospitals for the Treatment of the Insane. In conjunction with Dr. Allbutt's paper, Dr. F. H. Walmsley (Leavesden Asylum) will read a paper on the Desirableness of Throwing Open Our Asylums for the Post-Graduate Study of Insanity. Dr. T. Claye Shaw, F.R.C.P., will introduce a discussion on the Surgical Treatment of General Paralysis. Dr. G. H. Savage, F.R.C.P., will initiate a discussion on the Influence of Surroundings on the Production of Insanity. A contribution on the Truth of the Idea of Heredity, by Dr. Wm. Wallace (Glasgow), will form part of this discussion.

The following papers have been announced: Weak-minded Criminals: their Psychological and Anthropological Characteristics, by J. Baker, M.B. (H. M. Prison, Portsmouth); The Value of Sulphonal as a Mental and Motor Sedative, by J. A. Ewan, M.B. (Dorset County Asylum); Psychopathic Epidemics, by Theo. B. Hyslop, M.B. (Bethlem); Some Unusual Forms of General Paralysis, by A. Little, M.B. (Virginia Water); The Criminal Acts of Criminal Lunatics, by D. Nicolson, M.D.; Puerperal Insanity, by S. T. Smyth, M.D. (Bournemouth); Cancer in its Relations to Insanity, by H. Snow, M.D. (London); Association of Various Conditions of Development in Relation to Brain Power and Nutrition, by Francis Warner, M.D. (London).

Should the Committee of Investigation on Hypnotism present a report, it is proposed that this report be considered and probably discussed on Thursday, July 30th. In addition to those gentlemen who are to open discussions and read papers, the following will take part in the deliberations of the Section: Professor Gairdner, Sir J. Crichton Browne, Dr. Hughlings Jackson, Dr. Batty Tuke, Professor Ferrier, Dr. Macewen (Glasgow), Dr. Bateman (Norwich), Dr. Fletcher Beach, Dr. Mercier, Dr. Wiglesworth, Dr. Outterson Wood, Dr. Needham, Dr. Gayton, Dr. Strahan.

In the Section of Pathology, Dr. Hingston Fowler will open a discussion on Arrested Pulmonary Tuberculosis. Mr. F. G. Eve will open a discussion on Senile Changes in the Bones. Dr. Phineas Abraham will give a demonstration on Microscopic Sections of Skin Diseases. Dr. Carey Coombs will give a demonstration with Hæmoglobinometer and Two Cytometers.

The following papers have been announced: A Short Account of Herxheimer's Spirals in the Epidermis and Mucous Membranes, Illustrated by Microscopical Sections of Various Skin Affections, by Alfred Eddowes, M.D.; A series of Specimens of Heart Diseases, with Verbal Demonstration, by Francis Hawkins, M.D.; Paper and specimens, The Specific Gravity of the Blood in Disease, by E. Lloyd Jones, M.B.; Robert Maguire, M.D., will show specimens and make a communication on Lymphadenoma of the Solar Plexus with Bronzed Skin; A paper on the Accurate Measurements of the Cubic Contents of the Several Chambers of the Heart, by J. R. Radcliffe, M.B., and T. Stacey Wilson, M.B.; On the Real Anatomical Nature of So-called Arterio-capillary Fibrosis, its Symptoms During Life, and its Relation to Granular Kidney (during Bright's disease), by Thomas Saville, M.D.; Paper and specimens, The Insidious Bone Lesions of Mammary Carcinoma (second paper), by Herbert Snow, M.D.; Paper and specimens, Gynæcomastia, by Roger Williams, F.R.C.S. The following gentlemen have also promised papers: Dr. Handford, Dr. Sims Woodhead, Dr. W. Russell, and Dr. McMunn.

In the Section of Ophthalmology two subjects have been set down for special discussion: 1. The Treatment of Infantile Cataract; 2. The Treatment of Lachrymal Disease.

The following papers are announced: Vision Tests as Applied to Railway Servants, by W. M. Beaumont, M.R.C.S.; Some Cases of Retinal Detachment, by W. A. Brailey, M.D.; The Pathology of the Ophthalmoplegiæ, by W. J. Collins, M.D., and L. Wilde, M.D.; A Review of the Tests for Color-blindness, by F. W. Edridge-Green, M.D.; Cases of Sarcoma of Choroid Causing Death by Metastasis, by A. Hill Griffith, M.D.; The Value of Electricity in Affections of the Optic Nerve and Retina, by C. G. Lee, L.R.C.P.; Control of Railway Servants' Eyesight, by M. M. McHardy, F.R.C.S.Ed.; The Action and Uses of Prismatic Combinations, by A. S. Percival, M.B.; Some Points in the Treatment of Lamellar Cataract, by C. Wray, F.R.C.S.

In the Section of Diseases of Children the two following subjects have been set down for special discussion: 1. The Feeding of Infants up to the Completion of the First Dentition—to be opened by Dr. Henry Ashby, of Manchester; Dr. Cheadle, Professor Baginsky, of Berlin; Dr. Emil Pfeiffer, of Wiesbaden; Dr. Louis Marshall, of Nottingham; and Dr. Angel Money, will take part. 2. The Treatment of Pleurisy and Empyema in Children, and their Value—to be opened by Mr. R. J. Godlee; Mr. W. H. A. Jacobson, Mr. Watson Cheyne, Professor Baginsky, of Berlin, Dr. Emil Pfeiffer, of Wiesbaden, Dr. Angel Money, Dr. G. A. Carpenter, and Dr. Lewis Marshall, of Nottingham, will take part.

The following paper is announced: Osteotomy Generally; with Special Reference to Tarsectomy in Advanced and Intractable Cases of Talipes Equino varus, by John Ewens, L.R.C.P.

Section of Therapeutics: A discussion on Koch's Treatment of Consumption—to be introduced by the President. The following gentlemen will take part in the discussion: Mr. Watson Cheyne, Dr. E. Markham Skerritt, Dr. Barrs, Mr. Fowler, and others. A discussion on Anæsthetics will be introduced by Dr. Lauder Brunton. The following gentlemen will take part in the discussion: Dr. Dudley Buxton, Dr. Barrs, Mr. Hartley, Mr. Pridgin Teale, and others.

The following papers are announced: On the Use of Digitalis in Aortic Disease, by — Barrs, M.D.; On Anæsthetics, by Dudley Buxton, M.D.; On the Treatment of Exophthalmic Goitre, by H. W. Denton-Cardew, M.R.C.S.

The Practice of Medicine in France.—A new medical law has passed the French Chamber of Deputies by which no one shall be allowed to practise medicine in France without a diploma of Doctor of Medicine granted by the Government after examinations passed before a State institution of superior medical education.

Dr. J. C. Culbertson, of the Cincinnati *Lancet and Clinic*, has been appointed by the Board of Trustees to succeed Dr. John H. Hollister in the editorial control of *The Journal of the American Medical Association.*

The Mississippi Valley Medical Association will hold its seventeenth annual session at St. Louis, October 14, 15, and 16, 1891. The medical profession is respectfully invited to attend the meeting.

Port Physician of Philadelphia.—Dr. Henry Leffmann has entered upon the duties of the office of Physician of the Port of Philadelphia, to which he has been appointed by the Governor of the State and which position he has on a previous occasion most creditably filled.

The Medical Society of Franklin County will hold a meeting, to be followed by a banquet, at Chambersburg, July 21, 1891. Dr. John Montgomery will deliver an address of welcome. Dr. D. F. Unger will present "Observations on Cancer." Dr. Geo. S. Hull will consider "What the Eye Reveals to the Physician Concerning General Diseases." Dr. I. N. Snively will report upon "Some Unique Surgical Operations."

Montour County Medical Society.—The seventeenth annual meeting of the Montour County Medical Society will be held at the State Hospital for the Insane, Danville, Penna., June 18, 1891. Papers will be read by Dr. S. S. Schultz on "Limitation to Curative Work in State Hospitals for the Insane;" Dr. N. W. Voorhees on "Tuberculous Peritonitis;" Dr. H. B. Meredith on "Hypertrophic Cirrhosis of the Liver, with the Report of a Case;" Dr. J. R. Kimerer on "Peculiar Sequelæ of Pneumonia;" Dr. E. A. Curry on "Multiple Abscesses." Dr. James Oglesby will present a sketch of the Society, and the retiring President, Dr. C. B. Mayberry, will deliver an address.

New Lecturers at the Polyclinic.—Dr. H. R. Wharton has been elected Lecturer on Surgical Diseases of Children. In a part of the course the subjects of tracheotomy and intubation will be considered. Dr. Chas. P. Noble has been elected Lecturer on Gynecology; Dr. Jas. K. Young, Lecturer on Orthopædic Surgery; Dr. G. Betton Massey, Lecturer on Gynecological Electrotherapeutics, and Dr. Lewis H. Adler, Lecturer on Diseases of the Rectum.

The Congress of American Physicians and Surgeons will be held at Washington, from 3 to 6 P.M., September 22, 23, 24 and 25, 1891. Dr. William Pepper, of Philadelphia, is Chairman of the Executive Committee.

Association of the Military Surgeons of the National Guard.—The regular meeting of the Association of Military Surgeons of the Wisconsin National Guard was held in Milwaukee, June 20, 1891.

The proposed meeting of the Surgeons of the National Guard of the United States, which was to have been held in Chicago in July next, has been postponed until September. Due notice of the date of meeting will be given. Every effort will then be made to organize an "Association of Military Surgeons of the National Guard." About four hundred surgeons throughout the United States have thus far expressed a willingness to attend the meeting. At the first meeting papers will be read by Surgeon-General Bryant, of the New York N. G.; by Surgeon-General Yandell, of the Kentucky N. G.; by Surgeon-General Senn, of the Wisconsin N. G.; and by the Surgeon-General of the Illinois N. G. The Association will be entertained in Chicago by the local Guard.

W. W. Keen, A.M., M.D.—At the one hundred and twenty-third annual commencement of Brown University the honorary degree of Doctor of Laws was, among others, conferred upon Dr. William Williams Keen, Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College. In thus doing deserved honor to a distinguished alumnus, Brown University has added to its own laurels.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 16 TO JUNE 22, 1891.

By direction of the Secretary of War, WILLIAM C. BORDEN, *Captain and Assistant Surgeon*, will, upon the final abandonment of Fort Davis, Texas, report in person to the commanding officer Jackson Barracks, La., for duty at that post.—Par. 4, *S. O. 139, A. G. O.*, June 18, 1891.

MCKEE, JAMES C., *Lieutenant-Colonel and Surgeon.*—Having been found incapacitated for active service, on account of disability incident to the service, is, by direction of the President, retired from active service this date, under the provisions of Section 1251, R. S.—Par. 4, *S. O. 137, A. G. O.*, June 16, 1891.

TAYLOR, BLAIR D., *Captain and Assistant Surgeon*, is granted leave of absence for one month, to take effect on or about the 1st proximo.—Par. 3, *S. O. 65, Department of the Missouri*, June 15, 1891.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 20, 1891.

RUTH, M. L., *Surgeon.*—Detached from U. S. S. "Newark," and granted leave of absence for six months, with permission to leave the United States.

BRIGHT, GEORGE A., *Surgeon.*—Ordered to the U. S. S. "Newark."

PIGOTT, M. R., *Assistant Surgeon.*—Ordered to the U. S. Receiving-ship "Independence."

WELLS, HOWARD, *Surgeon.*—Detached from Naval Hospital, Chelsea, and wait orders.

STEELE, J. M., *Passed Assistant Surgeon.*—Ordered to Naval Hospital, Chelsea, Mass.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment, provided that the request for reprints be noted by the author at the top of the manuscript. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

INDEX.

ABBOTT, Koch's treatment in Berlin, 77
Abdominal hernia, 443
section, hernia as a sequel to, 385
preparation for, 385, 388
surgery, peroxide of hydrogen in, 402
tumors, auscultatory percussion in diagnosis of, 73
Abortion, treatment of uterine cavity in, Crowell, 460
Abscess of liver opening into a bronchus, Fisher, 467
Abscesses, cold, treatment of, 248
Absorption of medicaments from ointments, 306
Accommodation, traumatic paresis of, 187
Acids, arsenic in, 200
Acne, treatment of, 389, 418
Aconitine, a case of poisoning by, 615
Acromegalia, pathological anatomy of, 722
Actinomycosis, 499
case of, Ochsner, 97
Acute delirium, Chapin, 125
Lloyd, 122
Tull, 127
otitis media, Würdemann, 291
Adductor longus, rupture of sheath of, 409
Adenitis, cervical, 542
Adipositus universalis and diabetes, 223
Albuminuria in renal lithiasis, 445
Alcoholism, chronic, treatment of, 588
Alopecia, treatment of, 418
Amenorrhœa, treatment of, 561
American Electro-therapeutic Association, 255
Amœba of dysentery, pathogenesis of, 562
Amputations, major, one hundred cases of, Glazebrook, 68
Anæmia, salt solution in treatment of, 358
Anæsthetic, methyl-blue as an, 522
mixtures, 333
Anal reflex, 722
Anasarca, treatment of, 498
Anatomical knowledge, a novelist's, 701
Anastomosis, intestinal, 38
Anders, sarcoma of liver and omentum, 8
Andrews, repeated operations for facial neuralgia, 173
Aneurism, excision of an, 643
Angina pectoris, 521
trinitrin in treatment of, 358
Antagonism between erysipelas and syphilis, Horwitz, 324
microörganisms and the treatment of infectious disease, 699
Anthrax, treatment of, 306
Antipyretics, 190
Antipyrin and calomel, incompatibility of, 190
in treatment of gonorrhœa, 469
Antisepsis in obstetrics, 193
Antiseptic accouchement, 470
management of new-born infants, 166
papers, 444
Aphrodisiac pills, 561
Aristol in treatment of fissured nipples, 333
ointment, 140, 250
Army medical board, 227, 368
Arsenic in commercial acids, 200
in phthisis, 19
Arthritis deformans, Loomis, 57
Artificial feeding, 649
teeth impacted in larynx, 222
Aseptic methods in intra-nasal surgery, Roe, 352
Ashton, intestinal surgery, 230
porro-Müller operation, successful case of, 369
the technique of pelvic surgery, 658
Association of American Physicians at Berlin, 424
Asthma, cardiac, treatment of, 418
hay, for, 616
Astragalus, excision of for equino-varus, 81
Asylum, the Sheppard, 701
Atmospheric electricity, etc., relation of to a case of neuralgia, Catlin, 489
Atrophic rhinitis, treatment of, Loeb, 95
Atrophy of muscles following articular lesions, 361
Atropine for paralysis agitans, 469
sedative effects of, 165
use of in the treatment of localized muscular spasm, 587
Aulde, Dr., a notice from, 83
Aural cases, Dabney, 229
Auscultatory percussion in diagnosis of abdominal tumors, 73
Auto-toxæmia, 167

BALDY, extra-uterine pregnancy, 10
intestinal surgery, 230
minor uterine surgery, 541
Bartholow, Da Costa, 640
Baths, public, 723
Beaver, typhoid fever in Reading, Pa., 175
Bed-sores, treatment of, 444
Beef-preparations, nutritive value of, 716
Behrens, topical treatment of diphtheria, 514
Belladonna, in treatment of strangulated hernia, 139, 311
Belt, ocular signs in diagnosis, 490
Betol, 250
Bigelow, electricity in gynecology, 434
Binkley, a case of puerperal septicæmia, 689
Bladder, diseases of in old men, Jackson, 237
exstrophy of the, and epispadias, 616
extroversion of, 496
irritability of, prescription for, 164
Blepharitis, treatment of, 443
Blood, diagnostic value of fibrinous elements of, 194
Boils, treatment of, 222
Boldt, utero-vaginal ligature in posterior displacements, 453
Boone, operation for relief of hernia, 512
Boric acid, local applications of in constipation, 165
Bradfute, strychnine in treatment of failing circulation, 16
treatment of pneumonia, 375
Brain, extensive gunshot wound of, 202
Breast, cancer of, radical operation for, 692
Broad ligamant, varicose veins of, 694
Brokaw, extirpation of kidney for myxosarcoma, 313
Bromides, the doses of, 498
Bromoform, death from the use of, 18
Bronchial catarrh, chronic, Davis, 164
Bronchitis, chronic, treatment of, 277
Broncho-pneumonia, 444
Brooklyn, Chinese hospital in, 75
post-graduate college and hospital, 56
Brown, ozone and hydrogen peroxide, 179
treatment of gangrenous wounds and diseases, 101
Bulkley, relations of eczema to disturbances of the nervous system, 128, 158
Bull, ovariotomy for cystic tumor, 692
Bullet-wounds, a study of, 445
Burnett, reform in numbering prisms, 487

CÆSAREAN section, case of, 369
Calculi, renal, removed from lumbar muscles, 147
Calculus, renal, diagnosis and treatment of, 447
vesical, removed by supra-pubic cystotomy, 82
Calomel and antipyrin, incompatibility of, 190
Camphoric acid as an antisudorific, 249
in night-sweats, Hare, 384
Cancer, gastric, diagnosis of, 335
of breast, radical operation for, 692
of œsophagus, operations for, 168
of pancreas, 336
of stomach, treatment of, 443
Cantharidal collodion, 333
Carcinomatous deposits, secondary, in association with scirrhus of the breast, 690
Cardiac asthma, treatment of, 418
Carotid artery, ligation of the common, 522
Cart before the horse, 700
Cataract operations, after-treatment of, 351
Catlin, relations of the weather to a case of traumatic neuralgia, 487
Catlin's meteorological pain phenomena, 694
Cavities, pulmonary, the diagnosis of, 644
Cephalic version, two cases of, in shoulder presentation, 550
Cerebral circulation, action of drugs, etc., upon, 111
syphilis, case of, Pershing, 373
Norbury, 65
Cerebro-spinal axis, the diagnosis of traumatic lesions in the, and the detection of malingering referred to this centre, 634
Cervical adenitis, 542
Chancre, treatment of, 249, 497
Chancroid, treatment of, 140
Chapin, acute delirium, 125
clinical lecture, 496
Chicago, mortality in, 226
Chilblains, ointment for, 73
treatment of, 165
Chinese hospital in Brooklyn, 75
Chittenden, nutritive value of beef preparations, 716
Chloasma of pregnancy, ointment for, 74
Chloralamid, 278
Chloral-antipyrins, 165
Chloroform administration, statistics of, 498
anæsthesia, cremasteric reflex in, 359
and ether, deaths from, 721
in tracheotomy, 76
narcosis, long-continued, disturbances in metabolism following, 697
Chlorosis, copper in treatment of, 248
infantile, treatment of, 560
treatment of, 222
Cholelithiasis, influence of sweet oil on, 307
Cholera infantum, salt solution in, 358
necessity of quarantine against, 28

Chronic bronchitis, treatment of, 277
Circulation, cerebral, action of drugs, etc., upon, 111
failing, treatment of, Bradfute, 16
Cirrhosis of liver in childhood, 364
Clevenger, Catlin's meterological pain-phenomena, 694
Club-foot, intermittent traction in, 343
treatment of, 338
Cocaine-poisoning from instillations into middle ear, 247
Coe, persistent pain after laparotomy, 357
Cold abscesses, treatment of, 248
Colic, treatment of, 248
Colon, inflammation about the head of, 32
Comedones, ointment for, 109
Commissions by druggists to physicians, 700
Congenital hypertrophy of the hand, 616
Congress of American Physicians and Surgeons, 424, 451
of Hygiene and Demography, 340
Conjunctivitis, granular, 19
Constipation, local application of boric acid in, 165
of pregnancy, treatment of, 333
Convalescent homes, the London hospitals and, 701
Convulsions in children, treatment of, Davis, 217
Convulsive tic, treatment of, 469
Copper in treatment of chlorosis, 248
sulphate of, 588
